agricultural landscapes; therefore via proper conservation management for lapwings we are able to effectively promote biodiversity of agricultural landscape in general. We obtained over 3000 detailed observations from more than 1000 lapwing breeding grounds with great help of more than 200 volunteers across the Czech Republic during breeding seasons 2012–2014. Subsequently, 350 best localities (particularly wet fields regularly concerning large breeding colonies) were chosen for AES. Five-year concept of this AES for Northern Lapwing on arable land consists of ploughed field left unmanaged from winter until 15th of June. Then the field is sown with two types of plant seeds mixtures and ploughed again in late autumn. Pivotal step in 2015 is to convince the farmers to get involved in this AES. There is great potential of the project, e.g. AES efficacy evaluation on the same plots before and after AES implementation. Pros and cons of the chosen approach with detailed results will be thoroughly discussed during the presentation.

SYMPOSIUM #20 THE PAN AFRICAN CHIMPANZEE PROGRAMME: REMOTE VIDEO, ORGANIC AND ECOLOGICAL SAMPLING AT 40 TEMPORARY RESEARCH SITES ACROSS AFRICA

Hjalmar Kuehl

Max Planck Institute for Evolutionary Anthropology
Mimi Arandjelovic, Max Planck Institute for Evolutionary Anthropology; Christophe BOESCH, Max Planck Institute for Evolutionary Anthropology

Effective conservation planning requires more than just knowledge of a species' distribution and population size but also an understanding of their ecological, behavioral and genetic diversity. We established the Pan African Chimpanzee Programme, a never-before attempted, large-scale research project covering all possible habitats of the different chimpanzee subspecies (*Pan troglodytes*) across their entire range. The project aims to understand the socioecological and demographic drivers of chimpanzee culture and to document the diversity of chimpanzee behaviors to draw attention to important areas for conservation action. Since 2010, we have been collecting directly comparable data from 40 temporary and collaborative research sites in 14 countries across Africa. Sites were selected systematically and established for a duration of 12 to 17 months. A detailed field protocol based on non-invasive methods was created and implemented, including traditional monitoring techniques to record habitat characteristics and innovative approaches such as camera traps for assessing biodiversity and chimpanzee group demography. Additionally, organic materials for analyses on pathogen loads, stable isotopes to estimate dietary intake, genetic samples to determine chimpanzee population history, and carrion flies containing eDNA to assess biodiversity levels are collected. Extensive recces were required to establish each site to confirm

ape absence or presence in areas which were previously data deficient. The analysis of these large data sets has required the implementation and assessment of various novel techniques. For example, we are evaluating whether a web-based citizen science platform is better suited than automated animal detection software for identifying species and behaviours from over 2500 hours of camera trap video. We highlight other promises and pitfalls of large-scale data collection and meta-analysis on an important flagship and umbrella species for conservation.

TOWARDS A MORE STRATEGIC APPROACH TO OFFSETTING BIODIVERSITY LOSSES: THE ROLE OF SPATIAL PRIORITIZATION CONCEPTS AND TOOLS

Heini Kujala

The University of Melbourne

Amy L. WHITEHEAD, The University of Melbourne ; Brendan, A. WINTLE, The University of Melbourne

Governments and industries increasingly use offsets to compensate for the unavoidable impacts of development on biodiversity. However, high uncertainty about the biodiversity outcomes has led to significant criticism of offsetting strategies in the academic and policy literature. At the same time the ad-hoc application of offsets has raised concerns that the current guidelines might favour some species and communities at the expense of others, potentially failing to achieve the underlying offsetting objective of 'no net loss'. We explored ways to improve offsetting outcomes through regional offset planning approaches, which are underpinned by concepts of complementarity and irreplaceability from the conservation planning literature. We assessed different offsetting strategies in the Hunter Valley, Australia, to offset biodiversity losses arising from minimal to extensive mining expansion, using data for 569 flora and fauna species. We compared the more traditional 'like-for-like' approach to a complementarity based offsetting approach, and prioritized areas for protection, restoration, or both, to offset the anticipated losses. We evaluated the performance of the different strategies by calculating the area needed for offsetting and the expected change in regional biodiversity value and species' protection. The complementarity approach was clearly more efficient than the 'like-for-like' approach, both in meeting the offset requirements and improving the level of biodiversity protection in the region. Our results highlight the potential inefficiency of 'like-for-like' offsets and the benefits of a more strategic offsetting approach using principles of complementarity and irreplaceability. We show that concepts and tools from spatial conservation planning provide many opportunities for offsetting, enhancing our understanding of regional-scale impacts and providing more efficient identification of offset sites and improved biodiversity outcomes.

THE POTENTIAL OF NATURA 2000 NETWORK HAS NOT BEEN FULLY REALIZED DUE TO LACK OF INTERNATIONAL COORDINATION

Aija Kukkala

University of Helsinki

Anni ARPONEN, University of Helsinki ; Luigi MAIORANO, Sapienza University of Rome ; Atte MOILANEN, University of Helsinki ; Wilfried THUILLER, University Joseph Fourier - Grenoble 1 ; Tuuli TOIVONEN, University of Helsinki ; Laure ZUPAN, University Joseph Fourier - Grenoble 1 ; Lluís BROTONS, CTFC Forest Sciences Centre of Catalonia ; Mar CABEZA, University of Helsinki

The Natura 2000 network (N2K) is an ecological network of protected areas, covering two types of sites determined by the EU in two directives (Birds and Habitats Directives). The goal has been to protect biodiversity "irrespective of national or political boundaries". Here, we present the first EU-wide assessment of N2K with systematic conservation planning (SCP) methods using a large high-resolution multi-taxon species dataset. We address the two directives and EU policy in spatial prioritizations performed with Zonation conservation planning software. We evaluate how the outcomes of planning at the EU, member state, and bio-geographical level differ from each other. We show that average species ranges covered in N2K for directive species (Annex I Birds Directive, Annex II and IV in Habitats Directive) within our data is 34% while we could achieve 60 % coverage of species ranges with optimal areas. However, N2K protects better directive than non-directive species and does a better job than a random allocation of sites. N2K fails to cover some species while it succeeds to protect well some endangered species. Differences between taxa, both in existing N2K coverage and potential optimal coverage are substantial. While it would be possible to protect high fractions of the ranges of amphibians and reptiles, for mammals and birds the optimal solution reaches only moderate coverages. We show that planning in the bio-geographical level would have potential at least for Annex II (Habitats Directive) species. Besides N2K is regarded as a joint conservation effort, we show that current protection illustrates a process where decisions are done with interests of member states, and that better outcomes could be achieved with a community planning. To respect the original goal of protection irrespective of boundaries, collaboration between countries with application of systematic conservation planning is required when designing complementary conservation schemes for the EU.

EVALUATING WILDLIFE CONSERVATION STRATEGIES IN WEST AFRICAN RAINFORESTS

Denis Kupsch

Georg-August University Göttingen

Kadiri Serge BOBO, University of Dschang ; Matthias WALTERT, Georg-August University Göttingen

The Gulf of Guinea Forests constitute the largest continuous forest block of the whole West African biodiversity hotspot. To conserve its exceptionally diverse species pool, including endangered wildlife such as Elliot's Chimpanzee and Central African Elephant, several strategies had been implemented. In Southwest Cameroon a good number of protected areas had been established along with barely protected Forest Management Units (FMUs). In addition, sustainable land use practices were promoted in largely intact forest landscapes around reserves, which are dominated by rural agroforestry systems. However, hunting remained a major threat to wildlife and key species for conservation were already predicted to face extinction in reserves in the nearer future. Also, little is known about the status of wildlife in agroforestry matrices, which would be mandatory, since they are facing a new agro-industrial wave entailing habitat conversion and fragmentation, particularly in the context of palm oil. To evaluate the performance of conservation strategies, we carried out a systematic transect survey in an agroforestry landscape (survey effort L=182km) and compared the results with wildlife data provided by conservation agencies from Korup (L=176km) and Mt Cameroon (L=63km) National Parks as well as two FMUs (L=96km, L=47km). Our results highlight the alarming situation of chimpanzees and elephants numbering few hundreds and being largely confined to reserves. However, they were still encountered in agricultural matrices. While in FMUs also other hunted wildlife seem to approach extinction, their densities were considerably high in agroforestry systems, stressing their importance for stabilizing wildlife populations. We discuss that existing regulations need to be urgently enforced to avoid massive extinction by focusing on improved patrol management in reserves and binding landscape management plans to sustain rural agroforestry systems in place of agro-industrial developments.

CAN FROGS THRIVE IN OIL PALM? A STUDY OF THE EFFECTS OF HABITAT MANAGEMENT ON FROG DIVERSITY

David Kurz

University of Cambridge

Edgar TURNER, University of Cambridge ; Oliver KONOPIK, University of Würzburg ; Hannah BARKLEY, Woods Hole Oceanographic Institution ; Agung ARYAWAN, SMART Research Institute ; Sudharto PS, SMART Research Institute ; Jean-Pierre CALIMAN, SMART Research Institute ; Ade NETRAL, SMART Research Institute ; Jamie CRANSTON, University of Cambridge ; Sophus ZU ERMGASSEN, University of Cambridge ; Christine

CORLET, University of Cambridge ; William FOSTER, University of Cambridge

Every 25-30 years, oil palm plantations undergo a severe disturbance event in which large swaths of mature palm trees are clear-cut and re-planted with young palms. This process presumably leads to major ecological changes in the oil palm ecosystem, including changes to species assemblages that had developed over the previous three decades. We compared frog assemblages between mature (21-27 year old) and young, recently re-planted (1-2 year old) oil palm. After sampling 719 anurans from 14 species across 18 oil palm plots, we found that richness, abundance, and diversity of assemblages were all higher in mature oil palm. In addition, frog assemblage composition differed significantly between the two ages of oil palm. Some "forest-associated" frog species persisted and even thrived in mature oil palm but not young oil palm: we encountered five forest-associated frog species within mature oil palm plantations that were at least 50 km from any substantial tracts of forest. We therefore recommend that oil palm re-planting schemes preserve vegetative heterogeneity in the oil palm matrix so that important amphibian species are not lost from entire agricultural landscapes. We also studied the effect of understory vegetation removal on anuran assemblages in mature oil palm. We sampled anurans before and after six oil palm plots were treated with herbicide, and compared the change in assemblage structure to results from control plots. After recording 752 anurans from 13 species and 6 families, we found a significant difference in anuran assemblage composition by plot type over time. Our results indicate that the presence of understory vegetation may play a significant role in shaping the anuran assemblages that inhabit oil palm. Allowing understory vegetation to grow between palm trees and paths in plantations could be a simple management strategy that promotes more robust anuran assemblages within the oil palm landscape.

USING ELECTRICAL ENGINEERING TO AID MARINE CONSERVATION

Elizabeth Küsel

Portland State University

Martin SIDERIUS, Portland State University ; Lisa ZURK, Portland State University ; Jonathan Fink, Portland State University

Marine conservation efforts are commonly more complex than their terrestrial counterparts because of the large areas involved and the need for remote sensing to detect subsurface phenomena. Partnerships between conservation biologists and engineers can help overcome these limitations. We report on a project led by Portland State University (PSU) acoustic engineers, originally developed in conjunction with The Nature Conservancy, that demonstrates the value of

such collaborations. This work relies on a suite of underwater monitoring tools, first designed to help the U.S. Navy detect submarines, consisting of acoustic gliders that can surface and communicate with satellites and onshore stations, autonomous hydrophones on buoys, and open-source software. The two components of this program to date are (1) monitoring of marine protected areas (MPA) and (2) censusing of marine mammal populations. MPAs need frequent patrolling to detect and exclude intrusions by unauthorized fishing vessels. However fuel and personnel costs of ship-borne monitoring can be prohibitively expensive. The alternative hydrophone and glider-based monitoring system developed by PSU can be trained to distinguish friendly from hostile ships by the diagnostic sounds of their engines. This approach was tested successfully in Hawaii's Ahihi-Kinohi'ou Natural Reserve Area. The second application measures marine mammal populations based on a combination of acoustic signatures and ecological distance sampling techniques. These methods use four autonomously collected variables—number of detected cues or calls, probability of detecting a cue as a function of distance, rate at which animals produce cues, and fraction of false positive detections—to estimate population densities. This approach was used to census sperm whales in the Sea of Sardinia in summer 2014. These applications point to the value of expanded interactions between conservation biologists and engineers of all types.

FRAMING THE PRIVATE LAND CONSERVATION CONVERSATION

Alexander Kusmanoff

RMIT University

Christopher RAYMOND, University of South Australia ; Mat HARDY, RMIT University ; Georgina MAFFEY, University of Aberdeen ; Mark REED, Birmingham City University ; Sarah BEKESSY, RMIT University

Conservation on private land is becoming an increasingly important and significant part of global conservation efforts. The degree to which conservation on private land is successful is intrinsically linked to the engagement of willing landholder participants (amongst other factors). Despite much research into understanding the factors that influence landholder participation, studies show that only a small proportion of landholders tend to participate in private land conservation schemes. Although there has been widespread implementation of private land conservation policy instruments, there has been mixed success in engaging rural landholders in conservation initiatives. To understand how the private land conservation sector could better engage landholders in the future, we undertook an analysis of how contemporary communications from the sector currently communicate participation benefits to landholders, and whether these are likely to engage a broad or narrow range of landholders. Using the Australian private

land conservation sector as a case study, we undertook a survey of the messages of the key schemes across Australia and categorised the way in which the benefits offered by each scheme were framed. We categorised these as either benefits to the landholder, to society, or to the environment. These categories correspond to the egoistic, altruistic and biospheric value orientations that have previously been shown to influence human behaviour. Our results suggest too heavy a reliance on environmentally-themed messages which likely fail to engage more egoistically oriented landholders. This is particularly the case with market-based schemes. The results from this study have implications for the future design and communication of private land conservation schemes that seek to achieve wider landholder engagement.

HOW HUNTING AND PREY DYNAMICS INFLUENCE THE LARGE CARNIVORE OCCURRENCE IN THE EDGE OF THE WESTERN CARPATHIANS?

Miroslav Kutal

Friends of the Earth Czech Republic

Martin VANA, Friends of the Earth Czech Republic ; Josef SUCHOMEL, Mendel university Brno ; José Vicente López LOPEZ, Research Unit of Biodiversity (UO-CSIC-PA), Oviedo University ; Guillaume CHAPRON, Grimsö Wildlife Research Station, Department of Ecology, Swedish University of Agricultural & Sciences (SLU)

The conservation and management of wolves *Canis lupus* in the periphery of their distribution is challenging. Edges of wolf distribution are characterized by very few and intermittent occurrences of individuals, which are modulated by multiple factors affecting the overall population such as human-caused mortality, management regimes and food availability. As a consequence, understanding population dynamics in the edges of their distribution is not an easy task. However, this knowledge becomes crucial when hunting takes place nearby the edges, which may preclude population expansion. Here, using as example the occurrence of wolves in the Beskydy Mountains (Czech-Slovak border), which are the edge distribution of the wolf and Eurasian lynx (*Lynx lynx*) populations in West Carpathians, we explored how food availability and hunting in the Slovakian source affected the abundance of wolves in the edges of this population. While wolves are game species in Slovakia and protected species in Czech, lynx is strictly protected year-round in both countries. During 2003–2012, we monitored large carnivore occurrence by snow-tracking surveys and tested potential differences in the occurrence of these species in Beskydy Mountains and potential mechanisms behind detected patterns. We found significant differences in the occurrence of wolves and lynx in this area. The wolf was a very rare species and was recorded almost six times less often than the lynx. By using N-mixture models, we observed how the expected abundance of wolves

in the Beskydy Mountains were modulated by prey availability (inverse correlation and significant effect) and harvest the year before (positive correlation although non-significant) in the Slovakian wolf source. We discuss conservation and recommendations concerning large carnivore management.

ANOTHER AUSTRALIAN DESPOT. THE POTENTIAL FOR THE YELLOW-THROATED MINER TO ALTER THE AVIFAUNA ACROSS A VAST CONTINENTAL AREA

Alexander Kutt

Royal Botanic Gardens Victoria

Ralph MACNALLY, Institute for Applied Ecology, The University of Canberra ; James THOMSON, Institute for Applied Ecology, The University of Canberra ; Teresa EYRE, Queensland Herbarium

In Australia despotic communal native birds of the genus *Manorina* are known to have a significant effect on birds smaller than themselves. These species are known as “strong interactors”. We explored whether one species (the yellow-throated miner *Manorina flavigula*) not previously considered having a significant effect on other birds, greatly affected the composition of avifaunas in > 500 000 km² in north-eastern Australian rangelands. Repeated avian surveys were conducted in 368 locations, for which in-site vegetation and landscape-contextual measurements were made. Hierarchical Bayesian and mixed effect models were used to determine whether avian assemblages were affected by variation in abundances of the yellow-throated miner. Variation in the abundances of the yellow-throated miner appeared to be governed largely by vegetation cover in surrounding landscapes. Sites with < 70% retained woodland cover contained a homogenised avifauna. Abundances and richness of birds less massive than the yellow-throated miner (< 53 g) were negatively associated with abundances of the yellow-throated miner. The species affected were largely small bodied, insectivorous and common participants in mixed feeding flocks. We suggest that increasing abundance of the yellow-throated miner might result in a cascading effect on ecosystem function. In addition the mooted agricultural expansion and proposed associated land clearing in northern Australia would almost certainly favour the spread of the yellow-throated miner, and may severely affect the small bird community across a vast continental area.

POPULATION GENETIC ANALYSIS OF AN ENDANGERED SPECIES, RHODODENDRON AUREUM, AND ITS CONGENERIC SPECIES, R. BRACHYCARPUM, ERICACEAE

Myounghai Kwak

National Institute of Biological Resources

Hyosig WON, Daegu University ; Byoungyoon LEE, National Institute of Biological Resources

Rhododendron aureum Georgi, Ericaceae, is an evergreen bush, designated as endangered species by Ministry of Environment of Korea. *Rhododendron aureum* is being considered an alpine species and its populations and number of individuals increase to the north up to Kamchatka peninsula and Siberia. However, Korean *R. aureum* population is consisted of very small numbers of individuals only in the top of the Seorak Mountain, thought to be a relic population from glacial period. On the contrary, while *R. brachycarpum* D. Don ex G. Don distributes only in Japan and Korea, the *R. brachycarpum* populations can be found in several sites in Korea and distributes parapatrically with *R. aureum* in the several sites in Korea and Japan. This study was performed to compare the genetic diversity and structures of these two species using microsatellites. Firstly, nineteen transferable polymorphic microsatellite markers for *R. aureum* and *R. brachycarpum* were developed using next generation sequencing. The genotypes of 375 individuals from 15 populations from Korea, Japan, China, and Russia were obtained using 26 microsatellite markers including seven previously reported ones. In general, two species were well separated based on microsatellite data but several putative hybrids were found between *R. brachycarpum* and *R. aureum* in Japan. The populations of both species were highly structured according to the geographic distance. Genetic diversity of *R. aureum* is slightly higher than *R. brachycarpum*. However, the *R. aureum* population in the Seorak Mountain revealed the lowest genetic diversity. Thus, the strong action should be required to conserve *R. aureum* population in the Seorak Mountain as a southern boundary of *R. aureum* distribution.

EVALUATING UNIVERSITY STUDENTS’ UNDERSTANDING AND PERCEPTION OF SEA LEVEL RISE IN THE STATE OF TEXAS

Christine Lacayo

St. Edward’s University

Park NG, St. Edward’s University ; J WETHERBY, St. Edward’s University ; Michael WASSERMAN, St. Edward’s University ; Michael DISCH, St. Edward’s University ; Jorge BRENNER, The Nature Conservancy Texas

Anthropogenic climate change has important implications for all natural ecosystems and human societies, yet many populations are unprepared to deal with the consequences of droughts, stronger storms, forest fires, and sea level rise (SLR). One reason for this lack of preparation is a lack of understanding about direct connections between climate change and environmental consequences in portions of the U.S. workforce. To identify which professions are likely to have unprepared future employees to deal with climate change, we surveyed university students from six universities in Texas:

St. Edward's University, University of Texas Austin, University of North Texas Dallas, Embry-Riddle Aeronautical University Corpus Christi, University of Texas Medical Branch, and Texas A&M University Corpus Christi. We had three main objectives: 1) to examine the perception and knowledge of climate change and how it relates to SLR across all university students 2) to determine whether current and childhood geographic location (i.e., distance to coast) influences knowledge and perception of sea level rise, and 3) to compare differences in knowledge and perception based upon major and year in school. Our results have important implications for educators and policymakers, as they highlight fields and geographic regions that are currently ill prepared to deal with the imminent threats of climate change. Additional efforts to improve education in these areas will be necessary as all professions and geographic regions will be affected in some way by anthropogenic climate change.

CLIMATE CHANGE IMPACTS TO BIODIVERSITY IN THE BRASILIAN CERRADO AND IMPLICATIONS FOR LONG TERM CONSERVATION MANAGEMENT

Iara Lacher
UC Davis

The Brazilian Cerrado is an exceptionally biodiverse subtropical grassland biome containing over 10,000 species of plants of which 45% are endemic. Although the Cerrado encompasses 23% of Brazil's total area, it is experiencing such rapid habitat destruction that more than 50%, or almost 1 million kilometers, has been lost in the past 35 years. Unfortunately, current records show that only 2.2% of the Cerrado is under legal protection with approximately 20% of threatened and endangered species not represented in protected reserves. Thus, the Cerrado is quickly becoming a target of concern for conservationists throughout the globe. Climate change now threatens to exacerbate negative effects from habitat destruction and fragmentation, increasing the need to integrate potential impacts of climate change in reserve selection and prioritization. This project combines modeled species distributions with the most recent reserve prioritization scheme developed by the Centro Nacional de Conservação da Flora and the Lab Biogeografia da Conservação to highlight priority areas in the Cerrado expected to maintain relatively high species richness in the future. To do this, I modeled future potential suitable habitat for over 2300 terrestrial plant species found in the Cerrado biome, applying different spatial and temporal scales of climatic data depending on plant traits. I used the programming platform R for modeling and Bayesian data analysis. Results are depicted as probability distributions rather than discrete range maps, illustrating potential changes in species richness across the Cerrado as a result of climate change. The spatial overlap between my results, current conservation areas, and areas identified as

priority areas will highlight areas where efforts might be most fruitful for long term biodiversity conservation. Furthermore, this project illustrates an improved methodological framework for modelling functionally diverse plant species on large geographic scales.

THE EFFECTS OF THE CHARACTERISTICS OF HEDGEROWS ON CHIROPTERA AND ORTHOPTERA COMMUNITIES: WHAT IS THE RELEVANT SPATIAL SCALE TO DETECT THEM?

Aurelie Lacoeylle

Museum National d'Histoire Naturelle
*Nathalie MACHON, Museum National d'Histoire Naturelle ;
Jean-François JULIEN, Museum National d'Histoire Naturelle ;
Christian KERBIRIOU, Museum National d'Histoire Naturelle*

Biodiversity is threatened by the loss and fragmentation of habitats. One consequence is the removal of hedgerows networks. The role of hedgerows in maintaining biodiversity was well established, but the importance for biodiversity of the intrinsic characteristics of hedgerows and the quality of hedgerow networks along a spatial scale are poorly known for now. We chose to analyze three quality indices providing information at different territorial levels: density, structural diversity and wood production. We performed an acoustic survey in a grassland to estimate species abundance and community composition of bats and grasshoppers. Using an approach based on species and traits, we assessed how the hedgerow quality influenced the activity of these taxa at different spatial scales and focused on three types of traits: grasshopper mobility ability, bat foraging strategy and habitat specialization. Our results showed 1) the importance of studying the relevant spatial scale, 2) the importance of hedgerow quality for Chiroptera and Orthoptera. However the strength of the association between taxa and hedgerows varied substantially among the species and the spatial scales. Although it depends on the taxa, the production, density and structural diversity of hedgerows each had an overall positive effect. Our results suggested that effects were generally more important at large scales. The scale effect of the production index is the best predictor of activity for Chiroptera and Orthoptera taxa and traits. Our results showed the importance of studying the relevant spatial scale to detect the effects of the quality and quantity of hedgerows on the ecology of bat and grasshopper communities and could be used to improve conservation management. Finally, our results showed the effects of the types of hedgerows in order to suggest efficient and practical management actions for the conservation of hedgerows and Chiroptera and Orthoptera communities.

SYMPOSIUM 151 - HOST DIVERSITY AND DISEASE PREVALENCE: A CASE STUDY BASED ON BARLEY AND CEREAL YELLOW DWARF VIRUSES

Christelle Lacroix

INRA PACA-Avignon[INSTITUTE]University of Minnesota
Anna JOLLES, Oregon State University ; Eric SEABLOOM, University of Minnesota ; Alison POWER, Cornell University ; Charles MITCHELL, University of North Carolina ; Elizabeth BORER, University of Minnesota

Community assembly processes may provide a predictive framework for understanding the mechanisms underlying disease dilution (reduced disease prevalence with increasing biodiversity). The effect of biodiversity on disease prevalence may depend both on a heterogeneity in host traits related to disease spread and on the order of species loss in community disassembly. If host communities decay to a predictable subset of hosts, disease prevalence may reflect the competence of the remaining hosts. To test this hypothesis, we measured local host species abundance and prevalence of four generalist aphid-vectored pathogens (barley and cereal yellow dwarf viruses, Luteoviridae) in a sentinel ubiquitous annual grass host (*Bromus hordeaceus*, Poaceae) at 10 sites spanning 2000 km along the North American West Coast. We measured in laboratory and field trials virus infection, as well as aphid vector fecundity and feeding preferences on several host species. Virus prevalence increased as local host richness declined. Grass community disassembly in this system was non-random: hosts from our ubiquitous sentinel species dominating species-poor assemblages were among the most competent for vector production and virus transmission. These results suggest that non-random biodiversity loss led to predictable increases in disease prevalence, providing a clear mechanism by which disease dilution can occur.

NEW ZEALAND MARINE RESERVES DO AFFORD PROTECTION FOR THE ECOLOGICALLY, ECONOMICALLY AND CULTURALLY IMPORTANT BLACK FOOT PAUA, HALIOTIS IRIS.

Alix Laferriere

Victoria University Wellington
Jonathan GARDNER, Victoria University Wellington

Haliotis iris, an abalone commonly referred to as paua, is a New Zealand endemic species that inhabits rocky reefs and is the focus of important customary, recreational and commercial fisheries. Paua are long lived species with limited larval dispersal and adult movement patterns, which are life history characteristics that predict a positive response to marine reserve implementation. Demography and growth rates of paua populations are highly variable and habitat and fishing pressure have been suggested to influence the demography

of the population. Marine reserves, where fishing pressure is excluded, are an ideal laboratory to examine habitat effects on distribution, density and growth of paua. In the Austral summer of 2013 and 2014, we conducted surveys of *Haliotis iris* and habitat types via SCUBA within and outside five marine reserves in central New Zealand. *H. iris* was significantly denser in four reserves and size was significantly greater within five reserves, showing that marine reserves do afford protection for this iconic species. Habitat associations were a strong and significant driver of paua size. This is the first time that paua has been shown to respond positively to marine reserve implementation in New Zealand and these findings have direct relevance to paua conservation and management.

BEACH POLLUTION AT BOTH ENDS OF THE SPECTRUM: INSIGHTS FROM SLOVENIA

Betty J.I. Laglbauer

IMAR - Institute of Marine Research, University of the Azores
Rita Melo FRANCO-SANTOS, Universidade Federal do Paraná (UFPR) ; Miguel ANDREU-CAZENAVE, Pontificia Universidad Católica de Chile ; Lisa BRUNELLI, Ghent University ; Maria PAPADATOU, Ghent University ; Andreja PALATINUS, Institute for Water of the Republic of Slovenia ; Mateja GREGO, National Institute of Biology ; Tim DEPPEZ, Ghent University

The amount of marine debris in the environment is increasing worldwide, which results in an array of negative effects to biota. This study provides the first account of macrodebris on the beach and microplastics in the sediment (shoreline and infralittoral) in relation to tourism activities in Slovenia. The study assessed the quality and quantity of macrodebris and the quality, size and quantity of microplastics at six beaches, contrasting those under the influences of tourism and those that were not. Beach cleanliness was estimated using the Clean Coast Index. Although tourism did not seem to have an effect on macrodebris or microplastic quantity at beaches at the moment of this study, over 64% of macrodebris was plastic, and microplastics were ubiquitous. This pollution poses potential ecosystem threats, which calls for further research into the dynamics of beach pollution in Slovenia and eventual classification of plastics as hazardous materials. Standard measures are needed for marine debris assessment, especially in the form of an all-encompassing debris index. Recommendations for future assessments are provided for the Adriatic region.

LEOPARDS IN CHINA: CURRENT STATUS AND DISTRIBUTION

Alice Laguardia

Beijing Forestry University
Zhefeng ZHOU, Wocheng Institute of Ecology and the Environment ; Jan KAMLER, The University of Oxford ; Philip

RIORDAN, *The University of Oxford* ; Kun SHI, *Beijing Forestry University*

Historically, leopards (*Panthera pardus*) were distributed throughout most of China, however recent studies indicated leopards have disappeared from large areas of the country, probably due to habitat loss, low prey base, and poaching. We reviewed recent literature and interviewed specialists to determine the current status and distribution of leopards in China, which may contain up to 4 subspecies. In addition, camera trapping was conducted between 2008 and 2014 in Shanxi Province to monitor highly fragmented populations of the north Chinese leopard (*P. p. japonensis*), a little-known subspecies endemic to China. Results showed that leopards have declined dramatically in China, and they were confirmed only from 44 sites in 11 provinces, despite extensive surveys in many areas. Current populations are small and fragmented, and occur mainly in isolated nature reserves. Based on the number and size of protected areas where leopards still occur, we estimate a total population of only 174-348 individuals for *P. p. japonensis*, and <30 individuals for each of the other subspecies. In Shanxi Province, species distribution modeling highlights that forest cover is the variable that most influences leopard occurrence and it is positively correlated with the probability of leopard presence. The highest probability of leopard presence was found inside nature reserves, but also in areas 70-170 km from reserves. In Lishan National Park, we estimated a density of 0.96 leopard/100km² based on camera-trap data, which is first reliable density estimate of *P. p. japonensis* from anywhere within its distribution. Based on our findings, we recommend that a separate IUCN assessment be made for *P. p. japonensis*, and that this subspecies be classified as Endangered. We provide the first reliable estimates of the distribution and status of leopards in China, and this information will be important to help guide conservation efforts of this species throughout the country.

ISSUES CURRENTLY AFFECTING GYPS VULTURE POPULATIONS IN ASSAM, INDIA

Kulojyoti Lahkar

Wildlife Conservation and Study Centre
Robert W. RISEBROUGH, *The Bodega Bay Institute*

The populations of three species of Gyps vultures have been declined disastrously in the Indian subcontinent in the last decade as a result of contamination of livestock carcasses with diclofenac and possibly to other NSAIDs (non-steroidal anti-inflammatory drug) with similar properties. To know the status and to initiate a long term conservation process for two critically endangered vultures (*G. tenuirostris* and *G. bengalensis*), a survey was initiated in 2003 and thereafter surveying and monitoring regularly to know about the factors which are currently affecting their survival. These include

destruction of nests and cutting and thinning of nesting trees; egg collection for medicinal purposes, hunting chicks and adult birds for meat; being killed accidentally by vehicles and trains while feeding on carcasses on roads and railway tracks and, the deliberate poisoning of carcasses with pesticides and insecticides to kill carnivores. Three-year running averages of the number of nestings of both species suggest a decline in the order of 50% over the eight year period, with a particularly sharp drop recorded in 2010 – 2012. In order to ensure the long-term conservation of vultures in wild in Assam, we propose: awareness campaigns among local communities to protect nests, nestlings and nesting trees; to use safer drugs in veterinary medicine instead of diclofenac and other NSAIDs with similar properties, and to avoid the poisoning of carcasses likely to be consumed by vultures.

IS MY SPECIES DISTRIBUTION MODEL FIT FOR PURPOSE? MATCHING DATA AND MODELS TO APPLICATIONS

Jose Lahoz-Monfort

University of Melbourne

Gurutzeta GUILLERA-ARROITA, University of Melbourne ; Jane ELITH, University of Melbourne ; Ascelin GORDON, RMIT ; Heini KUJALA, University of Melbourne ; Pia LENTINI, University of Melbourne ; Michael MCCARTHY, University of Melbourne ; Reid TINGLEY, University of Melbourne ; Brendan WINTLE, University of Melbourne

Many conservation decisions are spatially-explicit, from choosing a suitable reintroduction site to planning the location of new protected areas or forecasting the impacts of future climate change on biodiversity distribution. The knowledge of where one or more species occur (distribution) or where the conditions are suitable for them to persist (habitat suitability) is often vital information to support such decisions. Species distribution models (SDMs) can provide the required estimated distributions/suitabilities, and have become a very popular quantitative tool to inform a range of conservation applications. However, users often underestimate the strong links between data type, model output and suitability for end-use. In our study (Guillera-Arroita et al. 2015 *Global Ecology & Biogeography*) we synthesize current knowledge and provide a simple framework that summarizes how interactions between data type and the sampling process (i.e. imperfect detection and sampling bias) determine the quantity that is estimated by a SDM. We draw upon the published literature and simulations to illustrate and evaluate the information needs of common conservation applications of SDM outputs. Predictions of models fitted to the most commonly available observational data (presence records) suffice for some applications, others require estimates of occurrence probabilities, which are unattainable without reliable absence records. Our literature review and simulations reveal that, while converting

continuous SDM outputs into categories of assumed presence or absence using a threshold is common practice, it is seldom clearly justified by the application's objective and it usually degrades inference. Matching SDMs to the needs of particular conservation applications is critical to avoid poor ecological inference and management outcomes. Our study aims to help modellers and users assess whether their intended SDM outputs are indeed fit for purpose.

124 MEASUREMENT OF BIODIVERSITY, OFFSET RATIOS AND RISKS IN THE APPLICATION OF MARKET-BASED INSTRUMENTS FOR CONSERVATION

Jussi Laitila

University of Helsinki

Atte MOILANEN, University of Helsinki ; Federico, M. POUZOLS, Science & Technology Facilities Council

There has been a trend towards increasing integration between biodiversity markets, private sector finance and biodiversity conservation. Many instruments, such as biodiversity offsetting and banking, tend to view biodiversity as a form of interchangeable currency. This is not straightforward, because biodiversity consists of the variety of living organisms in a complex, nonlinear and interlinked manner. Measuring biodiversity in space and time is inaccurate and uncertain, which leads to potential problems in the application of such instruments when the principle of no net loss should be maintained. We first discuss the characteristics of market-based biodiversity instruments and biodiversity finance. We review and identify risks and consequences to biodiversity of misuse and fraud in the application of such instruments. We next turn to biodiversity offsetting, whose effectiveness is often measured in terms of offset multipliers or ratios. One common problem of offsets is that they may exchange certain and almost immediate losses for uncertain future gains. We demonstrate, using a minimum offset multiplier method, that when accounting for time delay, no net loss multipliers can be quite large, in the order of dozens, contradicting some relatively low multipliers applied in practice.

TAMBU: A MELANESIAN MODEL FOR THE SUSTAINABILITY OF THE ADMIRALTY CUSCUS (SPILOCUSCUS KRAEMERI)?

John Lamarinis

Wildlife Conservation Society-Papua New Guinea Program
Nathan WHITMORE, Wildlife Conservation Society-Papua New Guinea Program

Tambu areas are a well-respected concept in Melanesian societies where a no-go zone is imposed on a section of forest or coral reef to preserve plants, animals and fish stocks. Such tambu areas are used for customary obligations and restocking resources. They have also been suggested as the basis for

conservation and sustainability in Melanesia. The Admiralty cuscus (*Spilocuscus kraemeri*) is an aboreal possum-like animal endemic to the Admiralty Islands of Papua New Guinea where it is a major source of terrestrial protein for much of the human population. The home range and movement patterns of 10 cuscus (8 females and 2 males) were investigated using radio telemetry in a 26 ha tambu area on Manus Island. Home range sizes were estimated using a 95% minimum convex polygon method and possible contributing factors to home range size were assessed through model selection on 12 candidate linear models. Home range size was highly variable (mean = 2.2 ha, 95% CI = 0.8 – 5.9 ha) and was not associated with body mass, age, or sex. The minimum size of a tambu area required to allow a self-sustaining population was estimated through application of Laplace's extension to Buffon's needle problem using the vital rates of a closely related surrogate species, the Common Brushtail Possum, *Trichosurus vulpecula*. The results suggest that at a 26 ha tambu area will likely only have a ~50% chance of being self-sustaining. On this basis we hypothesise that tambu are likely to have some utility for sustaining populations but the areas need to be expanded and networked to provide a measure of security at local scales.

SHOULD I STAY OR SHOULD I GO? CONSERVATION IMPLICATIONS OF INDIVIDUAL VARIATION IN BROWN PELICAN MIGRATORY STRATEGIES

Juliet Lamb

Clemson University

Patrick G. R. JODICE, US Geological Survey South Carolina Cooperative Fish and Wildlife Research Unit

Although Brown Pelicans (*Pelecanus occidentalis*) are resident throughout their range, some individuals regularly undertake postbreeding migrations of up to 3,000 km. Variation in migratory strategies could expose different subsets of the population to differing risk factors and play a substantial role in population dynamics of the species; however, little information exists on the prevalence or distribution of long-distance migrants. To address this information gap, we used GPS loggers to track postbreeding movements in 85 Brown Pelicans breeding across the northern Gulf of Mexico. For all individuals for which we obtained a complete migration cycle (n=66), we modeled migratory strategy (resident, medium-distance, or long-distance) as a function of sex, body condition, breeding location, and reproductive success during the most recent breeding season. We also used vulnerability mapping to assess the geographic distribution of known risk factors. We found that females were more likely to migrate long distances, while males were more likely to be resident. Body size was a significant predictor for males, with larger males more likely to remain resident, but was not significantly different between resident and migrant females. Likelihood of migration also increased with colony size. Neither body condition nor

breeding success influenced migratory strategy, and migration is highly consistent within individuals. Combining risk maps with migratory strategies, we predict that male pelicans will be more vulnerable to changing winter climate in the northern Gulf, while risks to females wintering in the southern Gulf remain largely unknown. Several migratory routes encompassed over-land portions, increasing vulnerability to terrestrial threats such as hunting and wind turbines. We conclude that differential migration patterns significantly influence the distribution of mortality risk in Brown Pelicans, particularly during the non-breeding season.

ENHANCING REFORESTATION IN DEGRADED TROPICAL PEATLANDS

Maija Lampela

University of Helsinki

Jyrki JAUHAINEN, University of Helsinki ; Harri VASANDER, University of Helsinki

Tropical peatlands of Southeast Asia are great terrestrial carbon stores and major hot spots of biodiversity. Main tropical peat ecosystem is peat swamp forest (PSF), a rain forest on top of up to 20 m deep peat. Currently peat swamp forests are converted to plantations and agriculture with breath-taking pace. Aside from conservation, also active restoration is needed on destroyed areas. Our work searches practical and affordable techniques for reforestation of degraded peatlands. Our study site was clear-felled open, drained and several times burnt deep peat area in the so-called Ex-Mega Rice area in Central Kalimantan, Indonesia. We chose five native PSF tree species known to have potential for reforestation. Seed material acquired from local forests was grown in a field nursery. At the age of 6-11 months seedlings were planted in the field in three blocks characterized by differing wetness conditions. We used three treatments: weeding (3 intensities), mounding and fertilizing, and their combinations to study the best practices to enhance seedling success. Growth and mortality of the seedlings and environmental variables (water table, temperature, light) were monitored for two years. Effects of treatments and environmental variables on the growth and mortality rates were tested with mixed-effect models. We conclude that of the three treatments, fertilizing had most clear positive effect both on growth and mortality in all tested species whereas mounding decreased mortality but the effects on growth were not clear. Weeding gave mixed results between the species. Of the environmental variables water table position was the most influential but the sensitivity of the species to water table fluctuations varied substantially. When labor and material costs are taken into account, our results can derive species-specific best option for reforestation scheme for these five species on degraded tropical peatlands.

USING COMMUNITY-BASED MICROFINANCE FOR CONSERVATION: LESSONS FROM CASE STUDIES IN RURAL ZAMBIA AND TANZANIA

Victoria Lang

Imperial College

Andrea P C WALLACE, Frankfurt Zoological Society ; Graham E. WALLACE, Frankfurt Zoological Society ; E J MILNER-GULLAND, Imperial College

Community-based microfinance programmes are increasingly being seen as a valuable component of conservation interventions. Such programmes aim to expand livelihood options, improve resilience, and reduce reliance on natural resources. Despite some promising reports, there is very limited empirical research examining their social and conservation outcomes. We evaluate socio-economic impacts of a microfinance initiative on participants and the wider community, effects on attitudes towards conservation and potential to foster behavioural change. We focus on savings and loans groups established by Frankfurt Zoological Society as Community Conservation Banks (COCOBAs) in North Luangwa ecosystem, Zambia and Serengeti ecosystem, Tanzania. Data were obtained from semi-structured interviews, focus groups and key informants. Overall, programme participants had greater wealth than non-participants and more positive conservation attitudes. There were also indications of pro-conservation behaviour changes. We were unable to conduct a Before-After-Control-Impact evaluation but evidence suggests that changes may be attributed to COCOBA participation. Although general wellbeing was equivalent between participants and others, specific economic wellbeing was higher for participants. Non-participants perceived wider community benefits from microfinance, whereas participants focused more on direct benefits to themselves and for conservation. Key success factors were identified across stages of COCOBA groups and included providing ongoing support and capacity building, mixed-sex groups with a positive culture, regular individual savings and offering large enough loans to support income-generating activities of a meaningful size. This is one of the first empirical evaluations of a conservation-focused microfinance initiative. Our findings suggest such approaches are a promising tool to promote socio-economic benefits, community-driven conservation and pro-conservation behavioural change.

SYMPOSIUM ID:122 - ACCOUNTING FOR ENVIRONMENTAL AND MARKET FEEDBACKS WHEN PRIORITISING LAND FOR CONSERVATION

Cecilia Larrosa

Imperial College London [INSTITUTE] National University of Singapore

Cristina BANKS-LEITE, Imperial College London ; Luis Roman CARRASCO, National University of Singapore ; Leandro Reverberi TAMBOSI, Universidade de Sao Paulo ; E J MILNER-GULLAND, Imperial College London

Increasingly conservationists use systematic conservation planning to decide when, where and how to invest limited funds to maximize conservation benefits. Important assumptions underlie this approach, in particular that environmental and economic conditions remain static over time. These assumptions generally do not hold; in fact, conservation interventions may themselves change the conditions, thereby invalidating the predictions of the models that guided the intervention design. We explore this issue with a case study of a payment for landowners to set aside private land to enable natural forest regeneration in the Atlantic forest of Brazil, a key global biodiversity hotspot with exceptionally high biodiversity and extreme land cover disturbance. We modelled the effect of including market and ecological feedbacks into prioritisation of areas for ecological set-asides within an agricultural landscape. We perform a spatially explicit prioritisation at a series of time steps taking three criteria into consideration: an area's potential contribution to biodiversity, its potential contribution to forest connectivity, and the opportunity cost of diverting land from production. The prioritization outcome at each time step has an effect on the three criteria in the following time step, at different spatial scales. We model the ecological feedbacks from changes in forest configuration and market feedbacks from foregone agricultural production, and explore the consequences for conservation outcomes of ignoring these feedbacks. Finally, we assess the trade-offs between the costs and benefits of accounting for feedbacks in this system. This is the first time both ecological and market feedbacks have been considered within a spatial conservation prioritisation.

LANDSCAPE SIMPLIFICATION AND INSECTICIDE USE: INSIGHT FROM A REGRESSION ANALYSIS OF THE CONTINENTAL US OVER 25 YEARS

Ashley Larsen

UC Santa Barbara

Steven GAINES, UC Santa Barbara ; Olivier DESCHÊNES, UC Santa Barbara

Insecticides have numerous negative externalities for human health, ecosystem services and ecological communities, and thus their efficient use is an economic and ecological priority. Simplified landscapes are thought to enhance insecticide use by reducing natural enemies and increasing connectivity of crops, but empirical tests of this theory are inconclusive. We investigated the relationship between landscape simplification and insecticide use using longitudinal data from USDA Census of Agriculture spanning 25 years for nearly 3000 counties

in the continental United States. The effect of landscape simplification was highly variable spatially and temporally with landscape simplification consistently correlated with higher insecticide treatment in some regions, but not in others. This variation was robust to the inclusion of annual weather and non-linear effects of cropland. Our results indicate that the landscape simplification – insecticide use relationship is complex and region specific. Thus, national-scale land use policy would benefit from actions that adequately reflect the spatial differences in the importance of landscape complexity to insecticide use.

ID # 165 THE EUROPEAN KNOWLEDGEBASE FOR BIODIVERSITY TO ASSESS PROGRESS - A PERSPECTIVE FROM EU

Frank Wugt Larsen

European Environment Agency (EEA)

The European Environment Agency (EEA) is an agency of the European Union and a major information source for those involved in developing, adopting, implementing and evaluating environmental policy. The presentation will introduce examples of the comprehensive knowledge base in the area of biodiversity, which is a significant (re)source for anybody working in the area of environment policy evaluation in a European context. For example, the EEA five-year assessment "The European Environment – State and Outlook 2015" (SOER 2015) (due in March 2015), which is an indicator-based assessment, providing a baseline for the European Union's 7th Environment Action Programme ("Living well, within the limits of our planet"); the "State of nature in the EU" assessment (due mid 2015), which provide results reported for the EU legislation for species and habitats; and the ongoing work in relation to the mid-term review of the EU biodiversity strategy to evaluate progress (due late 2015).

EFFECTS OF RECREATION ON ANIMALS REVEALED AS WIDESPREAD THROUGH A GLOBAL SYSTEMATIC REVIEW

Courtney Larson

Colorado State University

Sarah REED, Wildlife Conservation Society ; Adina MERENLENDER, University of California - Berkeley ; Kevin CROOKS, Colorado State University

Globally, the mission of most protected areas includes both biodiversity conservation and improving human welfare through resource use or nature-based recreation. Recreation has numerous benefits for human communities; however, an increasing number of studies are demonstrating negative effects on animal species. Understanding potential trade-offs between biodiversity conservation and recreation is critical for protected area policy and management. We conducted

a global systematic review of 218 articles on the effects of all types of recreation activities on any animal species. We quantified trends in publication rates and outlets, identified knowledge gaps, and assessed evidence for negative and positive effects of recreation. Whereas publication rates are low, evidence of impact is clear with over 93% of reviewed articles documenting at least one effect of recreation. Although responses are often species- or context-specific, some taxonomic groups (e.g., passerine birds, shorebirds, ungulates, and corals) had greater evidence for an effect of recreation. Counter to public perception, non-motorized activities had more evidence for a recreation effect than motorized activities. Snow-based activities also had greater evidence for recreation impacts than other activities, though sample size was low. Birds (39% of articles) and mammals (37%) were the focus of the majority of recreation studies, while studies of amphibians, reptiles, and fish were rare. Locations in South America, Asia, and Africa and responses at the population and community levels had low representation in the literature. Further, less than 10% of studies examined threatened species. Protecting biodiversity from harmful effects of recreation is a major concern for protected area managers facing rapidly increasing park visitation rates around the world. The conservation science community should provide data-based information to help guide solutions to these management dilemmas.

147 ESSENTIAL BIODIVERSITY VARIABLES FOR INVASION MONITORING

Guillaume Latombe

Monash University

Melodie McGeoch, Monash University

Unlike the systematic evaluation and monitoring process in place for tracking the status of threatened species at multiple spatial scales, no such process is yet in place for invasive species. The variables and metrics for doing so in a standardised way (necessary to underpin a robust observation system) have also not been fully developed, widely agreed to, or adopted. Invasion biology has over the last several decades produced a wealth of conceptual and evidence-based generalisations upon which a standardised observation system for invasive species can be designed, as well as assessment criteria for monitoring. Essential Biodiversity Variable (EBV) provide a valuable vehicle for designing such an observation system. All species populations can be defined by their abundance and distribution. This is true of species undergoing population declines as well as those expanding their ranges. Unlike threatened species, invasive species are those introduced by human agency beyond their native ranges, that establish viable populations, grow and spread and that negatively impact biodiversity. The concept of invasion therefore encompasses both process and impact components. Invasive species impact is a function of population abundance

x distribution (occupancy) x per capita impact. Therefore the measurements essential for studying, reporting and managing the threat that invasive species pose to biodiversity encompass at least two, and up to four, EBV classes, two core EBVs and a range of additional possibilities. EBVs facilitate the harmonisation of existing monitoring schemes and guide the implementation of new ones, especially in regions where information on biodiversity change is still very sparse, providing an opportunity to significantly advance a robust global framework for this key driver of biodiversity change.

SYMPOSIUM 163 - MOVING FORWARD FROM EBA: TRANSFORMATIVE CLIMATE ADAPTATION

Sandra Lavorel

CNRS

Matthew COLLOFF, CSIRO ; Michael DUNLOP, CSIRO ; Russell WISE, CSIRO

Adaptation to climate change must be acknowledged as a long-term driver of economic, social, political and cultural transformations. EBA strategies often ignore the slower transformational changes of biophysical and ecosystem processes expected under severe climate change, and risk to lead to maladaptation in the long-term. Alternative approaches are required to support strategic policy and actions. This presentation aims to introduce the Transformative Adaptation Research Alliance (TARA), which has developed an operational framework to study and support transformative adaptations. TARA links the three novel concepts of adaptation services, the values-rules-knowledge perspective on decision contexts, and adaptation pathways. Adaptation services are the benefits people derive from the capacity of ecosystems to moderate and adapt to the effects of climate change. Adaptation services progress from EBA by formally recognising the intrinsic ability of ecosystems to provide valuable services for societal adaptation by (i) buffering risks, (ii) providing options and (iii) transforming. However, for adaptation services to emerge and inform adaptation, a new perspective on decision contexts is required that reveals the need for transformation. Decision-making contexts are characterised by dynamic interactions between societal systems of values, rules and knowledge. Transformative adaptation will require shifts in norms, preferences and values to foster fundamental shifts in rules and innovative governance structures; and therefore new transdisciplinary knowledge to drive such social changes, and to achieve consensus on decisions and actions. The adaptation pathways approach provides a means of planning and implementation for such transformation by revealing critical elements for long-term climate adaptation? It informs timing within long decision timeframes and incorporates flexibility to enable social learning and co-creation, experimentation and iteration.

THE UTILITY OF CONCEPTUAL AND BAYESIAN NETWORK SOCIAL-ECOLOGICAL MODELS FOR PROTECTED AREA TIME AND RESOURCE ALLOCATION DECISION MAKING

Rebecca Laws

University of Queensland

Models are commonly developed to assist with conservation decision making but their utility to 'on the ground' resource allocation is rarely evaluated. We developed social-ecological staff time allocation models with staff at 10 National Parks in Australia. Conceptual models were developed through sharing mental models during one day workshops. Conceptual models were then parameterised to create Bayesian Network models through eliciting staff opinion of the importance of protected area values and threats, and the impact of management actions. Follow up workshops illustrated the application of the Bayesian Network models and further refined models. Structured interviews were used to evaluate the model building process and model utility immediately after workshops and several months later. Managers reported that the final models sufficiently reflected how their protected area actually functioned (average 8.5 on a scale of 1, poor fit, to 10, perfect fit, range 7 – 10, n=9). Sixty percent of managers said that they felt confident using the conceptual model as a decision support tool while an additional 30% said they could use the model with some reservations, while half said that they felt that they could also effectively use the Bayesian Network model. Forty percent of managers said that they would use the model for planning and decision support, 30% said they would probably use the model but only after some alterations and the remaining said that it was unlikely that they would use the model. Managers cited developing annual work plans as the most likely useful application of their model with revising the plan of management and management effectiveness reporting also possible uses. The biggest barriers to model use were identified as complexity of user interface, training requirements, the time required to use, update and refine, and difficulty predicting time spent on management activities. Models appeared to be effective tools under some circumstances.

161-ACHIEVING SUSTAINABILITY IN COASTAL MANAGEMENT: EMBRACING THE SOCIAL-ECOLOGICAL SYSTEMS APPROACH TO SMALL-SCALE FISHERIES

Elodie Le Cornu

Center for Ocean Solutions

Larry CROWDER, Center for Ocean Solutions

Over the past few decades, scientists and managers have adopted a variety of approaches to conserving biodiversity and ecosystem services in coastal ecosystems including marine protected areas and multiple-use ocean planning. But current approaches still struggle to fully integrate social data with ecological data to improve both ecological and social outcomes. As we transition toward ecosystem-based approaches that fully integrate the biophysical system, social system, and institutions, we need to embrace the complexity of human relationships with ecosystems, including their social, cultural, political, and economic dimensions, in order to develop and implement viable management strategies. Social-ecological system approaches can produce a more comprehensive understanding of these complex seascapes and aid in planning aimed at achieving sustainable social and ecological outcomes. Here we illustrate these concepts through the lens of rights-based management approaches to small-scale fisheries. We assess the critical enabling conditions underlying rights-based management and examine how – by making these conditions more visible – we can guide implementation to be more successful. While rights-based management approaches to small-scale fisheries are being actively implemented, the assumptions that underpin the theory of change have not been critically evaluated. This may preclude understanding what drives the relative success or failure of these initiatives. We developed a general theory of change for applying rights-based management approaches to small-scale fisheries and used it to structure a global review of case studies. For each case study, we assessed whether the assumptions were met, as well as the specific outcomes and the alternative outcomes (unintended outcomes) associated with specific strategies. Based on the results, we will present recommendations to guide efforts toward rights-based approaches to small-scale fisheries.

AN EXPERT-ASSISTED CITIZEN SCIENCE PROGRAM PROVIDES GENERAL PATTERNS ON BEE ASSEMBLAGES AT A NATIONAL SCALE

Violette Le Féon

INRA

Mickaël HENRY, INRA ; Eric DUFRÊNE, Observatoire des Abeilles ; Laurent GUILBAUD, INRA ; Emilie KOLODZIEJCZYK, Bergerie Nationale ; Fabrice REQUIER, INRA ; Bernard VAISSIÈRE, INRA

Data on species distribution constitute baseline information in biogeography and macroecology. Scientists in those topics require large datasets that cannot be gathered by individual research teams. In this context, the benefits of citizen science are extension of spatial and temporal sampling effort, cost reduction, as well as reconnection of people to nature. Bees represent a biological group that is highly diverse, difficult

to identify and with limited tools for identification at the species level, being therefore poorly suitable for classical citizen science. Here we report the first results of an ongoing citizen science program where a specific group of participants, teachers from agricultural high schools, were involved in standardized surveys of bees, which were then identified to species level by taxonomist experts. Bees were sampled by pan traps during three years in 20 schools spread over France. Overall the dataset includes 70 collections (year \times sampling site combinations) and 4574 specimens belonging to 195 species. All collections were dominated by a non-parasitic, soil-nesting species. In most cases this species was social and polylectic. A single species, *Lasioglossum malachurum*, dominated in 32 collections. Herein we confront this biological dataset to environmental data freely available at the national scale describing agricultural practices at the municipality level (High Nature Value index) and landscape context (Corine Land Cover). These analyses showed that (1) species richness increases with increasing proportion of herbaceous semi-natural elements in 100 m landscape sectors; (2) dominance (proportion of the most abundant species) decreases with increasing crop diversity; (3) the proportion of cavity nesting species and specimens increases when the intensity of fertilizer and pesticide use decreases. This expert-assisted citizen science program thus provides new insights on bee vulnerability to anthropogenic disturbances at a national scale.

DEMOGRAPHY AND SOCIALITY: ELASTICITY ANALYSIS IN A GORILLA POPULATION AFFECTED BY AN EBOLA OUTBREAK

Pascaline Le Gouar

University of Rennes 1

Sandra LE THIEC, University of Rennes 1 ; Amandine PIERRE, University of Rennes 1 ; Céline GENTON, University of Rennes 1 ; Jean-Sébastien PIERRE, University of Rennes 1 ; Michael SCHAUB, Swiss Ornithological Institute ; Nelly MÉNARD, CNRS

Identifying the life history traits that contribute the most to population growth rate is essential to assess persistence of endangered species, especially when catastrophic events perturb life history traits. In social species with complex links between demographic rates and social dynamics, it is challenging to analyze variation in growth rate when vital rates vary (i.e. elasticity analysis). In this purpose, we studied wild gorillas that experienced Ebola outbreak. Decreases in survival and reproduction, as well as perturbations in social transfers and immigration, were detected during Ebola outbreak. We aimed to understand how the outbreak modified vital rates' elasticity and how it impacted long term population viability. Using an age, sex and social structured population matrix model, we performed elasticity analysis and investigated effects of variations in social structure and immigration patterns on gorilla population growth rate. Demographic

parameters and social transfers were estimated for each epidemic period (before, during, after outbreak). Analysis of the asymptotic population growth rate showed that female matrix drove the population dynamics during non-epidemic periods, whereas it was the male matrix during the outbreak. Elasticity analysis indicated that variations in survival of adult females in breeding groups impacted the most the growth rate of population before and after outbreak. During outbreak, survival and social transfers of solitary silverbacks were the most critical parameters. Perturbation of initial social structure led to minor changes in population dynamics, while immigration was necessary to reach increasing population after outbreak. Simulations assuming that demographic parameters returned to pre-epidemic values immediately after outbreak suggested that the population will return to pre-epidemic size in 80 years. However, delayed immature males immigration, as detected with observational data, induced an additional 20 years delay.

177 - PARTICIPATORY AGENT-BASED SIMULATION TO FOSTER DIALOGUE AND BUILD TRUST BETWEEN LOCAL COMMUNITIES AND RESEARCHERS: A CASE STUDY ON BUSHMEAT HUNTING IN THE PERIPHERY OF KORUP NATIONAL PARK (SOUTH-WEST CAMEROON)

Christophe Le Page

CIRAD

Kadiri Serge BOBO, Dschang University ; Towa Olivier William KAMGAING, Dschang University ; Bobo Fernanda NGAHANE, Dschang University ; Matthias WALTERT, Georg-August University

To investigate the sustainability of bushmeat hunting activities in the region of the Korup National Park (South-West Cameroon), an agent-based model (ABM) representing snare trapping of blue duikers (*Cephalophus monticola*) was co-designed and used with local populations. Village meetings based on interactive computer simulations were structured in three successive steps. During the first step, an abstract representation of a village surrounded by a portion of forest was co-designed by directly manipulating the computer interface. Then, knowledge about the live-cycle traits and the behavior of blue duikers was shared through the demonstration of the individual-based population dynamics module of the ABM. The objective of the second step, introducing the hunting module of the ABM, was to elicit snare trapping practices through interactive simulation and to calibrate the hunting module by setting a value for the probability of a blue duiker to be caught by a snare trap. In a third step, a more realistic version of the ABM was introduced. The seven villages included in the process were located in the GIS-based spatial representation, and the number of 'Hunter'

agents for each village in the ABM was set according to the results of a survey. The demonstration of this realistic version triggered discussion about possible management scenarios based on reducing the number of hunters and/or the number of traps per hunter, but also on setting up temporal (rotating) reserves. A second round of village meetings was organized 8 months later to collectively explore with the finalized version of the ABM the pre-identified management options. The whole process resulted in enhancing the trust-building between the local communities and the research team. Some villagers established an association to promote activities related to environmental management, and the research team was given a plot of land to establish an accommodation belonging to Dschang University in the village.

151-DISEASE CONTROL IN WILDLIFE: EVALUATING A TEST AND CULL PROGRAMME FOR BOVINE TUBERCULOSIS IN AFRICAN BUFFALO

Nikki Le Roex

Stellenbosch University

Dave COOPER, Ezemvelo KwaZulu-Natal Wildlife ; Paul VAN HELDEN, Stellenbosch University ; Eileen HOAL, Stellenbosch University ; Anna JOLLES, Oregon State University

Providing an evidence base for wildlife population management is difficult due to limited opportunities for experimentation and study replication at the population level. We utilised an opportunity to assess the outcome of a test and cull programme aimed at limiting the spread of *Mycobacterium bovis* in African buffalo. Buffalo act as reservoirs of *M. bovis*, the causative agent of bovine tuberculosis (BTB), which can have major economic, ecological and public health impacts through the risk of infection to other wildlife species, livestock and surrounding communities. BTB prevalence data were collected in conjunction with disease control operations in Hluhluwe-iMfolozi Park, South Africa, from 1999-2006. 4733 buffalo (250-950 per year) were tested for BTB using the single comparative intradermal tuberculin (SCIT) test. BTB prevalence was spatially and temporally variable, from 2.3% to 54.7%. Geographic area was a strong predictor of BTB transmission in HiP, owing to relatively stable herds and home-ranges. Herds experiencing more intensive and frequent captures showed reduced per capita disease transmission risk and less increase in herd prevalence over time. Disease hotspots did not expand spatially over time, and BTB prevalence in all but the hotspot areas was maintained between 10-15% throughout the study period. Our data suggest that HiP's test and cull programme was effective at reducing BTB transmission, with capture effort and interval found to be the crucial components of the programme. The programme was thus successful with respect to the original goals; however, there are additional factors that should be considered in future cost/benefit analyses and decision making. These findings may be utilised and expanded

in future collaborative work between wildlife managers, veterinarians and scientists, in order to optimise wildlife disease control programmes and mitigate conflict at the interface of conservation, agricultural and urban areas.

ESTIMATING THE SUPPLY OF ECOSYSTEM SERVICES IN BOREAL FORESTS

Eric Le Tortorec

University of Jyväskylä

Adriano MAZZIOTTA, University of Jyväskylä ; Tähti POHJANMIES, University of Jyväskylä ; Maria TRIVIÑO DE LA CAL, University of Jyväskylä ; Mikko MÖNKKÖNEN, University of Jyväskylä

Human well-being is dependent on a number of critical processes that nature supplies, commonly referred to as ecosystem services. In particular, boreal forests provide several globally important services such as carbon storage and sequestration, as well as timber production. However, in order to maintain ecosystem services in landscapes we need methods to estimate the nature and magnitude of these services. Dynamic forest landscapes, with their long rotation periods, pose an interesting challenge when estimating the wide variety of ecosystem services that even single forest stands can provide. Measuring ecosystem services can be relatively straightforward for provisioning services such as the production of commodities (e.g. timber), but estimating maintenance and regulating services as well as cultural ones needs carefully thought out indicators. In order to accurately estimate the potential of a landscape to supply ecosystem services through time we need indicators that display both spatial and temporal sensitivity. A common way to estimate the ecosystem services supplied by landscapes has been through landcover classification, which is, however, a very coarse estimation method both spatially and temporally. In the case of managed forests we need indicators that can be quantified at the stand level or at even finer scales. Indicators also need to show temporal sensitivity since in the case of managed forests the composition of stands changes as the stand develops through time, and the supplied services can change through the rotation period of the stand. Here we present an overview of existing indicators that can be used to estimate the supply of provisioning, regulation and maintenance, and cultural services provided by boreal forests. In particular, we review spatially and temporally sensitive indicators that can be derived from reliable data based on commonly existing monitoring systems, and demonstrate their applicability in assessing ecosystem services.

SYMPOSIUM 171: UNDERSTANDING THE IMPACT OF CONSERVATION LEADERSHIP CAPACITY DEVELOPMENT: THE CASE OF THE CAMBRIDGE MASTERS IN CONSERVATION LEADERSHIP

Nigel Leader-Williams

University of Cambridge

Chris Sandbrook, UNEP World Conservation Monitoring Centre

Established in 2010, the Masters in Conservation Leadership at the University of Cambridge is a ground-breaking degree programme that aims to provide established conservation professionals with the skills they need to become successful conservation leaders. It does so by drawing on the academic and applied expertise offered by the organisations that comprise the Cambridge Conservation Initiative. The course has succeeded in attracting a diverse range of high-quality students from around the world. Now that it has been running for 5 years, it is possible to begin assessing the impact the course has had on alumni and ultimately for conservation. In this presentation we will provide an overview of the course and its students, and present early evidence on impact. We will also introduce the rest of the symposium on Building Conservation Leadership Capacity, and outline some ideas for future shared activities that might emerge from it.

ECOLOGICAL ENGINEERING TO INCREASE THE NURSERY POTENTIAL OF SHORELINE INFRASTRUCTURES

Gilles Lecaillon

Ecocean

Fabien DUBAS, Ecocean ; Philippe LENFANT, University of Perpignan ; Réda NEVEU, University of Perpignan ; Anaïs GUDEFIN, University of Perpignan

A key factor to the recovery and long-term sustainability of any fish stock is the protection of its young and juveniles so that these can reach maturity and spawn. Starvation and predation are two primary mechanisms affecting their mortality which is naturally important during settlement. However, with two-thirds of the human population concentrated around shorelines, modification of the natural coastlines is inevitable-crucial natural nurseries where young fishes usually find refuge from predation and nutrients to grow have strongly diminished and reduce significantly their chance of survival. A dedicated mitigation for the impacts caused by human coastal development occurring during these lifestyle stages is crucial to restore the connectivity, life cycles of fish and preserve ecosystem services. In 2013, a two years project called NAPPEX (Nurseries Artificielles Pour des Ports Exemplaires) has been implemented in six French Mediterranean marinas. The project's goals are the large scale deployment and the ecological benefits assessment of Biohut, a constructed fish

habitat designed for marinas to improve nursery habitats around urban waterfronts where restoration of the natural systems is no longer an option. This artificial habitat aims to restore ecosystem functions of nursery by protecting early life stage of fish from predation during their settlement period, thereby allowing them to mature to the point at which they will escape from predation and contribute to adult populations. The presentation will address the importance of protecting and restoring shoreline habitats and presents the results of the ecological benefits assessment of the Biohut performed in the six marinas by the scientists from the University of Perpignan.

PUTTING BIODIVERSITY ON THE MAP: CONSERVATION PRIORITIES IN GABON

Michelle Lee

University of Oxford

In data-poor tropical rainforest countries, "conserving biodiversity" can be an unclear and therefore elusive goal. We created a spatial information base to help the country of Gabon assess protection of its biodiversity resources and prioritize the species, habitats, sites and actions needed to meet conservation targets, across land managed by different sectors. We found that nine percent of terrestrial vertebrates met criteria for conservation attention, many of which are unprotected by law. Mapping priority species, ecological land units and formal sector land uses revealed a strong spatial structure – over one-third of species and habitats cover <1% of Gabon, and major extractive or conversion uses are limited to <5% of land. Despite an acclaimed national park network, we found species and habitat representation in existing protected areas to be relatively low, but could identify a number of near-optimal solutions that meet all targets, with minimal impact on land used for local livelihoods. We distill these solutions down to a handful of critical biodiversity sites, and examine the feasibility of protecting these sites where they overlap with permits in industrial sectors, making management actions explicit for the species and habitats they contain. The spatial structure of biodiversity and land uses dictates that for Gabon to achieve its conservation targets, biodiversity management on production lands must be stepped up – we are working with government agencies to improve species protection laws and integrate this information in management and land use plans.

ELEPHANTS IN HUMAN LANDSCAPES: BEHAVIOURAL AND SOCIAL RESPONSES TO RISK IN AMBOSELI, KENYA

Phyllis Lee

University of Stirling

Mark SOWERS, *Amboseli Trust for Elephants*; Keith LINDSAY, *Amboseli Trust for Elephants*; Vicki FISHLOCK, *Amboseli Trust for Elephants*; Harvey CROZE, *Amboseli Trust for Elephants*; Kadzo KANGWANA, *Amboseli Trust for Elephants*; Cynthia MOSS, *Amboseli Trust for Elephants*

We present a perspective of elephants as co-equal partner stakeholders in the Amboseli ecosystem of southern Kenya, along with the local land owners, the Maasai and their livestock. This well protected elephant population of some 1500 individuals ranges over 8000 km² of pastoralist rangeland, which has only in the last 4 years begun to become fragmented and fenced. Therefore understanding the dynamics of stakeholder interactions and use of space may contribute to ensuring the continued sharing of that space between species. Landscape usage patterns combined with threats (mortality, risk of injury) to stakeholders (elephants and people) are commonly used to indicate responses to risk. Here, we take an integrative and long-term approach that maps elephant responses to humans, using (a) historical dung locations from the 1990s; (b) recent elephant movements from tracking of collared female elephants in 2013; and (c) the location of human settlements and human, livestock or elephant injuries or deaths from 2006 to 2013. In addition to historical and recent usage mapping, we present a qualitative representation of elephant dispersal corridors based on 42 years of knowledge of their use of the landscape in relation to human settlements and vital water resources. We also examine elephant grouping patterns and densities over the very long term as behavioural responses to risks from humans.

ID 7. WILD GREAT APES AS SOURCES AND SENTINELS FOR EMERGING INFECTIOUS DISEASES

Fabian Leendertz
Robert Koch-Institute

Emerging zoonotic infectious diseases originating from wildlife pose a serious threat to human health. This is especially true in relation to microorganisms originating from great apes, whose close phylogenetic relationship with humans results in high potential for microorganism exchange. Intense contact between humans and great apes occurs during bushmeat hunting, which is widely practiced throughout most of the great ape's remaining habitats. I will present examples of how studies on the microorganisms of wild great apes can lead to the discovery of novel pathogens of potential importance for humans. I will also illustrate how these primates, living in their natural habitats, can serve as sentinels for diseases with high likelihoods of emergence into human populations. Greater efforts in broad geographic collection of non-invasive samples from live great apes, as well as systematic collection of samples from wildlife carcasses (either found dead or via

bushmeat studies), coupled with improvements in sample preservation and novel diagnostic capacities, will rapidly improve our understanding of the diversity and distribution of microorganisms in wild great apes. In addition, collaborations with projects focused on great apes habituated to human presence (for research and/or tourism) will allow for more in-depth studies. Linking non-invasive diagnostic data obtained from analyses of materials such as faeces and urine samples, with observational health data from wild great apes are a promising approach for the discovery of not only acute disease causing microorganisms, but also chronic infections, potentially very relevant for human health.

218 THE EU CONSERVATION DIRECTIVES - REFIT AND A PERSPECTIVE FROM THE EU COMMISSION

Stefan Leiner
EU Commission, Directorate B3 - Nature

The 1979 Birds Directive and the 1992 Habitats Directive provide a common EU framework that sets the standards for nature protection across the Member States. The aim of these directives is to contribute to ensuring biodiversity in the EU. A key component for this to be achieved is through conservation and sustainable use of an EU network of areas of high biodiversity value, called Natura 2000 which now consists of more than 27.000 sites covering over 18% of the EU terrestrial area and over 4% of the marine area. As part of its Smart Regulation policy the Commission has initiated a Regulatory Fitness and Performance Programme (REFIT). Under the first stages of this programme, the Commission has reviewed the entire stock of EU legislation and decided on follow-up actions, one of which is a 'Fitness Check' involving a comprehensive policy evaluation. The fitness Checks provide an evidence-based critical analysis of whether EU actions are proportionate to their objectives and delivering as expected. Evidence from the fitness check will be collected through a comprehensive and wide ranging consultation. The REFIT process is about making sure that EU legislation is 'fit for purpose'. There is no prefixed decision at this stage that the legislation will be changed and the objectives of the legislation are not being called into question. The results of the on-going Fitness Check of the Birds and Habitats Directives are expected to be ready by early 2016.

DISENTANGLING THE MULTIPLE EFFECTS OF LAND USE ON FISH ASSEMBLAGES IN AMAZON STREAMS

Rafael Pereira Leitao
INSTITUTO NACIONAL DE PESQUISAS DA AMAZONIA[INSTITUTE]Université de Montpellier
Cecilia Gontijo LEAL, Universidade Federal de Lavras[INSTITUTE]
Lancaster University; Jansen ZUANON, INSTITUTO NACIONAL

DE PESQUISAS DA AMAZONIA ; Paulo Santos POMPEU, Universidade Federal de Lavras ; David MOUILLOT, Université de Montpellier[INSTITUTE]James Cook University ; Jos BARLOW, Lancaster University[INSTITUTE]Museu Paraense Emílio Goeldi ; Robert M HUGHES, Oregon State University ; Philip R KAUFMANN, US Environmental Protection Agency ; SÉbastien VILLÉGER, Université de Montpellier ; Daniele KASPER, INSTITUTO NACIONAL DE PESQUISAS DA AMAZONIA ; Joice FERREIRA, Embrapa Amazônia Oriental ; Felipe ROSSETTI, Universidade de São Paulo ; Silvio FERRAZ, Universidade de São Paulo ; Jim THOMSON, University of Canberra ; Ralph MAC NALLY, University of Canberra ; Toby GARDNER, Stockholm Environment Institute

Land use change (LUC) can have a major impact on small streams and is of major concern in the tropics where rates of deforestation and land-use intensification remain very high. Yet the processes by which LUC alters tropical streams remain very poorly understood. Here we present results of the most comprehensive multi-scale assessment of the biological condition of headwater streams in the human-modified eastern Amazon, examining taxonomic and functional responses of fish assemblages to both LUC and changes in physical stream habitat. We sampled fish in 99 streams encompassing five river basins and two large regions, and characterized instream habitat by several physical attributes and key LUC variables, including density of road crossings, deforestation, and agricultural intensification. All 141 species were characterized in terms of their function using ecomorphological traits describing feeding, locomotion, and habitat. Overall we found that multiple drivers operating at different spatial scales influence stream condition, including taxonomic and functional diversity. Our results highlight the highly heterogeneous nature of such systems, where species turnover between stream sites represent 70% of gamma diversity, and assemblages exhibit distinct responses to similar drivers in different basins or regions. That said, some general patterns emerged, including a threshold of 70 to 80% of catchment forest cover above which water temperature is consistently lower than in more deforested areas; and a trend of functional homogenization due to the effect of road crossings. Our results underscore the importance of some landscape changes often unrecognised, such as road crossings and agriculture intensification that can have a marked effect on streams. We draw on the relationships observed in our data to suggest priorities for the improved management of stream systems in the multiple-use landscapes that characterise so much of the human-modified tropics.

THE EFFECT OF ROCK TYPE AND LANDSCAPE PROPRIETIES IN THE POPULATION DEMOGRAPHY, GENETIC STRUCTURE, PHENOTYPIC DIVERGENCE AND REPRODUCTIVE INVESTMENT IN A NEOTROPICAL MONTANE ORCHID

Bruno Leles

São Paulo State University

João A. N. BATISTA, Federal University of Minas Gerais ; Maria Bernadete LOVATO, Federal University of Minas Gerais ; Clarisse Palma SILVA, São Paulo State University

Knowledge of the role of Neotropical montane landscapes in shaping genetic connectivity and local adaptation is essential for understanding the evolutionary processes that have shaped the extraordinary species diversity in these regions. In the present study, we examined the landscape genetics, estimated genetic diversity, and explored the effect of rock outcrop type in demographic structure, morphological variability and reproductive strategies in seven natural populations of *Cattleya liliputana* (Orchidaceae). Nuclear microsatellite markers were used for genetic analyses. Spatial Bayesian clustering and population-based analyses revealed significant genetic structuring and high genetic diversity ($H_e = 0.733 \pm 0.03$). Strong differentiation was found between populations over short spatial scales ($F_{ST} = 0.138$, $p < 0.001$), reflecting the landscape discontinuity and isolation. Monmonier's maximum difference algorithm, Bayesian analysis on STRUCTURE and principal component analysis identified one major genetic discontinuity reflecting the variation in types of rock outcrops. Divergent genetic groups showed phenotypic divergence in flower traits and reproductive strategies. Approximate Bayesian Computation (ABC) modelling suggested low gene flow between populations at different rock outcrop and signs of population bottleneck. Demographic structure and increased sexual reproductive effort was associated with rock outcrop type and may be a response to adverse conditions for growth and vegetative reproduction. Here we show that divergent habitat (rock type) and restricted gene flow are drivers of population differentiation in Neotropical montane rock outcrops. These genetic divergence and rock type should be considered for an efficient conservation planning.

191 THE POWER OF BEHAVIOUR CHANGE. HOW TO APPLY SOCIAL MARKETING PRINCIPLES TO CONSERVATION ISSUES

Christiane Lellig

European Social Marketing Association / Stratageme Consulting Limited

Most of the current challenges the world faces today are manmade and therefore behaviour driven. These behaviours

follow the logics and norms of our societal systems. In order to drive positive change we need to address the system as much as the individual or group behaviour. There are three approaches to do so: legislation (enforcement), incentives (fiscal policies, subventions, etc.) and voluntary behaviour change, e.g. through the application of marketing techniques (Social Marketing). Social Marketing is defined as an approach that "seeks to develop and integrate marketing concepts with other approaches to influence behaviours that benefit individuals and communities for the greater social good." (ISMA, ESMA, AASM 2013). Ethical principles, audience insight and best practice as much as theory base are guiding the application of Social Marketing. Engagement with our audiences, preferably through participatory processes, is key when we aim at changing people's behaviours on a voluntary basis. Looking at conservation issues, studies in the UK and Switzerland suggest that it is people's love for nature, an innate fascination with the beauty of wildlife, that makes them willing to protect biodiversity. However, the same studies show that there is no awareness of the problem, i.e. the significant decline in biodiversity. Findings also show that approaches to enhance problem awareness through threatening images of landscapes in decay rather lead to problem denial and resignation than willingness to act. While framing of key messages is an important part of behaviour change programmes, creating the insight based foundations is the single most important and most neglected part to ensure success. A variety of projects in collaboration with NGO, retailers and government provide for some hands-on ideas how conference participants could enhance their project results by applying Social Marketing principles to conservation issues.

INTEGRATED ASSESSMENT OF TAXONOMIC, PHYLOGENETIC, AND FUNCTIONAL DIVERSITY REVEALS OPPORTUNITIES FOR CONSERVATION IN THE BRAZILIAN ATLANTIC FOREST

Priscila Lemes

Federal University of Goias

Federico M POUZOLS, University of Helsinki ; Tuuli TOIVONEN, University of Helsinki ; Mariana BATISTA, Federal University of Goias ; Levi C TERRIBLE, Federal University of Goias ; Thiago F RANGEL, Federal University of Goias ; Celio F B HADDAD, State University of São Paulo - UNESP ; Atte MOILANEN, University of Helsinki ; Rafael LOYOLA, Federal University of Goias

Spatial conservation prioritization should embrace different aspects of biodiversity, so as to protect nature in a well-balanced manner. Phylogenetic and functional diversity are powerful measures of their underlying evolutionary history and ecological processes. However, it is still unclear how to include these diversity measures into spatial planning and how to evaluate conservation outcomes with respect to said

measures. Here, we compared common spatial prioritization (based on species distribution) with analyses that incorporate functional traits and evolutionary information. We also verified the hypothesis that spatial prioritization based on different diversity measures (taxonomic, functional and phylogenetic) delivers different solutions. Therefore, we integrated these solutions into a more inclusive and meaningful strategy for spatial conservation prioritization, one which is more relevant for on-the-ground conservation efforts in Brazil, and identified high-priority areas for anuran conservation in each biogeographical region of the Brazilian Atlantic Forest. Our results demonstrated a relatively high congruence between spatial conservation plans based on different diversity measures and identified high-priority conservation areas for each of the ecoregions of the Brazilian Atlantic Forest. The conservation priority outputs by biogeographical region also illustrated a high congruence between prioritization scenarios (although exceptions were found, e.g. Alto Paraná Atlantic Forest). Finally, all previously existing protected areas were identified as high-priority areas. Overall, our results reveal high spatial congruence of conservation opportunities that can minimize the loss of both evolutionary potential and species distributions simultaneously. Given the level of urgency and the need for action in Brazil, the present conservation prioritization can be used to better inform decision makers about high priority areas for anuran conservation.

CONTEXT-DEPENDENT EFFECT OF INVASIVE ALIEN SPECIES ON NATIVE PLANT COMMUNITIES

Magdalena Lenda

Institute of Nature Conservation, Polish Academy of Sciences
Piotr SKORKA, Institute of Nature Conservation, Polish Academy of Sciences ; Renata GAJ, University of Life Sciences, Institute of Zoology

Invasive alien species are regarded as one of the greatest threats to global biodiversity. Nowadays, many invasive species co-occur in one habitat patch but most of studies focus of simple effects of only one invasive species on native communities ignoring interactions between invasive species. In this study we address question how two invasive alien plant – Goldenrods *Solidago* sp and Walnut *Juglans regia* species affect native flora when they occur alone and together in one habitat patch. We choose several abandoned fields in southern Poland where these species occurred separately, together as well as control fields without these invasive species and where native Birches *Betula pendula* grew with Goldenrods together. When alone, Goldenrods decreased number of native plants species comparing to control plots. In similar scenario Walnuts also decreased number of species and their diversity, but to lower degree than Goldenrods. However, when growing together, under Walnuts there emerged patches free of Goldenrods and this facilitated higher number native plants species and

their diversity than in the Goldenrod-only stands. Birches also reduced number of native plants but to a lesser degree than both invasive species and we did not find native Birches to facilitate native herbs when growing in stands invaded by Goldenrods.

CASCADING EFFECTS OF POLITICAL-RELATED CHANGES IN AGRICULTURE ON INVASION OF THE PERSIAN WALNUT IN FORESTS

Magdalena Lenda

Institute of Nature Conservation, Polish Academy of Sciences
Piotr SKORKA, Institute of Nature Conservation, Polish Academy of Sciences ; Michal WOYCIECHOWSKI, Institute of Environmental Sciences, Jagiellonian University

In recent decades alien Persian Walnut *Juglans regia* has become invasive in agricultural landscapes of Central Europe due to land abandonment and increase of native dispersers, the Rooks. In this study, we tested if presence of abandoned fields with alien Walnuts bearing seeds, landscape structure and management may facilitate further invasion of this tree into forest habitats by involvement of another native seed dispersers – Jays *Garrulus glandarius*, and Squirrels *Sciurus vulgaris* and passive dispersal by gravity during variable weather conditions. We selected 102 forests in southern Poland where we estimated Walnut presence and its density together with density of Jays as dominant Walnut seed disperser in forests. We also estimated seed harvesting rate by Jays on Walnuts growing in abandoned fields and in human settlements. Forest occupancy by Walnuts and their densities were positively correlated with covers of abandoned fields and human settlements with Walnuts bearing seeds. Forests that were located in the depression under surrounding landscape had higher probability of Walnut occupancy. Density of Walnuts in forests was positively correlated with density of Jays. Jays often harvested seeds from Walnuts in abandoned fields independently on their distance from a forest. This bird also frequently visited Walnuts planted in human settlements but only if they were in the proximity of forests. We also demonstrated that Walnut seeds that were hidden in arable fields by Rooks may passively reach forest edges especially on sloping fields that adds to propagule pressure in forest ecosystems and underlines the importance of local terrain configuration on invasion processes. Our study indicates that invasion of alien Walnuts into agricultural landscapes has vast spatio-temporal cascading effects that have led to further colonization of forest ecosystems by alien Walnut trees.

LINK THE UTILIZATION OF TRANSLOCATED WILDLIFE SPECIES TO THE BENEFITS AND PERCEPTIONS OF CONSERVANCY MEMBERS

Selma Mekondjo Wardine Lendelvo

University of Namibia

Lawrence KAZEMBE, University of Namibia ; Helen SUICH, Australian National University ; John MFUNE, University of Namibia

The Community-based Natural Resources Management (CBNRM) programme in Namibia aims at providing opportunities for rural communities to improve their livelihoods by utilizing wildlife for tourism and other wildlife related activities through establishment of conservancies. Conservancies, which are run by local farmers in communal areas, aim at fulfilling the objectives of both biodiversity conservation and socio-economic development through sustainable harvesting. In order to achieve these objectives, it was essential to restock or build up wildlife populations in conservancies through translocation. Translocation is defined as a deliberate, human-induced movement of living organisms from one area to another. This study aims at linking the utilization of translocated species to the community benefits in the Nyae Nyae conservancy. This conservancy is predominantly inhabited by the Ju/'hoansi (San) people who are nomadic hunter-gatherers. A total of number of 2200 ungulate individuals from 8 species was translocated into the area. According to the results, although the majority of Nyae Nyae conservancy members receive benefits from the conservancy in the form of cash, meat, and community projects, training as well as cultural importance of wildlife. These benefits were related to the performance of wildlife populations and factors that affecting these populations. In addition, the annual quotas for wildlife species issued by the Ministry of Environment and Tourism were underutilized. Underutilization of allocated wildlife quotas has implications on the expectations and perceptions on benefits and wildlife management as a whole. The conservancy programme is the key driver for community development this area, dominated by the most marginalized community of Namibia.

82 - ACCOUNTING FOR HOW LANDOWNER CHARACTERISTICS AND BEHAVIOUR INFLUENCE CONSERVATION OPPORTUNITIES IN THE EASTERN AMAZON

Gareth Lennox

Lancaster University

Identifying locations that offer the greatest opportunities for conservation investment requires an understanding of spatially heterogeneous social-ecological systems. Conservation researchers have often identified areas of greatest conservation opportunity as those with high conservation value and low cost when conserved using a single investment mechanism, such as fee-simple purchases or easements. Such approaches fail to contend with variation

in landowners' ability and willingness to engage with the various conservation options available to them, which may be independent of cost constraints but have a profound effect in limiting the success of any policies. Drawing on extensive ecological and socioeconomic survey data from 36 watersheds in the Eastern Amazon assembled as part of the Sustainable Amazon Network, together with state-wide remote sensing and agricultural census data for the state Brazilian state of Pará, we investigated how and where to target alternative land management options - such as improved fire and forest management, reforestation, and avoidance of further degradation or clearing of remaining forests - after accounting for the relative importance of spatial variability in conservation values, economic costs and the propensity of landowners to engage in conservation work. We achieved this by developing a stochastic global search optimization framework that allows for multiple conservation policy mechanisms to be used simultaneously and in a spatially constrained manner. In accounting for differences in actor behaviour as a central part of the analysis, the practical outcomes of this research, and the policy recommendations that follow from it, represent a marked advance on existing conservation planning work in the Amazon region. More generally, these results can help draw broader conclusions as to how landowner behaviour and attitudes towards conservation may have a major effect in modulating the success of conservation interventions.

SPATIAL PRIORITISATION FOR MULTI-ACTION CONNECTIVITY CONSERVATION SPENDING

Pia Lentini

The University of Melbourne

Brendan WINTLE, The University of Melbourne

It is now well-recognised that habitat quality, area, and connectivity all need to be maintained and enhanced to ensure the ongoing persistence of declining fauna, and that much of this will have to take place on private land. As a result, increasing funds are being invested in connectivity conservation initiatives, but managers of these projects often face the difficult task of weighing up competing objectives to determine where this money is spent, and on what specific actions. We present a spatially-explicit approach which allows natural resource managers to transparently allocate funding from connectivity initiatives, using the freely available linkage mapper software graphab and the recently-released corridor penalty functionality in the spatial prioritisation software Zonation. This takes into account all key considerations but is still accessible to those with a basic understanding of statistics and spatial analysis. We demonstrate our approach using a case study from the Connecting Country initiative in northern Victoria, Australia, which seeks to enhance habitat connectivity for a range of declining woodland birds through investing \$6M in restoration works and environmental stewardship on

private land. We considered four potential actions that could benefit woodland birds: revegetation, grazing management, weeding and fencing. For the prioritisation process we draw on both species distribution and connectivity modelling for the target species, as well as information about the cost and likely conservation outcomes of each of the potential management actions. At the end of the process, managers are able to produce a priority map showing what actions should be carried out on which properties for both broad and fine-scale connectivity considerations. Our approach allows for the allocation of funds from connectivity schemes in a manner which is transparent and supported by solid quantitative ecological evidence.

A GLOBAL ANALYSIS OF FERAL AND FREE-RANGING CAT DIET

Christopher Lepczyk

Auburn University

Daniel HOUSE, University of Hawaii at Manoa ; Jocelyn

LINDNER, University of Otago ; Elsa BONNAUD, Université Paris

Sud ; Tim DOHERTY, Edith Cowan University

Free-roaming and feral cats are considered amongst the 100 worst invasive species in the world. Given their widespread introduction our goal was to conduct a global assessment of species depredated by cats and found cat diet. Specifically, we quantified diets of domestic cats throughout the world, described the diet taxonomically, by conservation status, and location. Globally, cat diet contained 1,072 unique species, of which 430 (41%) were insular. Birds and mammals constituted the majority (82%) of the diet, with feral cats depredating nearly 18 times more species than domestic cats on islands. Several human commensal species, such as house mouse and European rat, were found most often across studies and a large portion of studies were from Pacific Islands. Nearly 17% (69) of the island species depredated were listed as species of concern level or greater on the IUCN Red List. Our results approximately double previous estimates of species found in cat diets and species accumulation curves suggest that the current estimate may be conservative. Our findings are particularly relevant for conservation by further refining the degree to which cats act as invasive generalist predators.

161-SYNTHESIS FOR INTEGRATED SOCIAL-ECOLOGICAL FRAMEWORK TO SUPPORT MARINE SPATIAL PLANNING

Christopher Lepczyk

Auburn University

Simon PITTMAN, NOAA ; Lisa WEDDING, Stanford University

Marine spatial planning has made great strides in protecting and conserving a variety of marine systems around the world. Increasing the utility of marine spatial planning is viewing

it through the lens of social-ecological systems frameworks. In this concluding talk, we synthesize the use and value of social data in planning, how they can be used to broaden our definition of seascapes, and ultimately how we can move towards a more integrated approach of marine spatial planning. Additionally we identify not only the progress, but the challenges and key questions awaiting an integrated approach.

SEEING THE OCEAN THROUGH THE EYES OF SEABIRDS: A NEW PATH FOR MARINE CONSERVATION?

Amelie Lescroel

Centre d'Ecologie Fonctionnelle et Evolutive
Raphaël MATHEVET, Centre d'Ecologie Fonctionnelle et Evolutive ; Matthieu AUTHIER, Observatoire PELAGIS (CRMM) ; Clara PÉRON, University of Tasmania-IMAS ; Pascal PROVOST, Réserve Naturelle Nationale des Sept-Iles ; Akinori TAKAHASHI, National Institute of Polar Research ; David GRÉMILLET, Centre d'Ecologie Fonctionnelle et Evolutive

To cope with the social-ecological crisis that is affecting our oceans and coastal areas, conservation and management policies shifted from a paradigm of separated ecological and human systems governed by top-down policies, to one of more horizontally-governed social-ecological systems. However, 1) the extreme complexity of social-ecological systems, 2) the incapacity of marine protected areas alone to counter environmental degradation, and 3) the lack of consideration of asymmetries between participants in public participation processes, have prevented this shift to yield the expected results. To overcome these obstacles, we propose to use seabirds both as indicators of marine ecosystem health and as ambassadors of less visible, and often less charismatic, marine species to make progresses on marine policies and global conservation issues. Seeing the ocean through the eyes of seabirds therefore implies: 1) identifying, characterizing and quantifying the interactions between seabirds and human activities, 2) identifying ecological solidarities and vulnerability transfers among the different habitats used by seabirds, and 3) studying and developing the use of visual data collected on and by seabirds as a springboard for stakeholder cooperation. Here, we develop these three research avenues and give concrete examples of implementation in the English Channel. Using GPS loggers and video cameras deployed on Northern gannets (*Morus bassanus*), we were able to 1) identify, characterize and quantify the interactions between gannets and fisheries, 2) identify ecological solidarities between their breeding (the English Channel) and wintering (especially the coastal waters of West Africa) grounds, and 3) successfully use maps of GPS tracks and videos of gannet-trawlers interactions to address global marine conservation issues with fishermen, shellfish farmers, NGO representatives, environmental

managers and scientists. While there is no single, idealized solution to the marine social-ecological crisis, we believe that our interdisciplinary approach can help meeting the challenges of managing common-pool marine resources by enhancing ecosystem stewardship both in protected and unprotected areas.

SESSION # 197 A BOLD STRATEGY FOR BIODIVERSITY CONSERVATION

Elaine Leslie

Leslie

Ray SAUVAJOT, Leslie [INSTITUTE] National Park Service

As we edge closer to the National Park Service Centennial, we have much to celebrate. Science and stewardship have a prominent role in park, more than any time in our history, and yet there is reason for concern. The diversity of native species, and the genetic material they contain and the processes to which they are critically linked, is declining at an unprecedented rate. We are losing our nation's wealth, species richness, role/function, and a biodiverse landscape. This leads to destabilization of ecological processes and reduction in vital ecosystem services. We must acknowledge that biodiversity also has cultural and historical connections that we can't afford to lose. We must act. Parks are critical preserves of biodiversity in the face of increasing global changes yet they tend to be managed largely as isolated islands. Scientific consensus cautions that managers plan for connected ecosystems across broad spaces and that ensure the restoration of ecosystems and their keystone species. The NPS is committed to playing a leadership role in a strategy that will benefit biodiversity conservation across the landscape. Laws, policies, and programs implicitly or explicitly support the conservation of biological diversity. Although these protection efforts represent a significant investment in conservation, they have been insufficient to stem the tide of biodiversity loss and degradation. Now needed is a cohesive and comprehensive approach for designing this cornerstone strategy. We examine a national biodiversity conservation strategy in which the NPS plays a significant role. It is only with a national strategy that we can manage toward clear outcomes and evaluate the success of our progress toward the conservation of biodiversity. In taking a national approach, the NPS hopes to cultivate a support network, a community of practice among a myriad of global partners, with one common goal of biodiversity conservation and stewardship in the 21st century.

HIGH INTENSIFICATION DECREASES PHYLOGENETIC DIVERSITY OF PLANT COMMUNITIES IN MONTANE AND SUBALPINE AGO-ECOSYSTEMS

Malie Lessard-Therrien

University of Bern

Jean-Yves Humbert, University of Bern ; Raphaël Arlettaz, University of Bern

Below the tree line in the Alps, grasslands are maintained by human farming activity since centuries. A long history of extensive exploitation and different cultural and natural contexts has resulted in a rich assemblage of species in these habitats. However, in the recent decades, pressure to increase agricultural productivity has led to an intensification of the farming practices which have negative impacts on biodiversity. Our definition of biodiversity ranges from genetics to the ecosystem level. The aim of this ongoing research project is to find an optimal management where farmers obtain good hay yields while maintaining semi-natural grassland ecological integrity. Since 2010, different management treatments were applied in montane and subalpine meadows across the Swiss Central Alps. Surveys were conducted on the vegetation during the summer 2014. We found that phylogenetic diversity, along with the overall species richness decreased in the most intensive management treatment. Plants coverage responded differently according to their functional groups. The grasses coverage remained stable across control and management treatments. Any kind of management involving fertilization increased the forbs coverage. The legumes coverage was enhanced by both irrigation and/or fertilization. Further surveys are being conducted on insects and belowground organisms during summer 2015. Our results will be broadcasted to farmers and stakeholders and will serve to draw new guidelines for the future development of montane and subalpine agricultural systems.

IMPACTS OF A ROAD CONSTRUCTION ON WATERBIRD POPULATIONS AT ASUNCIÓN BAY, PARAGUAY

Arne Lesterhuis

Guyra Paraguay

A. Alberto Yanosky, Guyra Paraguay ; Marianela VELILLA, Guyra Paraguay

The Asunción Bay is a relatively small bay (c.600 ha in total) located along the northern outskirts of Asunción, the capital of Paraguay. Despite the relative small size of the area, over 290 species of birds have been recorded here, including 89 species of waterbird of which 22 are Nearctic migratory shorebirds. The waterbird community at the Asunción Bay responds to waterlevel fluctuations with numbers increasing when waterlevel is low (austral spring and summer) and decreasing when waterlevel is high (austral autumn and winter). Regular monitoring of waterbirds by Guyra Paraguay since 2000, has shown the site to be of great significance for waterbirds, and especially as a stopover site for Nearctic shorebirds during their southbound migration. High counts of the Near threatened Buff-breasted Sandpiper *Calidris subruficollis* triggered the

sites designation as an IBA and Western Hemisphere Shorebird Reserve Network site, and due to its importance to birds in general, it was declared an Ecological Reserve in 2005. The recent development of a coastal road has presented important opportunities for the urban population of Asunción to reconnect with its natural heritage, but unfortunately dredging to create the embankment for this road in 2010 destroyed close to 70% of the habitat in the bay used by waterbirds. The disappearance of muddy beaches on the bay caused the drastic reduction of the total number of Nearctic shorebirds that regularly visited the Bay, but also caused changes in abundance and diversity of resident waterbird populations. The Municipality of Asunción and the Ministry of Public Works have agreed to work with Guyra Paraguay to implement a series of habitat recuperation and management measure to improve remnants habitats for both waterbirds in general and shorebirds in particular.

RESTRICTING ACCESS TO INVASION HUBS ENABLES SUSTAINED CONTROL OF AN INVASIVE VERTEBRATE

Mike Letnic

University of New South Wales

Jonathan WEBB, University of Technology Sydney ; Tim JESSOP, La Trobe University ; Tim DEMPSTER, University of Melbourne

Biological invasions often occur through expansion of satellite populations that become established at 'invasion hubs'. Theoretical studies suggest that targeted control at invasion hubs can effectively suppress the populations and impacts of invaders, but there is little empirical evidence that such control activities can suppress both populations of invaders and their impacts. In Australia's arid rangelands, small dams that are used as reservoirs at artificial livestock watering points (AWP), function as invasion hubs by providing an invasive vertebrate, the cane toad (*Rhinella marina*), with refuge from extreme aridity during the annual dry season. Cane toads are toxic to many Australian predators, consequently some predator species have declined following toad invasion. Here, we ask whether sustained control of cane toads and alleviation of their impacts on native species can be achieved by restricting their access to water. First, we constructed fences to exclude toads from dams and maintained these fences for one year. Toad populations at fenced dams were suppressed by 1-2 orders of magnitude compared to unfenced controls and procedural controls. Second, we compared toad numbers and their impacts on monitor lizards at AWP fitted with two types of reservoir, dams and steel tanks. Toads have little access to water at tanks. In comparison to dams, toad numbers were low at steel tanks, and monitors were more abundant in the vicinity of tanks than dams. Conversely, small lizards, the prey of monitor lizards were more abundant near dams than tanks. Our study demonstrates that sustained control of invader populations and their impacts can be achieved by restricting their access

to invasion hubs. Elimination of invasion hubs could be conducted reactively, to control established populations of invaders, or conducted strategically, by rendering invasion hubs unsuitable for colonization ahead of the invasion front to prevent further population spread.

141 TROPHIC AND DIVERSITY CASCADES FOR RESILIENCE AND POLICY REFORM IN AGROECOSYSTEMS

Deborah Letourneau

University of California

Daniel KARP, University of California

Density-based trophic and diversity cascades are dynamic processes in agroecosystems, whereby community characteristics like relative abundance, species richness or evenness in one trophic level indirectly affects changes in a non-adjacent trophic level. On-farm research from the Central Coast of California shows how density and diversity cascades dampen potential shocks in commercial organic food production and marketing. Specifically, vegetational resource diversity at the landscape scale has indirect effects on the richness or evenness of arthropods and pathogens on the third trophic level. We show how these dynamics can increase biological control of key pests and reduce the likelihood of food contamination. However, food safety mandates and emerging policy threaten these biological processes, thus disrupting critical resiliency mechanisms and ecosystem services.

73. LINK BETWEEN SELF-RECRUITMENT, LOCAL RETENTION AND PERSISTENCE IN MARINE METAPOPULATIONS

Christophe Lett

IRD

Tri NGUYEN-HUU, IRD ; Marion CUIF, Direction des Pêches Maritimes et de l'Aquaculture ; Pablo SAENZ-AGUDELO, Universidad Austral del Chile ; David KAPLAN, Virginia Institute Of Marine Science

Accurately estimating connectivity, the exchange of individuals among distant subpopulations, is of central importance to understanding marine metapopulations dynamics and to effectively managing marine resources, for example via the creation of marine protected areas. Two main indices are used to assess the tendency for self-maintenance of local marine populations: self-recruitment (SR), defined as the ratio of locally produced settlement to settlement of all origins at a site; and local retention (LR), the ratio of locally produced settlement to local egg production. LR has a clear relationship to self-persistence of individual sites, however SR is easier to measure experimentally. We use theoretical, simulation and empirical approaches to bridge the gap between these two indices, and

demonstrate that there is a proportional relationship between SR and LR for metapopulations close to a stable state and with lifetime egg production (LEP) approximately uniform over space. Therefore, SR provides information on relative rates of LR for systems satisfying these conditions. Furthermore, the ratio between LR and SR can be used to evaluate global persistence of metapopulations, and therefore provides valuable information not necessarily available if only LR is considered.

FLUKEBOOK: CONNECTING STAKEHOLDERS IN CETACEAN CONSERVATION SCIENCE THROUGH POWERFUL WEB-BASED TOOLS AND SOCIAL MEDIA

Jacob Levenson

U.S. Department of Interior

Shane GERO, Dominica Sperm Whale Project

As a result of their large spatial and temporal ranges, conservation of cetaceans requires collaboration between diverse stakeholders. Current collaborative attempts either limit citizen science involvement by lacking an intuitive design, or limit integration between research institutions by having isolated databases. Flukebook is the first web platform that engages both the research and citizens science aspects of conservation. It provides researchers with the detailed scientific tools needed for analysis and transboundary collaboration without sacrificing interactivity or approachability for citizen scientists wanting to engage in the project. Researchers have access to data management tools; photo-matching algorithms and a global catalog of individuals; and connectivity to common analytical tools for mark-recapture; genetic, and socio-ecological studies. At the research level, data sharing is accomplished on a peer-approval basis which leads to growing inclusiveness. For citizens scientists, Flukebook enables participants to receive automatic profile updates on individuals they have sighted, encouraging repeat participation and engagement in conservation initiatives in those regions. During beta testing, whale watch operators, citizens, and researchers have connected to share data from 700+ individuals among thousands of sightings. Flukebook acts as a singular tool, filling gaps in species distribution, individual movements, social associations and genetic structure.

THE ECOLOGICAL IMPACTS OF CLIMATE CHANGE CAN BE GREATER IN THE TROPICS THAN THE ARCTIC

Teng Li

University of Hong Kong

David L. Thomson, University of Hong Kong

Tropical temperatures are rising more slowly than arctic temperatures, and the ecological impacts of tropical climate change have often been assumed to be smaller. Some exceptions have recently been found, notably ectothermic species, which are unable to regulate their body temperatures

physiologically and which may be especially vulnerable to rising temperatures in the hot tropics. If they are already living at or above their optimal temperatures in hot regions then further warming could have much more negative effects than in cooler regions. Endotherms are often thought to be buffered from thermal stress, but here we look at whether this is actually the case. Even if tropical endotherms can thermoregulate physiologically, they remain vulnerable to the indirect effects of rising temperatures on the systems, habitats, and ectothermic species upon which they depend. By studying the Grey Plover *Pluvialis squatarola* which migrates between arctic and tropical regions, we demonstrate for the first time that the population growth rates of an endotherm can actually respond positively to higher temperatures in the cold arctic, but negatively to higher temperatures in the hot tropics. We propose that rising tropical temperatures may be important not just for ectotherms, but more generally for endotherms as well.

A BOLD PLAN FOR MAKING CONSERVATION MORE COMPELLING AND EFFECTIVE

William Lidicker

University of California

In spite of widespread, long-standing, and heroic efforts by numerous of conservationists and organizations, conservation accomplishments on a global scale have only been marginally successful. Certainly, progress in stemming the tide of human exploitation of resources, biodiversity declines, social unrest, energy requirements, climate change, warfare, terrorism, food scarcity, uneven distribution of wealth, and economic and political refugees, to name some of the dilemmas facing the human enterprise, has not come close to keeping up with needs. Although there remain grounds for optimism, we clearly need some bold new initiatives to significantly enhance the effectiveness of the conservation message. To do this we need to start with some basic principles of population dynamics. Six of the most basic and relevant principles are outlined. These scientific basics can then serve to anchor a cohort of strategic policies that address the objectives of human welfare and survival. Seven examples of such strategies are: 1) Devise ways to slow and then stop human population growth as urgently and humanely as possible; 2) Eliminate the confrontational approach that now dominates the human enterprise. We will not succeed without cooperation within the human family that focuses on our common goals, not our differences; 3) Develop procedures for dealing with non-cooperating individuals, interest groups, political parties, and nations. The common welfare must prevail over those who prefer selfish objectives or genocide; 4) Maintain an optimistic attitude to encourage cooperation, but without abandoning reality; 5) High levels of education must be sustained in order to have rational discussions of shared goals; 6) Income disparities must not

exceed modest levels that are commensurate with geography, relative contributions to human welfare, and variations in possession of special skills valued by communities; and 7) Provide adequate support for basic research in conservation.

BALANCING ECONOMIC COSTS AND THE ABILITY TO DETECT CHANGE IN SURVIVAL FOR OPTIMISING CAPTURE-RECAPTURE SURVEY DESIGN OF LONG-LIVED BIRDS

Nicolas Lieury

IMBE Aix-Marseille Université

Aurélien BESNARD, CEFE-EPHE ; Sébastien DEVILLARD, LBBE Université Lyon I ; Olivier GIMENEZ, CEFE-CNRS ; Cécile PONCHON, Conservatoire des Espaces Naturels de Provence ; Alexandre MILLON, IMBE Aix-Marseille Université

Capture-recapture surveys (CR) have become popular tools in a context of evidence-based conservation and a growing number of practitioners include the marking of individuals when implementing population monitoring. Estimating environmentally-induced variability in survival is indeed of paramount importance for assessing population viability, especially for long-lived animals where survival is often the key driver of population dynamics. CR surveys have proved their efficiency in quantifying change in survival rates in relation to e.g. environmental conditions or the set-up of rescue actions, and are thus highly valuable for guiding conservation plans. Many such surveys however, although being particularly costly, are implemented without an appropriate assessment of what could be an optimal design, and this may impair management success. Based on a general life history and a monitoring strategy inspired from long-lived raptors, we propose here an integrative simulation experiment that combines the main components of a CR survey together with precise economic costs derived from existing monitoring programs. In particular, we explore the outcomes of the trade-off between the ability to detect a given change in survival rates and the effort dedicated to CR surveys (in terms of number of birds ringed/year, juvenile-to-adult ratio in ringed birds, resighting strategy and survey duration). Our ultimate aim is to propose to both practitioners and researchers a comprehensive set of guidelines ensuring an optimal resource allocation for designing new CR surveys or improving existing ones.

CHARACTERIZATION OF MHC CLASS II SUPERTYPES IN THE NEW ZEALAND ENDEMIC HOCHSTETTER'S FROG

Mette Lillie

Faculty of Veterinary Science, University of Sydney

Catherine E. GRUEBER, Faculty of Veterinary Science, University of Sydney ; Jolene T. SUTTON, University of Hawai'i at Mānoa, Department of Biology ; Robyn HOWITT, Landcare Research ;

Phillip J. BISHOP, Department of Biology, University of Otago ; Dianne GLEESON, Institute for Applied Ecology, University of Canberra ; Katherine BELOV, Faculty of Veterinary Science, University of Sydney

The New Zealand native frogs, family Leiopelmatidae, are among the most archaic in the world. All four species are among the top 100 evolutionarily distinct and globally endangered (EDGE) amphibians. *Leiopelma hochstetteri* (Hochstetter's frog) is a small, semi-aquatic frog with numerous, fragmented populations scattered across New Zealand's North Island. The MHC is a large gene family with a vital role in the vertebrate immune response and is useful an indicator of adaptive genetic variation to evaluate immunogenetic health. We characterized the major histocompatibility complex (MHC) class IIB gene (DAB) in *L. hochstetteri* from a spleen transcriptome, and then compared its diversity to neutral microsatellite markers to assess the adaptive genetic diversity of five populations. Positive selection and extreme population differentiation have contributed to very high diversity. In total, 74 DAB alleles were characterized and only two alleles were shared by more than one population. We identified four supertypes based on clustering analysis on the DAB alleles. All supertypes were represented in four of five populations, albeit at different frequencies. The Ottawa population was an exception to these observations, with only two DAB alleles present, representing two supertypes. This low immunogenetic diversity in Ottawa may predispose this population to a greater risk of extinction from emergent disease.

THE INFLUENCE OF REGULATORY FRAMEWORKS ON CORPORATE SUSTAINABILITY POLICIES AND PRACTICES IN THE PALM OIL INDUSTRY IN BRAZIL AND INDONESIA

Celine Lim
Yale University

Concerns surrounding the palm oil industry have resounded around land use change from deforestation and the negative social impacts on rural smallholders. Sustainable palm oil development can occur but must be managed with a landscape approach that strives to balance large-scale agriculture with positive outcomes for conservation and communities. Indonesia's palm oil sector is well developed but has a notorious reputation for the destruction of primary rainforest. Brazil's palm oil sector is expanding, with a strong rhetoric of rural development and expansion on degraded lands. There are intentions that its trajectory will be unlike that of Southeast Asia. This exploratory research examines government regulations, programs and support structures in Indonesia and Brazil and asks how they may have driven current corporate policies of oil palm companies. It focuses

on two social and environmental sustainability outcomes: 1) inclusion and benefits for smallholders and 2) avoiding and reducing deforestation, maintenance of conservation areas, and development on degraded lands. I looked at case studies of companies in Indonesia (East Kalimantan) and Brazil (Pará) that are domestic and mid-sized to explore their sustainability practices and motivations. My methods included an extensive literature and document review, including smallholder surveys, government documents, seminar reports and presentations. I also conducted interviews with key informants in Indonesia and Brazil, including field researchers, smallholders and sustainability managers of the case study companies. Government intervention in the industry in each country occurs to a different degree, and has both enabled and disabled sustainability outcomes. The land permitting and zoning process as well as market incentives heavily affect sustainability policies. For a company to engage in sustainability, the public sector has to play a significant role in providing the support structures needed.

THE POPULATION GENETIC ANALYSIS OF AN ENDANGERED KOREA FIR (*ABIES KOREANA*) AND CONSERVATION IMPLICATION

Jina Lim
National Institute of Biological Resources
Myounghai KWAK, National Institute of Biological Resources ; Byoungyoon LEE, National Institute of Biological Resources ; Jeong-Ki HONG, National Institute of Biological Resources

The *Abies koreana* E. H. Wilson, known as one of the charismas trees, is an endemic and rare species from Korea, whose distribution is limited to the high elevation of mountains in the Jejudo Island and the southern region of Korean peninsula. This species is considered to be endangered by IUCN because of repeated population reduction. Its congeneric species, *A. nephrolepis* (Trautv. ex Maxim.) Maxim. is distributed to the central and northern parts of Korea, Manchuria, and Siberia. We tried to investigate genetic status of *A. koreana*, comparing with *A. nephrolepis*. In order to understand genetic characteristics of two *Abies* species, the population genetic studies including extensive sampling will be desired. Thus, we conducted firstly developing microsatellite markers. Using one individual of *A. koreana*, 160Mbp (325,776 reads) of genome sequence was obtained by conducting the Roche 454 GS-FLX Titanium sequencing. Among them, we extracted the sequences including the repeat motifs of di- and tri-nucleotide repeats using a bioinformatic analysis. Two hundred eighty eight pairs of PCR primers were tested in order to amplify the fragments with repeat motifs and a total of 71 primer pairs were successfully amplified in both species. Among 71 primer pairs, 10 pairs showed the polymorphism in *A. koreana* and *A. nephrolepis*. Population genetic analysis of 433 individuals from 18 populations, reflecting their geographic distributions

is being performed with 13 microsatellite including previously reported ones. The genetic structure and basic statistics of genetic analysis will be presented. We believe that these analyses will contribute to understand current *A. koreana* distribution and the relationships between populations and to prepare conservation strategies.

BOTH CURRENT AND HISTORICAL LANDSCAPE CONFIGURATION AFFECT PLANTS AND BUTTERFLIES IN FRAGMENTED FARMLANDS

Regina Lindborg

Stockholm University

Riccardo BOMMARCO, Swedish University of Agricultural Sciences ; Erik ÖCKINGER, Swedish University of Agricultural Sciences ; Lorenzo MARINI, Swedish University of Agricultural Sciences

There is an increasing awareness that not only area and isolation, but also the landscape surrounding habitat patches influence population persistence and species diversity in fragmented landscapes. In addition, populations can exhibit transient dynamics in response to historical land use, where slow extinctions and immigration delay the arrival to a new equilibrium. Here we assess under which current and historical land use circumstances an extinction debt occurs for plants and butterflies by examining the effects of grassland fragmentation in different landscape matrix. The organisms were studied in replicated semi-natural grassland patches of different sizes and isolation, embedded in landscapes dominated either by forest, arable land or a mix of these. Habitat loss was estimated in each landscape by comparing modern maps to ~45 year old digitized aerial photographs. We found positive effects of current patch area on species richness of butterflies but not of plants. Richness of both plants and butterflies was lowest in patches in landscapes dominated by arable land and highest in forest-dominated landscapes. Differences in matrix response among organism groups probably impinge on differing mechanisms. A forest matrix is likely to provide additional resources for butterflies whereas plant diversity in grassland can be explained by habitat generalists more easily invading these patches. Richness of specialist plants was best explained by historical habitat connectivity, whereas richness of butterfly specialists responded to both historical habitat area and connectivity. This suggest that also short-lived herbivorous insects could experience extinction debt if linked to the slow extinctions of persistent and long-lived plants. Our study shows the importance of considering both current and historical land use as well as landscape matrix characteristics when aiming at conserving multiple organism groups in fragmented landscapes.

101 LARGE, OLD TREES: RETAINING AND GROWING SMALL-SCALE CRITICAL STRUCTURES

David Lindenmayer

Australia National University

William LAURANCE, James Cook University ; Sam BANKS, Australia National University ; Adrian MANNING, Australia National University ; Erik NELSON, Bowdoin College

Large old trees are key elements of vegetation structure in many natural and human-modified ecosystems globally. These range from forests and woodlands (including mangrove systems), to agricultural and urban environments. An array of empirical studies in these contrasting ecosystems indicates that large old trees are disproportionately important for ecological processes and many elements of biodiversity. These processes including storing carbon, producing flowers and seeds, providing habitat for wildlife (including threatened vertebrate and invertebrate taxa), and facilitating animal movement across landscapes. Populations of large old trees are declining in many ecosystems worldwide as a result of a suite of threatening processes that manifest in different, often ecosystem specific ways – logging, fire, over-grazing, weed invasion, and deliberate removal for human safety. These processes can accelerate the rate of loss of existing trees, impair the recruitment of new cohorts of large old trees, or both. The outcome will be a “functional extinction” of large old trees as a critical age cohort of trees in many ecosystems. The critical ecological roles played by large old trees coupled with the long lag times between their loss and recruitment has significant implications for conservation policy. First, it means that planting new trees as an offset for the loss of large old trees is a flawed approach to offsetting ecological impacts of tree removal. Second, very long-term policies are essential to conserve populations of large old trees – far beyond the typical time horizons of resource management agencies and government. Third, the array of long-term negative impacts of large old tree removal must be far better recognized in resource management policies and on-ground management practices.

PHOENIX FLAGSHIPS: CONSERVATION VALUES AND GUANACO REINTRODUCTION IN AN ANTHROPOGENIC LANDSCAPE

Adrien Lindon

CH2M HILL

Meredith Root-Bernstein, Aarhus University

Multiple forms of valuation contribute to public acceptance of conservation projects. Here we consider how aesthetic, intrinsic and utilitarian values contribute to public attitudes towards a proposed reintroduction of guanaco (*Lama guanicoe*) in a silvopastoral system of central Chile. The nexus among landscape perceptions and valuations, support for

reintroductions, and management of anthropogenic habitats is of increasing interest due to the proliferation of conservation approaches combining some or all of these elements, including rewilding and reconciliation ecology, for example. We assessed attitudes and values through an online questionnaire for residents of Santiago, Chile, using multiple methods including photo-montages and Likert scale assessments of value-based statements. We also combined the questionnaire approach with key informant interviews. We find strong support for the reintroduction of guanacos into the Chilean silvopastoral system ("espinal") in terms of aesthetic and intrinsic values, but less in terms of utilitarian values. Respondents preferred a scenario of espinal with guanacos and expressed interest in visiting it, as well as support for the reintroduction project on the basis that guanacos are native to central Chile. We suggest that reintroduced guanacos could serve as a "phoenix flagship species" for espinal conservation, that is, a flagship species that has gone regionally extinct and is known but not associated with the region in the cultural memory. We consider how the lack of local cultural identity can both help and weaken phoenix flagships, which we expect to become more common.

88-A COMPARISON OF SOFT AND HARD REINTRODUCTIONS OF THE CRITICALLY ENDANGERED WYOMING TOAD (ANAXYRUS BAXTERI)

Luke Linhoff

Florida International University

Maureen DONNELLY, Florida International University

The Wyoming toad (*Anaxyrus baxteri*) is a critically endangered species found only in Albany County, Wyoming, USA. In 1993, the Wyoming toad was listed as extinct in the wild, but it survived in captivity. Many wildlife translocation studies have shown how different release protocols can impact the successful establishment of reintroduced animals. Previous reintroductions of the Wyoming toad have typically utilized a hard release strategy for both translocation of larvae and adults. In contrast, allowing an animal to acclimate to the release site, known as a soft release, has been shown to decrease animal stress while increasing initial survivability in some taxa. After multiple reintroduction attempts of the Wyoming toad between 1992 and 2012 had limited success, efforts to study the causes of failure and explore new methods were undertaken by the Wyoming toad recovery team. In the summer of 2014, we performed a paired release of two groups of captive bred toads at Mortenson Lake, Wyoming, USA. Twelve individuals were hard released and twelve individuals were soft released after acclimating in an outdoor enclosure for 14 days. All released toads were fitted with a custom harness allowing for the external attachment of a novel harmonic tracking device. We tracked all toads for up to eight weeks to compare activity patterns, site fidelity, survival and home range

size in both groups. Finally, we examined the acquisition rates of the pathogenic fungus *Batrachochytrium dendrobatidis* (Bd) by collecting skin swabs from the reintroduced toads each week following their release. Results will be presented.

A GLOBAL DATABASE OF RIVER AND CATCHMENT ATTRIBUTES TO FACILITATE AQUATIC ECOSYSTEM MODELLING AND CONSERVATION PLANNING

Simon Linke

Griffith University

Bernhard LEHNER, McGill University

As river conservation planning is entering its second decade, the science behind planning for investment to protect freshwater bodies is steadily advancing. However, uptake of these methods is still hindered by technical aspects in many cases. Two key obstacles are a) defining the network topology that describes the connected nature of a river system and b) the patchy data sources that often hamper conservation planning and add bias to data rich areas. To facilitate broader application of modern species modelling and conservation planning methods, we designed a global database of river and catchment attributes, linked to the HydroSHEDS data framework which provides global river network and watershed delineations based on a digital elevation model (DEM) at 15 arc-second resolution. As part of this data framework, the HydroBASINS layer offers a hierarchical, nested breakdown of subcatchments. At the highest level of subdivision, Australia, for example, is split into 60 000 subcatchments. For each of these subcatchments, we calculated a suite of local (within subcatchment), as well as upstream (entire watershed area) attributes for a variety of both natural and human influenced descriptors. These include hydrological variables (including runoff and discharge estimates), climate, terrain, soils, vegetation, topology, and network geometry. To characterise human disturbance, we summarised land use measures, including new data on agricultural production, as well as location and storage volume of dams, population and urbanisation. In addition, we introduce a free application tool that will convert the network topology of HydroBASINS to files easily useable in conservation planning packages such as Marxan and Zonation. We will demonstrate a continental application of the data and the network tool based on data from South America. After beta-testing, we anticipate that both the attribute layers and the tool will be freely available in early 2016.

ID: 193 REWILDING LARGE CARNIVORES: NEW WILDERNESS OR WILD NOVEL ECOSYSTEM?

John Linnell

Norwegian Institute for Nature Research

Luigi BOITANI, University of Rome "La Sapienza"

With a few important exceptions, Europe's large carnivore populations have made a remarkable recovery during the last 30 years. There are 17,000 bears, 12,000 wolves, 9,000 lynx and around 1,250 wolverines in Europe today. One third of the continent's surface is home to at least one species of large carnivore. Conservation is now moving from a phase of "saving from extinction" to "living with success". This recovery has the potential to be viewed as one of the most ambitious rewilding efforts being undertaken anywhere on the globe. However, now that extinction is no longer an immediate threat a considerable debate is emerging concerning the appropriate recovery targets and management regimes. Questions like "how many carnivores are enough?" and "how should they be managed?" are hotly contested. On one hand, there is a movement to integrate them into existing wildlife management structures that focus on hands-on approaches like sustainable harvest, balancing competing land-use interests, and conflict containment. These views conceptually fall within the emerging "novel ecosystem" discourse. On the other hand, there are voices calling for hands-off approaches like continual protection from killing by humans and the restoration of natural ecosystem processes. These views fall into the emerging European "wilderness" discourse. Underlying these different views are widely different value systems and beliefs concerning the appropriate place of humans in nature. We explore the ecological and societal dimensions underlying the possibilities and practicalities of the range of potential strategies that lie between these two extremely different points of view. There is an urgent need to resolve various scientific issues associated with recovery goals because the ongoing debates are threatening to split the conservation movement, fracture potential pro-conservation alliances, and provide space for an increasingly organized anti-carnivore movement.

STRESSED IN THE CITY; WHY COMMON SPECIES ARE IMPORTANT

Paul Lintott

University of Stirling

N BUNNEFELD, University of Stirling ; K PARK, University of Stirling

Urbanisation is one of the most dramatic forms of land use change which relatively few species can adapt to. The fragmentation and loss of semi-natural habitats has reduced species richness resulting in biotic homogenisation. Declines in biodiversity have also led to the estrangement of people from nature with the consequence that urban green space is undervalued. In urban areas, the widespread distribution and high abundance of relatively common species also has the potential to reengage the public with nature and garner support for wider conservation action. However, common

species are often perceived to require little attention, as uninteresting, and their significance is frequently overlooked despite their importance to ecosystem functioning. Over the past four years we have studied bat activity using acoustic surveys within fragmented urban woodlands, along urban waterways, and within urban gardens at both local and landscape scales across the U.K. Pipistrelle bats (*Pipistrellus pygmaeus* & *P. pipistrellus*) were the most frequently recorded and widespread of all British bat species. We found that even those bat species considered to be relatively well adapted to city living were negatively affected by high concentrations of built environment. In this talk, using bats as an example, we discuss why common species merit our attention and conservation effort within cities and recommend management strategies at multiple spatial scales to protect and improve urban habitats for their benefit.

CONSERVING SIBERIAN CRANES IN CHINA THROUGH SUSTAINABLE WATER MANAGEMENT

Chunyue Liu

Northeast Institute of Geography and Agroecology, Chinese Academy of Sciences

Hongxing JIANG, Research Institute of Forest Ecology, Environment and Protection, Key Laboratory of Forest Protection of State Forestry Administration, Chinese Academy of Forestry

Siberian Crane is the world's third rarest crane, and listed in the IUCN Red List as a critically endangered species. The total population is estimated at 3,500 birds, of which approximately 98% belongs to the East Asian population. The Momoge National Nature Reserve, listed in Ramsar international important wetlands in 2013, is the most important stopovers along the eastern flyway. The Momoge NNR is the alluvial area in the lower reaches of Nenjiang River, which is in the semi-arid area of western Songnen Plain in Jilin Province, Northeast China. Since 2007, over 80% world population of Siberian Cranes used the Etoupao area for about 1.5 months during each migration season, which is the study area covering less than 5000 hectares in the middle of Momoge. With lack of effective water management, the crane distribution and populations are instable and changeable in this region. Predictions indicate that this region is sensitive to climate change, with conditions expected to become hotter and drier. To increase the resilience of wetland biodiversity, especially Critically Endangered Siberian cranes and other threatened waterbirds at Momoge NNR through sustainable and participatory water management practices that respond to increased water variability under the influences of human pressures and climate change. The presentation will show the achievement about strengthen conservation at Momoge by developing climate change adaptation plans, supported by a range of other activities including applied research at

these and nearby sites. The presentation will also demonstrate climate change adaptation to secure key conservation values and livelihoods for local communities, alleviating conflicts that impact wildlife and people, and helping local people to identify economic options less vulnerable to climate variability, thus better able to sustain local resources.

COMMUNITY-BASED HUMAN-WILDLIFE CONFLICT MITIGATION: A SUCCESSFUL CASE FROM WOLONG NATURE RESERVE, CHINA

Wei Liu

Human and Environment Linkage Programme
Beilu DUAN, Human and Environment Linkage Programme ; Meng MING, Human and Environment Linkage Programme

Human-wildlife conflict is a major threat to global biodiversity conservation. As a “public bad”, human-wildlife conflict cannot be effectively and sustainably mitigated without active participation of the affected communities. Here we report a successful case of community-based human-wildlife conflict mitigation from Wolong Nature Reserve, China, located in the SW-China Mountains global biodiversity hotspot. Wolong is most famous for hosting the largest wild panda population in China and is also home to ~5,000 local farmers. Crop raiding by wildlife was pervasive and remained unsettled by the government due to financial and policy limitations. Local people took various measures to protect croplands and/or scare crop raiders away. Almost all measures turned to be ineffective and caused additional problems, with some dangerous for people and livestock and others illegal and threatening wildlife and forests. To tackle this issue, wired fences were introduced to the reserve to mitigate human-wildlife conflict. We compared crop raiding impacts in three local communities - ZJL, ZMS and CBY, where fences were installed in ZJL by the government (in 2012) and in ZMS by us (in 2013) with intensive involvement of community members. We conducted baseline and follow-up surveys on household losses and attitudes. In 2013 Crop damages in ZMS (~5%) was much lower than ZJL (~24%) and CBY (~35%). We also found a range of indirect benefits and an improvement in community members’ attitude toward conservation. Through field surveys and habitat assessment we determined that the potential impacts of the fences on wildlife at landscape scale was not significant. Local government has recently provided fund to scale up the ZMS experience to the whole reserve. Applying Ostrom’s design principles in common pool resources management, we further discuss the importance of community participation and cross-sector partnership in mitigating human-wildlife conflicts.

SEASONAL ACTIVITY PATTERNS OF UNGULATES IN QINLING MOUNTAINS BASED ON CAMERA-TRAP DATA

Xuehua Liu

School of Environment, Tsinghua University, Beijing 100084
Xiaodong JIA, Northwestern University, Shaanxi 710069 ; Xingzhong YANG, Northwestern University, Shaanxi 710069 ; Pengfeng WU, School of Environment, Tsinghua University, Beijing 100084 ; Melissa SONGER, Smithsonian Conservation Biology Institute, Front Royal, Virginia 22630, USA ; Qiong CAI, Shaanxi Guanyinshan Nature Reserve, Foping County, Shaanxi 723400 ; Xiangbo HE, Shaanxi Foping Nature Reserve, Foping County, Shaanxi 723400

Between August 2009 and April 2013, in Guanyingshan Nature Reserve, Shaanxi, China, we collected photo data on six ungulates (*Budorcas taxicolor*, *Naemorhedus griseus*, *Elaphodus cephalophus*, *Capricornis milneedwardsii*, *Muntiacus reevesi* and *Moschus berezovskii*) with 18 infrared cameras. Using the relative abundance index (RAI), we analyzed their activity patterns and seasonal differences. The results show that: (1) the total RAI reaches 58.71%, the RAIs were 28.02% for *B. taxicolor*, 13.24% for *N. griseus*, 10.08% for *E. cephalophus*, 4.21% for *C. milneedwardsii*, 2.26% for *M. reevesi*, and 0.90% for *M. berezovskii*. (2) The monthly RAIs (MRAI) of six ungulates reflected seasonal activity patterns. *B. taxicolor*, *N. griseus*, *E. cephalophus*, *C. milneedwardsii*, *M. reevesi* show similar patterns, which were most active in summer, inactive in autumn and winter, and then active again in spring. In reverse, *M. berezovskii* was most active in winter and least active in summer. (3) The time-period relative abundance indices (TRAIs) of six ungulates reflect their daily activity patterns. *B. taxicolor* and *N. griseus* have similar daily patterns with a peak at 06:00-20:00, while *E. cephalophus*, *M. reevesi* and *M. berezovskii* show obvious crepuscular habits. *C. milneedwardsii* has two peaks at 02:00-06:00 and 20:00-22:00 implying nocturnal activities. (4) Comparison of daily activity patterns among four seasons show that *B. taxicolor* display a different pattern in spring with a peak at 16:00-20:00. Compared with other seasons, *N. griseus*, *E. cephalophus* and *C. milneedwardsii* have different patterns in winter with either a delayed or advanced activity peak. For *M. reevesi*, spring daily activity patterns showed two peaks at 00:00-10:00 and 18:00-20:00. Camera trapping data analysis help us to understand the activity patterns of these ungulates in Qinling and to provide a theoretical basis and data support for the nature reserves to protect these ungulates efficiently.

76: EVALUATING THE IMPACT OF SPECIES-BASED INTERVENTION: THE CONTRIBUTION OF REINTRODUCTIONS TO SPECIES RECOVERY.

Natasha Lloyd

Centre for Conservation & Research, Calgary Zoological

Society

Axel MOEHRENSCHLAGER, Centre for Conservation & Research, Calgary Zoological Society ; Michael HOFFMANN, IUCN Species Survival Commission

Humans have been moving species around the planet for millennia. Reintroductions, as a species conservation tool, have been constantly increasing in frequency within the last few decades and the science around translocations is constantly improving. As such, species reintroductions are now a ubiquitous tool within the discipline of conservation. The global use of reintroductions is reflected not only in terms of the scientific literature but also in terms of the number of applied conservation translocation programs. As this species-specific, intensive management technique is implemented in more and more places around the world, the taxonomic diversity benefiting is also ever-increasing. However, conservationists repeatedly state that reintroductions often fail, citing papers from over a decade ago. We challenge this view as being outdated, and pose the question how successful are reintroductions as a conservation strategy? Intriguingly, recent studies are revealing positive outcomes from reintroductions both on a local and global scale. We suggest that reintroductions are frequently successful and have made a real impact for species recovery and often for the restoration of ecological function. Given the improving science and impact of reintroductions, we attempt to delineate the potential role that conservation translocations can play in addressing new or accelerating threats to biodiversity.

ID163 THE IMPORTANCE OF FOREST AND TREES FOR ECOSYSTEM-BASED ADAPTATION IN RURAL LANDSCAPES

Bruno Locatelli
CIRAD-CIFOR

Ecosystems provide important services that can help people adapt to climate variability and change. Scientific literature provides evidence that EBA with forests and trees can reduce social vulnerability to climate hazards; however, uncertainties and knowledge gaps remain. Pilot projects under implementation also provide information on EBA and can serve as learning sites. Based on different sources of information from scientific literature and experiences on the ground, we discuss the potential of forests and trees for EBA in several cases: forests and trees providing goods to local communities facing climatic threats; trees in agricultural fields regulating water, soil, and microclimate for more resilient production; forested watersheds regulating water and protecting soils for reduced climate impacts; forests protecting coastal areas from climate-related threats; and forests regulating rainfall at the regional or continental level. We discuss uncertainties, knowledge gaps

and controversies regarding EBA. We show that uncertainties are important for adaptation based on the regulating services of forests and trees for protecting watersheds and coastal areas and regulating regional rainfall. The multiple benefits of EBA for biodiversity conservation and climate change are also well recognized but trade-offs exist between ecosystem services or between their beneficiaries. Better understanding is needed of the efficiency, costs, and benefits, and trade-offs of EBA with forests and trees.

THE IMPORTANCE OF BIODIVERSITY FOR MULTIPLE ECOSYSTEM FUNCTIONS IN A HUMAN-MODIFIED TROPICAL LANDSCAPE

Madelon Lohbeck

Wageningen University
Lourens POORTER, Wageningen University ; Miguel MARTINEZ-RAMOS, Centro de Investigaciones en Ecosistemas ; Frans BONGERS, Wageningen University

Biodiversity loss is expected to have large negative consequences for ecosystem functioning. Biodiversity is thought to be especially important for the multifunctionality of ecosystems, as different species contribute to different functions, but support for this idea comes mainly from experimental studies. We evaluated the importance of biodiversity for multiple ecosystem functions in a human-modified tropical forest landscape in Chiapas, Mexico. We quantified five key ecosystem functions (standing above-ground biomass, biomass productivity, litter production, wood decomposition and litter decomposition) at the landscape level, and evaluated to what extent individual species contribute to these functions. The species that contributed most to the different ecosystem functions were largely the same small set of dominant species, indicating a limited role of biodiversity for ecosystem multifunctionality. The use of simulations enabled teasing apart the relative importance of species richness, species dominance and species functional traits, and demonstrated that only when minimizing dominance do different species (with different functional traits) contribute to different ecosystem functions. The present study, like most studies on biodiversity-ecosystem functioning, focuses on a narrow range of (biogeochemical) functions. Future studies should address the consequences of biodiversity loss on ecosystem multifunctionality in natural ecosystems, including a wide range of ecosystem functions.

NATURETRADE: CREATING A MARKETPLACE FOR ECOSYSTEM SERVICES

Peter Long

University of Oxford
David BENZ, University of Oxford ; Gillian PETROKOFKY, University of Oxford ; Sandra NOGUE, University of Oxford ;

Marc MACIAS FAURIA, *University of Oxford*; Alistair YEOMANS, *Sylva Foundation*; Richard PIGGOTT, *Sylva Foundation*; Gabriel HEMERY, *Sylva Foundation*; Kathy WILLIS, *University of Oxford*

In spite of their importance in sustaining human well-being, ecosystem services have not commonly been an object of private-market transactions owing to intrinsic market failures such as lack of information and high transaction costs. Naturetrade is a tool to, where possible, overcome these market failures - allowing private markets for ecosystem services to develop, while simultaneously supporting improved ecosystem service provision. Naturetrade is a free, easy-to-use, web-based, ecosystem service mapping tool and trading platform that will enable European landowners to measure the ecosystem services provided by their lands, and facilitate beneficiaries of ecosystem services to contract with landowners for the continued and enhanced provision of these services. The tool is based upon assimilation of high resolution satellite data and environmental modelling to allow the state of the environment to be characterised at 30m resolution every 3 months. The ecosystem services include; water flow regulation, crop pollination, soil erosion protection, carbon in above-ground biomass, and recreational amenity. www.naturetrade.net

SYMPOSIUM # 20: INTEGRATED NON-INVASIVE HEALTH-MONITORING FOR DISEASE RISK ANALYSIS IN WILD APES

Elizabeth Lonsdorf

Franklin and Marshall College

Dominic TRAVIS, *University of Minnesota*; Thomas GILLESPIE, *Emory University*; Iddi LIPENDE, *The Jane Goodall Institute*; Karen TERIO, *University of Illinois*; Tiffany WOLF, *University of Minnesota*; Michele PARSONS, *Emory University*; Carson MURRAY, *The George Washington University*; Beatrice HAHN, *University of Pennsylvania*; Anne PUSEY, *Duke University*

Disease and other health hazards pose serious threats to the persistence of wild ape populations. The total chimpanzee population at Gombe National Park, Tanzania has declined from perhaps 120-150 in the 1960's to around 100 by the end of 2013, with death associated with observable signs of disease as the leading cause of mortality. Moreover, this park contains the only habituated population of chimpanzees in which individuals are positive for Simian Immunodeficiency Virus (SIVcpz), which has a substantial negative impact on the health, reproduction and survival of wild chimpanzees. In 2004, we began a non-invasive health-monitoring program in the two habituated communities in the park to 1) determine the population prevalence of clinical signs of ill health, 2) institute non-invasive diagnostics for pathogen identification, and 3) determine potential routes of transmission and methods of disease risk mitigation. Observational health data

is collected in a standardized format on known individuals during focal follows conducted by Tanzanian field staff. Non-invasive diagnostic sampling includes parasitology, virology, bacteriology, endocrinology and histopathology, making the Gombe chimpanzee population one of the best-studied in terms of both behavior and disease. Our work highlights the need for a large, collaborative team and long-term data to fully understand and mitigate the impacts of disease for wild ape populations.

TOWARDS IMPLEMENTATION OF A GLOBAL PLAN OF ACTION FOR CONSERVATION, SUSTAINABLE USE AND DEVELOPMENT OF FOREST GENETIC RESOURCES

Judy Loo

Bioersivity international

For the first time a Global Plan of Action (GPA) prioritizing conservation of forest tree genetic diversity has been developed (FAO 2013) and widely endorsed by most of the world's countries. Among the 27 Strategic Priorities for Action (SPs) listed in the GPA, 12 of them, such as "Strengthen the contribution of primary forests and protected areas to in situ conservation of FGR", have a specific focus on conservation. Notwithstanding the value of regional and international support, if the SPs are to be achieved, most of them must be implemented at the national or sub-national levels. Historically, little attention has been paid to genetic diversity in the design of forest conservation strategies or guidelines; even when developing conservation plans for tree species at risk, genetics has not generally been considered. How can these SPs that concern the conservation of tree genetic diversity be achieved without adding unrealistic cost and complexity to conservation plans and actions? To address this implementation challenge, we suggest that demystification is needed and conservation practitioners must understand basic principles of population genetics. Furthermore we recommend that measurable proxies for genetic diversity be integrated into protected area monitoring and inventory schemes.

LIVING WITH PREDATORS: ANTHROPOLOGICAL APPROACHES TO IBERIAN LYNX REINTRODUCTION

Margarida Lopes Fernandes

CRIA-FCSH

Clara ESPIRITO SANTO, *CRIA-FCSH*; Amélia FRAZÃO-MOREIRA, *CRIA-FCSH*

Reintroductions of species are opportunities to apply a multidisciplinary approach to conservation, including anthropology. We are studying the return of the most threatened felid in the world to Portuguese natural areas, concerning attitudes of local people towards the process of

reintroduction and perceptions about lynx and carnivores. Results of ethnographic work and 95 semi-structured interviews reveal claims for economic compensation and guarantee of wild rabbit abundance, the main prey of the lynx. However, advantages of the reintroduction were indicated by informants, including the chance of saving the species, ecological equilibrium and a distinctive value for the territory. There is an association between restriction of human activities and species conservation, being a reaction to one idea of "natural parks" and "restored natural ecosystems" where wild animals are released and there might be no place for humans. This case study reveals a European rural context where human-environment interactions are changing rapidly: stakeholders have low scientific knowledge about lynx but local ecological knowledge subsists in 'specialists'. Local discourse is dominated by the idea of nature as a commodity, and conservation projects are viewed ambivalently. The lynx is admired and associated with exotic wild felids but living with predators is still a nuisance as they are competitors for game species. Stakeholders request more information from the administration on this theme but more involvement and participation is recommended. Qualitative analysis can be explored for the design of communication material and the identification of key issues indicated by stakeholders towards conservation processes for example we used data on lynx local memory in a public exhibition about the species. Anthropological approaches provide insights into the complex social representations which are built around species and nature conservation.

GENETIC RESTORATION FOR THE RECOVERY OF THE IBERIAN LYNX (LYNX PARDINUS) POPULATION IN DOÑANA, SW SPAIN

Guillermo López

Agencia de Medio Ambiente y Agua de Andalucía
Laura SORIANO, Estación Biológica de Doñana, CSIC ; Gema RUIZ, Agencia de Medio Ambiente y Agua de Andalucía ; Elena MARMESAT, Estación Biológica de Doñana, CSIC ; María LUCENA, Estación Biológica de Doñana, CSIC ; Miguel Angel SIMÓN, Consejería de Medio Ambiente de la Junta de Andalucía ; José A. Godoy, Estación Biológica de Doñana, CSIC

The steep decline suffered by the Iberian lynx in the second half of the 20th century left two isolated populations in Doñana and Eastern Sierra Morena, with 42 and 60 total individuals (nine and 18 territorial females), respectively, in 2002. Previous studies revealed a pattern of low diversity - both for microsatellite markers and MHC genes -, high inbreeding and strong differentiation. Signs of genetic erosion were especially evident in the Doñana population, and genetic and survival and reproduction parameters became concomitantly deteriorated there. These circumstances prompted the implementation of a genetic management program aimed

at mitigating the effects of genetic erosion in the Doñana population. A total of six lynxes from the Eastern Sierra Morena population were released in Doñana in the period 2007-2012. Successful reproduction of two of the six translocated lynxes and their descendants has resulted in higher microsatellite diversity and lower differentiation between populations. The introduction of novel alleles has also alleviated the lack of MHC variation that might have been limiting immune response. The restoration of genetic diversity has been accompanied by an improved reproductive output, and no outbreaks of infectious diseases have been detected since 2007. The productivity of admixed males was significantly higher than that displayed by pure males, while survival was unaffected by the genetic ancestry of the individuals. The genetic reinforcement of the Doñana lynx population provides an example of successful integration of conservation genetics into conservation practice.

ARE CHEF'S UP TO THE TASK? BRINGING SUSTAINABLE SEAFOOD TO THE TABLE

Rocio Lopez De La Lama

University of Cambridge

Gastronomy is the main expression of our relationship with nature, which determines our wellbeing. Nowadays, Lima (Peru) is being recognized as the culinary capital of Latin America, thanks to its diversity of ingredients and variety of local cooking practices, mainly seafood. For thousands of years seafood has been the main resource for coastal development, and the reason behind the maritime foundation of Andean civilization. The recent culinary boom has created a constant and high demand of resources that has itself triggered a growing socio-economic force. This new market situation benefits many poor people, especially fishermen and farmers, for whom gastronomy is the perfect opportunity to increase their incomes and raise out of poverty. However, seafood is the last wild resource we take advantage off and special regulations must be implemented in order to assure sustainability. Involving key stakeholders related to gastronomy and seafood is crucial for effective coastal and marine stewardship and to secure the sustainability of marine resources' use. In order to reach a sustainable use of seafood, it is crucial to determine the knowledge and comprehend the attitudes and practices of the related stakeholders. Therefore, this study delivers the first baseline of knowledge, attitudes and practices of chefs towards marine ecosystems and seafood choices in Peru. This baseline enable us to identify information gaps, attitudes and misconceptions in daily practices of chefs and their relationship with seafood, information that can then be linked to ongoing campaigns or use to develop strategies seeking to increase the knowledge of, or change behaviors directed to; marine ecosystems and their resources in Peru. The long lasting idea is to forge a community of citizens that care

for their environment, empowered to start participating in the appropriate management of the marine ecosystem.

MANGROVE-HUMAN INTERACTIONS: HISTORICAL INSIGHTS, CURRENT STATUS AND PERSPECTIVES IN THE TROPICAL EASTERN PACIFIC

Juliana Lopez-Angarita

University of York

Alex TILLEY, Fundacion Talking Oceans ; Richard COOKE, Smithsonian Tropical Research Institute ; Callum ROBERTS, University of York

From the subsistence economies of early native pre-Columbians to the globalized world, mangroves have played an important role for the development of human society. More than 90% of the world's mangroves are located in developing countries, where rates of destruction are growing rapidly at large scales. In order to design effective conservation strategies for mangrove management, it is critical to understand the natural and anthropogenic dynamics of these coastal wetland habitats. In this work we use retrospective techniques to reconstruct mangrove forest history in the Tropical Eastern Pacific, exploring the change in attitudes towards mangroves and uses through time. We examine available historical estimates of mangrove area and evaluate the representation of mangroves in the protected area systems of Costa Rica, Panama, Colombia and Ecuador, examining existing policies regarding mangroves. Archaeozoological evidence shows that mangroves were exploited for many thousands of years by pre-Columbian societies. Unsustainable, post-conquest deforestation prevailed during the next 400 years. Since 1990, despite increasingly positive attitudes towards mangroves and their inclusion in protected areas systems and conservation policies, mangrove cover has continued to decline. Historical ecology provides an insight into the evolving uses and attitudes towards mangroves in relation to their decline in the region, generating important lessons that should be taken into account in decision making. This study represents an important step towards promoting regional strategies for mangrove management as it generates a better understanding of the underlying drivers of mangrove decline in the Tropical Eastern Pacific. Given the myriad negative consequences of mangrove loss recorded worldwide, countries of this region need to strengthen their protection systems, taking into account the importance of mangroves for local livelihoods.

EXPLORING THE RELATIONSHIP BETWEEN LAND-BASED ACTIVITIES, MANGROVE HEALTH AND FISHERIES STATUS IN A RAMSAR WETLAND

Juliana Lopez-Angarita

University of York

Alex TILLEY, Fundacion Talking Oceans[INSTITUTE]Smithsonian Marine Station

Despite improvements in mangrove protection in recent decades, mangrove area keeps declining globally. Mitigating the loss of these ecosystems and maintaining their ecological functionality is imperative for many communities that depend on the multiple ecosystem services provided by mangroves. In developing countries, where rates of mangrove deforestation are high, poor coastal communities present a high dependence on mangrove products and services for their livelihoods. In the Pacific coast of Panama, where mangrove forests are abundant in estuaries, communities rely on artisanal fishing as their primary economic activity. However, land based economic activities such as agriculture; impose a threat to mangroves health. We examined the effect of land based impacts (agriculture, aquaculture and towns) on mangrove forests in the Gulf of Montijo, an important protected area and RAMSAR wetland located on the Pacific coast of Panama, with the purpose of identifying the state of this ecosystem and its relationship with the productivity of artisanal fisheries of the area. Using satellite images, interviews with locals and fisheries landings information, we constructed a spatial model of cumulative impacts. Results showed that in spite of the protection status of the Gulf of Montijo, mangrove forests are being affected by the agricultural activities taking place around them, compromising the health of these ecosystems. The most productive fishing grounds were located further away from towns and close to mangrove islands where impact from the mainland is low. This work shows the relevance and utility of incorporating publicly available satellite images into impact assessments to aid in marine spatial planning and protection of key coastal habitats.

TOWARDS COLLABORATIVE WORK BETWEEN SCIENTISTS, MANAGERS AND STAKEHOLDERS FOR CONSERVATION OF HUASCARÁN NATIONAL PARK (PERÚ)

María López-Rodríguez

Assessment and Monitoring of Global Change, University of Almería[INSTITUTE]Dept. Biology and Geology. University of Almería

Perú is one of the 17 megadiverse countries in the world. To preserve its ecosystems and the services they provided, 17% of Peruvian territory has been declared as protected area. The protected territory is organized as a National Network that includes the most representative ecosystem of the country. This Network includes 77 protected areas with different level of legal protection. In the last decades, they are under increasing human pressure, and therefore its conservation could be at risk. In this context, effective management actions based on the best knowledge and adaptive governance are highly demanded. Science-Policy Interfaces (SPIs) represent an excellent tool to face this challenge. SPIs are social processes used to open frontiers between scientists, stakeholders and managers for addressing environmental issues collectively, but their use in the context of conservation biodiversity it is still scarce. With the aim to enhance the decision-making process in protected areas of Perú, we developed a SPI process in Huascarán National Park. This is one of the best samples of tropical glaciers ecosystems in the world, and climate change is affecting the development and welfare of human populations that directly depend on National Park ecosystems. To develop the SPI experience, we founded a community of practice integrated by scientists, stakeholders and managers, and launched co-learning and knowledge co-production processes between them. A knowledge brokering approach and the use of a graphical tool help us to clarify the roles involved in the collective actions, to facilitate mutual understanding, and to promote a culture of shared responsibility between social actors involved. 18 collaborative actions to address sustainability in the National Park were achieved by community of practice. In addition, the goal to continue with the collaborative work in the long-term was considered essential for dealing with environmental problems related to park conservation.

DISPERSAL RATES OF BIRD SPECIES AFFECT UNEQUALLY THEIR RESPONSES FACE THE GLOBAL CHANGES

Romain Lorrillière

MNHN

Frédéric JIGUET, MNHN ; Luc DOYEN, CNRS-GREThA

Biodiversity is threatened by numerous environmental changes among which land-use and climate changes. The consequences of global changes on birds community dynamics include polewards range shifts and declines of abundances, particularly for specialist species compared to generalist species. The viability of birds meta-populations depends largely on their ability to disperse. The present study investigates how dispersal

ability influences species viability in the context of global changes. We propose a multi-species and meta-population model where dynamics depend on both climate and land-use drivers. We used data from a large scale Breeding Bird Survey over Metropolitan France monitoring 37 species (farmland specialist species and generalist species). At the national scale and for each species, this model makes it possible to estimate values of dispersal rate. These dispersal rate are important parameters to explain variations of population abundances, i.e. including dispersal ability and abundances of neighbouring populations significantly improved the fit of the model when compared to a model including only climatic and land-use variables. We found a significant unimodal relation between habitat specialization of species and their dispersal rate (dispersal rate has a maximum for an intermediate specialization) interpreted as a trade off between the risk to fail to find a suitable habitat and the necessity to disperse to these habitats. In terms of meta-populations trends, this results in dispersal rate having no influence on specialists populations trends while there is a positive correlation for generalists. Using large scale empirical data, this is the first study showing the extent to which dispersal promotes species viability and how specialization to habitats restricts this capacity. Levels of dispersal can thus have a strong influence on the reshuffling of species communities, and should be taken into account in models predictions such as niche modeling.

IMPACTS OF WATER USE AND GLOBAL CLIMATE CHANGE ON AQUATIC VERTEBRATE BIODIVERSITY IN THE DRAA BASIN, SOUTHEASTERN MOROCCO

Soumia Loulida

*Cadi Ayyad University, Faculty of Science-Semlalia
Mohamed NAIMI, Cadi Ayyad University, Faculty of Science-Semlalia ; Safaa BENDAMI, Cadi Ayyad University, Faculty of Science-Semlalia ; Mohammed ZNARI, Cadi Ayyad University, Faculty of Science-Semlalia ; Adil MOUMANE, Cadi Ayyad University, Faculty of Science-Semlalia*

The Drâa valley in southeastern Morocco is one of the 10 most arid watersheds on earth. The valley is also an area of rich cultural diversity and home to an estimated 750,000 people who earn a living from this fragile desert oasis. Yet, it is under threat from human encroachment and global climate change. In this area, dry periods frequently eliminate superficial flow, alternating with violent flash floods. In addition, a major dam was constructed upstream in 1972 and river flows are now severely constrained as water is held back for human use. The trend of increasing aridity and anthropogenically mediated salinisation strongly aggravates the already severe human impact on the aquatic biodiversity. Using ecologically relevant bioindicators allows highly sensitive insight into this rapidly changing ecosystem. In this study, we investigated the distribution, abundance and tolerance capacities of some

aquatic vertebrates and their relationship with and salinisation in the main river basins draining arid areas of the Draa basin, based on field sampling and experimental tests. We inventoried 13 species including 7 native fish (2 relict cichlids: *Coptodon zillii* and *Oreochromis aureus*; 4 cyprinids: *Luciobarbus* spp. and 1 salmonid: *Salmo trutta*), 4 anuran amphibians (*Pelophylax saharicus*, *Barbarophryne brongersmai*, *Bufo* *boulengeri* and *Amietophrynus mauritanicus*), a water snake (*Natrix maura*), and the Blue-eyed Pond turtle (*Mauremys leprosa saharica*), with a variable salinity tolerance affecting their presence and abundance in the water bodies. During dry periods, most populations are fragmented into widely separated pools of water in an intermittent and increasingly brackish to saline waters. Long periods of high salinity revealed to be likely to adversely affect some taxa, such as turtles, exposed to severe dehydration and/or osmotic stress. Consequently, populations of some species are on the verge of extinction and require that they should be given full protection.

MODELING THE RECOLONIZATION OF A LARGE CARNIVORE USING OPPORTUNISTIC DATA.

Julie Louvrier

CEFE, CNRS UMR 5175

Christophe DUCHAMP, Office National de la Chasse et de la Faune Sauvage ; Eric MARBOUTIN, Office National de la Chasse et de la Faune Sauvage ; Olivier GIMENEZ, CEFE, CNRS UMR 5175

Most large carnivores are facing high extinction risks due to harvest or deterioration of their habitat. Because predators and men exploit the same resources, their management is a great challenge involving opposite conservation vs economic objectives. In this context, assessing large carnivores' range dynamics is needed for decision makers to delineate zoning areas where a species is protected or predict areas with high risks of conflicts due to attacks on cheptel. However, monitoring the distribution of large carnivores is notoriously difficult due to their elusive behavior and their tendency to occupy large areas at low density. Across Europe, several countries have set up networks of observers to cope with these difficulties by collecting signs of presence of large carnivores. However, when mapping species distribution, the analysis of opportunistic data raises several issues due to the absence of standardized protocols. In particular, a greater observation effort can lead to more signs of presence independently from the actual species distribution. Therefore, ignoring uneven observation effort can lead to biased inference about the ecological state variable of interest. We assessed the spatial dynamics of wolf (*Canis lupus*) in France that has been recolonizing the country since the early 90's. We used 20-year non-invasive survey of geo-referenced signs of presence. We quantified the variability in the observation effort by i) estimating the spatial density of observers over time and ii)

accounting for heterogeneous recording effort by stratifying the observer prospection range according to professional activities. We then used dynamic occupancy models to assess the range dynamics of the species while accounting for imperfect species detection. Our results emphasize the importance of carefully characterizing the observation effort when mapping species distribution. Our approach has the potential to serve as a tool to predict human-wildlife conflicts.

90. CAN THE GROWING OF TRANSGENIC MAIZE THREATEN PROTECTED LEPIDOPTERA IN EUROPE?

Gabor L. Lövei

Aarhus University

Niels HOLST, Aarhus University ; Andreas LANG, Buero Lang

The large-scale growing of transgenic GM maize in North America seems to have created serious problems for the migratory lepidopteran, the monarch butterfly (*Danaus plexippus*), a unique species and conservation icon. In Europe, transgenic GM maize is one of the few crops authorised for commercial cultivation, although the acreage devoted to GM maize is not extensive. We used our earlier modelling results concerning the threat to the peacock butterfly (*Inachis io*) which indicated that in several areas of Europe, this species could be under threat by GM maize growing. We checked the larval phenology to identify other protected European butterflies that can be under threat due to phenological overlap. Additionally, we analysed the spatial distribution of maize growing and the distribution of protected areas in Europe, based on the Natura 2000 protected area network. The landscape analysis indicates that insect-resistant GM maize does pose a threat to several protected European lepidopteran species via maize pollen deposition on their food plants. The possible future spread of herbicide-tolerant maize poses an equal or even larger threat, which can be mitigated by careful landscape management. Special attention needs to be devoted to Eastern and South-eastern Europe, as they contain a large share of the European biodiversity of agricultural landscapes.

THE INFLUENCE OF MICROCREDIT-FUNDED BUSINESSES ON HUMAN WELFARE AND BUSHMEAT CONSUMPTION AMONG COMMUNITIES IN SERENGETI, TANZANIA

Asanterabi Lowassa

TAWIRI

Abuu MVUNGI, University of Dar es Salaam ; Loiruck NAIMAN, Frankfurt Zoological Society ; Andrea WALLACE, Frankfurt Zoological Society ; Anke FISCHER, Frankfurt Zoological Society

Bushmeat is harvested illegally in western Serengeti, Tanzania to provide cash and protein. Recently, microcredit-funded business have been initiated in Serengeti as an intervention that integrates conservation aims and human development

needs, to curb illegal bushmeat hunting and improve human livelihoods. The credit scheme aims to facilitate income generation to make local residents less dependent on bushmeat hunting. Our study investigated the impact of microcredit-funded business on the number of bushmeat meals consumed and perceived wellbeing of a household by using a quasi-experiment, comparing households from the same villages who had ($n=63$) and those that had not ($n=58$) participated in the microcredit scheme. The comparison focused on (a) the sources and amounts of protein consumed, as reported in a dietary recall exercise and (b) self-reported wellbeing and uses of the loans. Data was collected on a monthly basis over a 10 months-period. Results suggested that on average, households participating in the microcredit scheme consumed significantly less bushmeat than those not participating. Credit-takers tended to consume more non-bushmeat protein meals (such as beef, fish or chicken) than non-credit takers. Loans were found to improve household welfare by covering costs of, for example medical care, schooling and modernised housing. Approximately fifty percent of credit-takers established a small business, but most of these businesses were not able to sustain themselves due, not least, to the limited credit-size and a short period until repayment was due. We conclude that longer runtimes for credits and the provision of accessible advice for credit-takers could increase the sustainability of these businesses. In addition, facilitation of marketing the products would raise the impact of the microcredit scheme, thereby improving both livelihoods and wildlife conservation.

THE ROLE OF LOCAL KNOWLEDGE IN YANCHENG NATIONAL NATURE RESERVE MANAGEMENT

Yuan Lu
Otago University

Nature reserve is considered to be a good way to preserve biodiversity and natural ecosystems. However nature reserve is constantly facing economic development pressure from surrounding communities. Co-management is sometimes considered as a solution for both conservation and community development. According to literature, local knowledge (LK) can play an important role in co-management of nature reserve, but there are very few such studies in China. In order to fill the gap, the researcher chose Yancheng National Nature Reserve (YNNR) to carry out the research because it is the first and largest tidal flat nature reserve in China to protect rare migratory birds and their habitats. It is also an international biosphere reserve and a wetland of International Importance. The aim of the research is to find out if there are any LK useful for the management of the reserve and what are the challenges of and opportunities for the integration of LK into co-management of YNNR? Through more than a

month's on-site observation, semi-structured interviews with local people, nature reserve staff and scientists, the research found out that although the locals have detailed knowledge about fishery, farming, salt production and reed production, they have very limited knowledge concerning birds and their habitats. Such lack of knowledge undermined their ability to cooperate with the nature reserve for conservation. Additionally, most interviewees considered development is contradictory to conservation, because most developments are at the cost of environmental degradation. In order to achieve conservation goals, the higher level government must change their perception of development, and shift the GDP oriented economy to eco-oriented economy.

URBANIZATION INCREASES HONEYBEE SURVIVAL AND HONEY PRODUCTION

Lea Lugassy
National Museum of Natural History
Colin FONTAINE, National Museum of Natural History ; Romain JULLIARD, National Museum of Natural History ; Gerard ARNOLD, CNRS, UPR 9034 LEGS

In a context of global enthusiasm for urban beekeeping, cities are seen by many as a new haven of peace for honeybees, where floral resources are abundant, diversified and mostly pesticide-free. Initiated by beekeepers and fuelled by media, the idea that honeybees do better in urban areas than in the surrounding countryside has largely spread, but was never scientifically addressed. Based on data from 428 apiaries located in and around Paris metropolis, we studied the effect of urbanization on winter mortality and honey production. We found that urbanization decreases mortality and increases honey production, an increase that appears to be unrelated to urban floral resources.

CARNIVORE MANAGEMENT IN WESTERN-CANADA: PERCEPTIONS OF A LETHAL MANAGEMENT PARADIGM

Victoria M. Lukasik
University of Calgary
Shelley M ALEXANDER, University of Calgary

Attitudes towards large carnivores across much of the world have historically been fear-based, with elimination of these species from the landscape desirable. Research in the last century has underscored the vital role large predators play in ecosystem diversity and stability. With this understanding and the rise of the environmental movement, there has been a shift towards accepting, protecting, and re-introducing these species. Contemporary studies in Europe highlight context-specific management strategies that prioritize traditional and nonlethal tools, which foster coexistence between humans and large carnivores, even in human-dominated

landscapes. In Western Canada, management practices remain predominantly lethal (e.g. culls, poison, trapping) and prioritize human interests (e.g. livestock protection, large game populations) over other species. These anthropocentric views are increasingly rejected by citizens and scientists. The reason for this disconnect between science and practice is unclear and the focus of the present research. Wildlife managers from Alberta, British Columbia, and Northern Canada were interviewed to determine their personal perspectives and professional experiences with carnivore (i.e. wolf, cougar, and coyote) management. Transcribed interviews were coded in NVivo 10. Initial results showed that participants had scientific training and valued implementation of scientific knowledge. Perspectives on the role of hunting varied, but a general focus on population numbers over individuals or packs, and avoidance of ethical discussions was common. Also expressed was a sense of 'making the best' of a difficult political climate, where managers have little power to limit recreation and industrial activities. Implications of the political climate and perspectives of managers on the health of our ecosystems will be discussed, as well as a comparison of the North American versus European approach to carnivore management.

EFFECT OF THE CATTLE PRESENCE ON TEHUANTEPEC JACKRABBIT (*LEPUS FLAVIGULARIS*) MICROHABITAT SELECTION IN EFFECT OF THE CATTLE PRESENCE ON TEHUANTEPEC JACKRABBIT (*LEPUS FLAVIGULARIS*) MICROHABITAT SELECTION IN SOUTHERN OAXACA, MÉXICO.

Alma Luna

Universidad Autónoma de Nuevo León
Tamara Rioja, Universidad de Ciencias y Artes de Chiapas ; Laura SCOTT, Universidad Autónoma de Nuevo León ; Arturo CARRILLO-REYES, OIKOS: Conservación y Desarrollo Sustentable, A.C.

For the first time we determined whether the presence of cattle has any effect on microhabitat use (feeding and resting sites) of the Tehuantepec Jackrabbit (*Lepus flavigularis*), an endangered endemic species from Oaxaca, Mexico. Currently, the major risk to this lagomorph is due to the intense habitat fragmentation (livestock, agriculture, urban development) and poaching. Between November 2013 and December 2014, 21 adult radio-collared jackrabbits were monitored in pastures with and without cattle at Santa Maria del Mar, Oaxaca, México. We located every radio-collared jackrabbit in 8 day tracking periods, recording 12-18 positions per jackrabbit. Locations were registered every 15 minutes. We registered that the Tehuantepec jackrabbit prefers to set its feeding sites ($\lambda=0.8010$, $p=0.0020$) and its resting sites ($\lambda=0.6605$, $p=0.016$) in pastures with cattle presence. Probably the Tehuantepec jackrabbit is favored by the presence of cattle because this

is conditioning the existence of certain plant species that could serve as food source for the jackrabbit, through the establishment of seedlings from excreta cattle. Also, pastures with cattle have the appropriate conditions for the resting sites establishment due to the open and short grass areas, which allows *L. flavigularis* to detect the presence of predators (feral dogs, snakes, eagles) as already reported. Understanding the relationship between livestock and the Tehuantepec jackrabbit population dynamic is critical for conservation efforts for this endangered leporid.

TWO SPECIES OF POISON FROGS AND SUSTAINABLE AGRICULTURAL PRACTICES, AN ALTERNATIVE FOR THE CONSERVATION OF THREATENED AMPHIBIANS IN COLOMBIA.

Victor F. Luna-Mora

Natural Heritage Foundation [INSTITUTE] University of Tolima
Manuel GUAYARA, Natural Heritage Foundation ; Camila MORALES-RUEDA, CAFEXPORT ; Alejandro GUAYARA, Natural Heritage Foundation

Tolima's poisonous frog (*Andinobates tolimensis*) and dotted frog (*A. dorisswansonae*), are two endemic species, sympatric and in endangered extinction; due mainly to the impact of agricultural activities unsustainable like extensive animal breeding, exotic tree crops and the influence of coffee dominant crop in the región which since 90's has cause an accelerated destruction of original ecosystems. In consequence, the rural landscape is dominated by coffee crops, pastures and subandean forest patches highly fragmented and isolated. Before restricted potential habitats distribution and farmers precarious social-economic conditions, as a result of deep agricultural crisis in Colombia, which increases ecosystems threats and pressures, species and their ecological process, Coffee Friend of Tolima's poisonous frogs appears like an initiative that has been constructed with an active participation of local communities, in search of viable economic options, defense of territory, food sovereignty and protection of natural resources. Additionally, this initiative has three major components: participative research, education and training, which have led to progress in this long process is just beginning, learning and unlearning through mistakes committed, with the firm conviction that "working together can go further". An initiative gaining strenght among communities who have learned about the process, it's the generation of a environmental friendly label with frogs, that currently conducts Fundacion Herencia Natural, for provides standards of protection and responsible use of wáter sources, riparian forests and associated biodiversity crops. This will allows a farmer's life quality improvement and will generate conservation agreemets to protect and renovate andean forest remnants; thus, a flagship product of colombian economy like coffee is, carries a message from Andean mountains to

the world regarding biological protection and a sustainable development of a small coffee area.

DIFFERENT FLAGSHIP STRATEGIES - SHOULD WE USE FLAGSHIP SPECIES OR FLAGSHIP FLEETS IN BIODIVERSITY CONSERVATION?

Piia Lundberg

University of Helsinki

Annukka VAINIO, Natural Resources Institute Finland (Luke);

Anni ARPONEN, University of Helsinki

Flagship species are species that manage to capture the attention of the public, and are mostly used by non-governmental organizations to raise funds and conservation awareness. They are usually charismatic species, mainly large vertebrates, where the tiger and the giant panda are unquestionably the most well-known and iconic flagship species. Although charismatic high-profile species may manage to attract more funds, they may not be the ones of highest priority from a broader biodiversity conservation perspective because of inadequate ecological surrogacy power. Still funds may be earmarked to protect solely those species, which highlights the need to evaluate the cost-effectiveness of flagship species. The aim of this study is to improve the use of flagship species in biodiversity conservation. We evaluated with a willingness-to-pay (WTP) study the effectiveness of different types of conservation flagships in fundraising. We focused on birds and mammals, and covered strategies from use of single flagship species to flagship fleets (a set of charismatic species), compared with using habitat types or generic "biodiversity conservation" in fundraising. We also evaluated whether the information given on the intended use of the donation influenced WTP, for example, using the funds to protect the species' habitat, as opposed to using the flagship for purely marketing purposes. Our results point out to what sort of campaigns people are willing to donate as well as the role of charisma in allocating money for conservation of different species. Our recommendations can help NGOs to raise funds more effectively. In a further study, the results will be used in combination with data on surrogate power to assess overall cost-effectiveness of different surrogate strategies.

ASSESSING BENTHIC RESPONSES TO FISHING DISTURBANCE OVER BROAD SPATIAL SCALES THAT INCORPORATE HIGH ENVIRONMENTAL VARIATION

Carolyn Lundquist

NIWA

Judi HEWITT, NIWA

Marine benthic habitats are modified by a number of human-related disturbances. When these disturbances occur over areas of high environmental variability, it is difficult to assess impacts using either species richness or individual species distributions

due to species-specific responses to environmental drivers (e.g., exposure, sediment, temperature). Impact assessment can be more difficult when broad spatial scales are involved, as different regional species pools may be sampled. Even when effects on individual species can be detected, it is difficult to upscale from individual species to ecosystem scale effects. Here, we use a functional group approach to assess broad scale patterns in ecological processes with respect to fishing and environmental drivers. We use data from field surveys of benthic communities from two large, widely separated areas in New Zealand's EEZ (the Chatham Rise and the Challenger Plateau), and assigned 828 taxonomic units (usually to species) into eight functional groups related to important ecosystem processes and likely sensitivity to and recovery from disturbance to the seafloor. These included: opportunistic early colonists with limited substrate disturbance; opportunistic early colonists with considerable substrate disturbance; substrates stabilizers (e.g. tube map formers); substrate destabilizers; shell-hash creating species; emergent epifauna; burrowers; and predators and scavengers. We were able to observe, even at this broad scale, effects of fishing disturbance on benthic functional composition. Functional response varied between functional groups, with some being tolerant of fishing impacts, whereas others showed rapid declines with minimal fishing effort. The use of a functional group approach allows assessment of impacts across regions and species, allowing better generalizations of impacts to inform management and decision making.

175 SCENARIO ANALYSIS AND MODELLING OF BIODIVERSITY AND ECOSYSTEM SERVICES

Carolyn Lundquist

NIWA

One of the first IPBES assessments is Deliverable 3c, which provides the foundation for the use of scenario analysis and modelling of biodiversity and ecosystem services in regional, global and thematic assessments. The assessment will provide guidance for "evaluating alternative policy options using scenarios and models; including multiple drivers in assessments of future impacts; identifying criteria by which the quality of scenarios and models can be evaluated; ensuring comparability of regional and global policies; including input from stakeholders at various levels; implementing capacity-building mechanisms to promote the development, use and interpretation of scenarios and models by a wide range of policymakers and stakeholders; and communicating outcomes of scenario and model analyses to policymakers and other stakeholders" (IPBES/2/16/Add.4). Models and scenario analysis include the effects of changes in indirect drivers (e.g. socio-political, economic, technological and cultural factors) on direct drivers of change in, and therefore pressures on, biodiversity

and ecosystems (e.g. habitat conversion, exploitation, climate change, pollution, species introductions); the impacts of change in direct drivers - both negative, and positive (e.g. through policy or management intervention) - on nature; and the consequences of changes in biodiversity and ecosystems for the benefits that people derive from nature, and that therefore contribute to human well-being. In addition to outlining the objectives of this IPBES deliverable, I will also discuss the expert nomination and selection procedures and contact points for those interested in future involvement with IPBES assessments; the role of experts (including authors and reviewers) in assessments; and the internal and external review processes that have been put in place to safeguard the integrity and scientific robustness of the assessments.

CONSERVATION AND ECOTOURISM FOR DEVELOPMENT : WHO IS SACRIFICED? THE LOWER KINABATANGAN IN SABAH

Clotilde Luquiau

Centre Asie du Sud-Est

Conservation areas are often economically valorized through tourism in order to ensure development and to enhance the acceptability of the local population. Ecotourism is a sub sector of tourism that explicitly refers to the wellbeing of the local populations and as well as the protection of the environment. Protected areas are territories where ad hoc institutions are built in order to preserve the weak balance between the conservation of nature, the need of the inhabitants and the economic activities. In the wildlife sanctuary of the lower Kinabatangan, located in the north of Borneo in the Malaysian state of Sabah, the vulnerability of people and nature has been the cradle of original alliances between the inhabitants, the institutions, the activists, the scientists as well as the tour operators. Is the protection of nature enforced against the prosperity of the human societies? Based on the fieldwork conducted during my PhD, I argue that this binary question does not enable to grasp what is at stake in protected areas. I apply the terminology of geography such as space, landscape and territory to provide a grid which is more adapted to analyze the local geopolitics in place.

CONSERVATION ETHICS AND RISK PERCEPTIONS ASSOCIATED WITH HUMAN-WILDLIFE CONFLICT: IMPLICATIONS FOR ENCOURAGING STEWARDSHIP

Michelle L. Lute

Indiana University

Meredith L. GORE, Michigan State University

Carnivores like gray wolves present a significant management challenge because they can pose risks to humans. Although wolf populations are established in several regions of

North America and Europe, wolves still face threats from human intolerance and related behaviors, ranging from lawsuits and ballot initiatives to retaliatory killing. Wildlife managers know values and emotions can affect behaviors, but the extent to which affective (i.e., general feelings) risk perceptions, conservation ethics and emotional dispositions (e.g., reactions to wolf depredation, hunting wolves) interact to influence support for wolf conservation is unknown. Our objectives were to (a) create a novel theoretical framework for measuring conservation ethics and its impacts on risk perceptions and (b) test the framework's ability to predict the relationship between conservation ethics, risk perceptions, and stewardship behavior. We conducted a web-based survey of wolf stakeholders (n=1239) in Michigan in October-November 2013 and used path analysis to determine influences on the ethics-behavior relationship. Approximately three-quarters of respondents valued wolves and engaged in activities to support wolves in part because of their connection to a larger ecosystem. Intrinsic value for wolves predicted behaviors aimed at benefiting wolves. Affective risk perceptions and emotional dispositions influenced the relationship between ethics and behaviors. Results have implications for engaging stakeholders in managing human-wildlife conflict and encouraging stewardship of expanding carnivore populations. The role of emotion in human judgments related to conservation may be an important predictor of behavior and policy support; addressing emotion in decision processes may lead to more positive outcomes. Conservation ethics may provide comparable if not more useful information than traditional selection models for predicting public attitudes about carnivores and human-wildlife conflict management.

FISH CARBON: VALUATION OF MARINE VERTEBRATE CARBON SERVICES AS A MEANS TO PRIORITISE MARINE BIODIVERSITY CONSERVATION

Steven Lutz

GRID-Arendal

Angela Martin, Blue Climate Solutions

Can the value of 'Fish Carbon', the carbon cycling service provided by marine vertebrates, including fish, mammals and turtles, assist policy makers to prioritise biodiversity conservation in addressing the climate change challenge? Marine vertebrates are not included in most models of carbon cycling and their role in global climate change and carbon sequestration is largely invisible. However, recent scientific research has identified seven biological mechanisms provided by marine vertebrates that result in carbon sequestration, and one mechanism which may provide a buffer against ocean acidification. These mechanisms may have disproportionately large impacts on carbon uptake, storage and release, and all may contribute to the mitigation of climate change. The ecosystem-based Fish Carbon services provide a framework for

future scientific endeavour, but also permit innovative policy and management action based on the best available scientific information and the precautionary principle; an approach called for by the FAO and United Nations in the management of marine resources and in climate change policy. While reducing emissions remains at the forefront of national and international climate change initiatives, the vital role of ocean ecosystems as carbon sinks, including the contribution of marine vertebrates, may aid by mitigating against the severest effects. Fish Carbon provides a direct channel through which governments and the private sector can meet national, regional and global commitments on climate change and sustainability. The recognition and valuation of marine vertebrate carbon services may provide incentive for improved marine management, including biodiversity conservation, habitat protection and sustainable resource extraction, as a positive action toward mitigating climate change.

CAN PLANTS BE USED AS INDICATORS OF THE IMPACTS OF LIVESTOCK GRAZING ON CARABID BEETLES IN UPLAND CALCAREOUS GRASSLANDS?

Ashley Lyons

Edge Hill University

Paul ASHTON, Edge Hill University ; Ian POWELL, Edge Hill University ; Anne OXBROUGH, Edge Hill University

Calcareous grasslands are some of the most diverse habitats in Europe. However, agricultural intensification since the 1950s has led to a dramatic decline in habitat cover and increased fragmentation. In Britain, the majority of calcareous grasslands are situated in upland areas which have been overgrazed, particularly with sheep. Recognition of this has prompted a change in grazing practices, from high intensity sheep grazing to low intensity cattle grazing over the last fifteen years in an attempt to maintain and enhance areas of calcareous grassland. However, the preference of grazing at a low intensity with cattle is solely based on a perceived benefit to the plant community which is often derived from anecdotal evidence. This paper firstly examines the effects of long term low intensity grazing with sheep, cattle and no grazing on plant and carabid beetle diversity. Secondly, it explores whether plant species richness or composition can be used as a proxy for estimating carabid beetle assemblages under different grazing regimes. Carabid beetles are important in grassland ecosystem function, fulfilling roles as predators, herbivores and detritivores, and acting as a food source for other organisms. As with many invertebrate groups Carabid sampling is time consuming and requires specialist knowledge; this paper will determine if more readily identifiable components of the plant community can be used as a proxy. Across three upland limestone areas in Britain carabid beetles were sampled with pitfall traps and plant species richness and cover were recorded during summer 2013. Carabid beetle and plant diversity were linked

to grazing type and carabid beetle and plant diversity were related to each other. Implementation of appropriate grazing treatments can aid conservation of plants and carabid beetles. Management recommendations are made to inform best practice for supporting biodiversity.

BIODIVERSITY CONSERVATION IN AQUATIC AGRICULTURAL SYSTEMS: A STUDY OF INDIGENOUS FRESHWATER FISHES IN KHULNA, BANGLADESH

Heidi Ma

Zoological Society of London

Saima Sharif NILLA, CGIAR Research Program on Aquatic Agricultural Systems ; Zohura MEERA, CGIAR Research Program on Aquatic Agricultural Systems ; Kevin T. KAMP, CGIAR Research Program on Aquatic Agricultural Systems ; Robert J. WHITTAKER, University of Oxford School of Geography and the Environment

Freshwater fish biodiversity is fascinating, highly valued, and under threat. Their diversity is underpinned by the heterogeneous habitats they occupy. As the keystones of aquaculture production and a vital component of food security in many developing countries, freshwater fishes have been increasingly overharvested from open waters and intensively cultured in modified environments. In Bangladesh, smallholder agriculture densely occupies fertile floodplains and wetlands and relies heavily on ecosystem goods and services such as indigenous fish. This study investigates the community structure, pond habitats, and human use and perceptions of indigenous freshwater fish in Khulna, south-western Bangladesh. Fish were sampled using drift-nets in study ponds and floodplains surrounding the homesteads. The presences or absences of living and non-living plants and other physical habitat structures were recorded. Interviews were conducted with farmers about the abundance of indigenous species and reasons of their decline. Participatory action research, particularly involving women, was implemented through each stage of this study. We identified common and rare species. *Channa punctatus*, *Amblypharyngodon mola*, *Anabas testudineus*, *Salmostoma bacalia* and *Aplocheilichthys panchaxarethe* the most frequently occurring and most abundant species. Little overlap between species and habitat associations indicate that homestead ponds and unmanaged water bodies support considerably different indigenous species communities across villages. This study contributes to filling the data gaps of biodiversity science in fish and investigates the potential for habitat restoration in smallholder aquaculture ponds. Primary data collected in the field complement theoretical frameworks discussed in the literature and advocates land-sharing between wildlife and agriculture in densely-populated yet biodiverse regions.

REPRODUCTIVE AND EARLY LIFE HISTORY ASPECTS OF AN ENDEMIC ENDANGERED FRESHWATER FISH OF THE CHILEAN HIGHLANDS.

Consuelo Macaya Solís

Universidad de Chile

Irma VILA PINTO, Universidad de Chile

Reproduction and early life history stages of the genus *Orestias* (Teleostei: Cyprinodontidae), endemic of Andean high plains (Altiplano) aquatic ecosystems, have been barely studied. *Orestias ascotanensis* Parenti, endemic to the springs that feed the Ascotán Salt Bed in Chile is critically endangered due to reduction and fragmentation of its habitat, mainly caused by the negative water balance of the altiplanic systems and water extraction for mining activities. Between April and May 2014, 50 individuals were captured and kept in the laboratory under controlled conditions. After an acclimation period, mature females were induced to spawn through hormone therapy with Ovaprim® by artificial fertilization. Males showed color changes and courtship behavior and females slightly bulging belly. We obtained eggs of 1.5 to 1.8 mm size which developed tens of filaments giving them high adhesion and protection. The embryonic development at 20° C (± 1) lasted between 14-18 days and it was divided into 5 periods and 21 stages. Eggs showed a discoidal meroblastic cleavage and early pigmentation at 70 hours. The hatched larvae are on flexion state, equipped with pectoral and caudal fins and a functional mouth and eyes, allowing them to move and hunt from the second day. After 5-7 days from hatching, the larvae absorbed the yolk sac, and starting from day 24 they began developing the anal and dorsal fins and showed changes on coloration pattern. Low number of eggs per spawning, large eggs in proportion to adults and high survival of embryos (46.7%) agreed with partial spawners. Intense pigmentation and highly prepared hatching larvae for the free life could be an adaptation for extreme conditions. Finally, these results are relevant for the design of future actions for the protection of this species as hydrological restoration, artificial reproduction to restore subpopulations most affected and cryopreservation of gametes as a protection to genetic diversity.

MONITORING THE EFFECTIVENESS OF SILVER FIR FOREST RESTORATION: EFFECTS OF SCALE AND TYPE OF RESPONSE VARIABLE

Simona Maccherini

Department of Life Sciences, University of Siena

Giovanni BACARO, Department of Life Sciences, University of Trieste ; Giangiacomo GIOVANNETTI, Department of Life Sciences, University of Siena ; Alessandro CHIARUCCI, BIGEA,

Department of Biological, Geological and Environmental Sciences, Alma Mater Studiorum, University of Bologna

Monitoring restoration effectiveness implies that restoration actions should be evaluated using multi-scale approach and modelling. This allow to address the limitation caused by patters and ecological variation in sites. Identifying resources to monitor is also a fundamental step. We evaluated the effect of grain (e. g. the dimension of the sampling unit) for testing the response of species composition (for both presence/absence and abundance data) and species richness in in 3 Sites of Community Importance (SCI) in Tuscany (central Italy) subject to restoration management. Results demonstrated that grain size and type of response variable determine the ability of discriminating among control/reference and impact sites. Outcomes corroborate the hypothesis that monitoring multiple species at multiple spatial scales could improve the monitoring efficiency in restoration ecology. This study was funded by the European Commission, LIFE-Nature Project: RESILFOR (REstoring SILver-fir FOrest) LIFE08 NAT /IT/000371.

TRADE-OFFS BETWEEN AGRICULTURAL PRODUCTION AND BIODIVERSITY CONSERVATION IN COMPLEX LANDSCAPES OF THE ARGENTINEAN DRY CHACO. MOVING FORWARD THE SPARING/SHARING ANALYSIS

Leandro Macchi

Alexander von Humboldt

Hector Ricardo GRAU, Instituto Ecologia Regional, CONICET ; Ben PHALAN, Zoology Department, Cambridge ; Tobias KUEMMERLE, Alexander von Humboldt

Studies focus on the relationship between agricultural production and biodiversity conservation usually focus on one gradient ranging from a natural reference land cover type (typically forest) to an intensive productive land use. However, many semi-arid ecoregions such as the dry Chaco are characterized by a mosaic of different land covers, including natural grasslands and woody vegetation with different degrees of transformation, frequently aimed at meat production. Here we analyzed the associations between avian biodiversity and meat productivity of forest, natural grasslands, three types of livestock production systems, and soybean crops in northern Argentina dry Chaco; an area of c. 19 million ha characterized by high conservation value and rapid land use change. We estimated current regional production and future possible productions constrained by the regional governmental zonation. Using yield/density fitting models we explored which conservation strategies maximizes bird's populations for the current and future production levels. We compared the strategies of land sparing (high yield production and protected areas), land sharing (low intensity production systems in a wildlife friendly matrix) or an intermediate

strategy. We explored baselines landscapes with different forest:grasslands proportions. For the current production we found a similar number of birds species favored by a sparing and sharing strategies. Land sparing was the best strategy to satisfy future production levels minimizing bird's populations. Finally, we discuss future lines of studies to relate more clearly the conservation strategies with optimization and spatial analysis.

RISK OF TICK EXPOSURE IN CALIFORNIA OAK WOODLANDS

Andrew Macdonald

University of California, Santa Barbara

Conservation of biodiversity and protection of human health are central challenges for humanity in the face of anthropogenic change, and are increasingly recognized as fundamentally intertwined. Emergence of many zoonotic diseases, including Lyme disease (LD) in North America, is linked to land use and climate change through effects on reservoir hosts and/or vectors. While incidence of LD is increasing throughout North America, little is known about vector tick abundance or seasonal activity in southern (S) California. A recent study suggests that in highly endemic northwestern (NW) California, potentially infectious ticks are active year round resulting in higher risk of human exposure. Here we were interested in determining whether activity patterns, and thus risk of tick exposure, in S California mirror those in the north or are truncated leading to reduced risk of exposure. We used standardized drag sampling in oak woodland, as well as a range of other common habitats in S California, to determine seasonal abundance of the primary vector (*Ixodes pacificus*) of the pathogen, and compared patterns in S California to those observed in NW California. We found that seasonal activity of *I. pacificus* in S California is significantly shorter, and relative abundance significantly lower, than in NW California. We also found significantly higher abundance of *I. pacificus* in oak woodland habitats than in other habitats. These results suggest that risk of tick exposure is lower in S California than in NW California, and that oak woodland habitats pose the greatest risk. *I. pacificus* ticks are highly susceptible to environmental conditions, and under projected climate change endemic areas of NW California are expected to become hotter and drier, more closely approximating current climatic conditions in S California, which may lead to a reduction in risk of tick exposure and tick-borne disease in western North America.

116. CONSERVATION FOR PEOPLE AND NATURE

Georgina Mace

University College London

How can conservation goals be accommodated on a crowded planet? In the past it was common to regard nature conservation as an end in itself, and to envision large areas of intact wilderness where the patterns and processes of wild nature played out unperturbed by people. I will argue that this is neither tenable nor desirable as a vision for the 21st century. People are ultimately dependent on nature in many ways, and our future wellbeing depends on a sustainable but dynamic relationship with the rest of life on earth. This requires a more deliberative assessment of the ways in which people and nature are interdependent, considering the pathways whereby people depend on nature, and nature reacts to people's use and management. There is a wide variety of these relationships. Some of the rarest or most fragile species can only be conserved in wilderness areas, and they therefore define a need to make space for nature. But many other species are intricately associated with people, and will thrive in anthropogenic landscapes and seascapes. Over longer timescales, and over larger spatial scales, people and nature both depend on diverse, evolving and heterogeneous ecosystems. These longer term needs add another layer to planning, and to designing resilient nature networks for the 21st century.

151- CONSERVATION AT THE SCIENCE-POLICY INTERFACE: LEVERAGING HEALTH CONNECTIONS FOR A NEW PATH

Catherine Machalaba

EcoHealth Alliance and Future Earth ecoHEALTH

Peter DASZAK, EcoHealth Alliance ; Anne-Helene PRIEUR-RICHARD, DIVERSITAS ; William B. KARESH, EcoHealth Alliance

Conservation provides an understanding of the natural world that can be critical for public and animal health priorities. For example, analyses of the ecology of bats, primates and patterns of hunting or disease-driven declines have provided better ways to forecast and prevent Ebola virus, SARS and other zoonoses. However, conservation and health decision making typically occurs through separate channels. Leveraging conservation's value to health can engage a wider group of stakeholders in conservation efforts, generating health motivation for policy change that addresses drivers of both disease and biodiversity loss. There are evolving opportunities for the conservation community to inform health-relevant policy, including through collaboration with national authorities from the public health, agriculture and environment sectors, as well as in intergovernmental policy such as through the UN's Convention on Biological Diversity-World Health Organization Joint Work Programme, the World Organisation for Animal Health, and the IUCN Species Survival Commission Wildlife Health Specialist Group. Additionally, the science-policy interface is typically viewed as one-directional,

but we argue that it can be optimized through design of scientific studies that fluidly address policy questions to make information directly actionable to the health community. This is especially relevant to conservation where there are currently limited mechanisms employed for proactive assessments of benefits and consequences for biodiversity and health, such ecosystem service considerations of proposed land use decisions. Key areas of shared conservation-health policy opportunities and policy processes will be highlighted to encourage a new path for science-policy engagement that can help the conservation community broaden its impacts.

ADMIXTURE IN REINFORCED PLANT POPULATIONS

Nathalie Machon

Sorbonne Universités, MNHN, UPMC, CNRS

Monika ZAVODNA, Sorbonne Universités, MNHN, UPMC, CNRS ;

Vincent PELLISSIER, Sorbonne Universités, MNHN, UPMC, CNRS ;

Jawad ABDELKRIM, Sorbonne Universités, MNHN, UPMC, CNRS

In the framework of reinforcement of declining plant populations, it is sometimes necessary to admix individuals from different origins to increase genetic diversity and fitness of the populations through heterosis. However, the risk associated with this practice is a possible co-occurrence of maladaptation and outbreeding depression. The outcome of such programs is therefore often uncertain. The process of admixture (interbreeding between individuals from different origins) has been poorly studied in plants, despite its importance in conservation genetics. Our presentation is based on a study that aimed to restore the population of the Sandwort *Arenaria grandiflora* L. in the Fontainebleau forest, France. This study began in 1999 when three identical populations were created in the Fontainebleau forest, each population established from 2/3 of local plants, and 1/3 of non-local plants. After 8 and 12 years of no human intervention in the maintenance of the populations, genetic diversity of the founders and reintroduced populations was assessed using 10 species-specific microsatellite markers. Our results revealed progressed admixture among individuals of the reintroduced populations. In addition, we evaluated the relationship between individual flowering (as a measure of fitness) and admixture levels. We found that this relationship is likely driven by conflicting effects of heterosis, inbreeding and outbreeding depression and local adaptation. A better understanding of the admixture process can directly contribute to the improvement of conservation programs.

INSTITUTIONS AND TRUST IN A CENTRAL INDIAN TIGER RESERVE

Biljana Macura

University of Padova

Researchers agree that local people trust, social acceptability and positive attitudes towards agencies that govern protected areas are some of the major ingredients for the successful conservation. In context of top-down exclusive conservation in human-dominated forested landscapes of India, people-park conflicts are frequent because of limited space and resources, incompatible interests, unequal power and benefit flows. In such context, local community trust towards park management authority can be an important source of legitimacy and compliance with the park rules. This study uses household data from 16 villages located in the buffer zone of Pench Tiger Reserve, Madhya Pradesh, India: 1) to measure the level trust towards the management authority, and 2) to determine predictors of the trust (or lack of it). Study results are expected to highlight the importance of economic (benefit flow from the park, compensation for the crop or cattle loss) as well as institutional (level of social inclusiveness, local acceptance of resource access rules) context for the trust building.

THE LOST GENERATION HYPOTHESIS: COULD CLIMATE CHANGE DRIVE ECTOTHERMS INTO A DEVELOPMENTAL TRAP?

Dirk Maes

Research Institute for Nature and Forest (INBO)

Hans VAN DYCK, UCL ; Dries BONTE, Ghent University ; Rik PULS,

Ghent University ; Karl GOTTHARD, Stockholm University

Climate warming affects the rate and timing of the development in ectothermic organisms. Short-living, ectothermic organisms such as insects showing thermal plasticity in life-cycle regulation could, for example, increase the number of generations per year under warmer conditions. However, changed phenology may challenge the way organisms in temperate climates deal with the available thermal time window at the end of summer. Although adaptive plasticity is widely assumed in multivoltine organisms, rapid environmental change could blur the relationship between environmental cues that organisms use to make developmental decisions. Developmental traps are scenarios in which rapid environmental change triggers organisms to pursue maladaptive developmental pathways. This occurs because organisms must rely upon current environmental cues to predict future environmental conditions and corresponds to a novel case of ecological or evolutionary traps. Based on preliminary experiments, we argue that the dramatic declines of the Wall Brown (*Lasiommata megera*) in NW Europe may be an example of a developmental trap. This formerly widespread, bivoltine (or even multivoltine) butterfly has become a conundrum to conservationist biologists. A split-brood field experiment with *L. megera* indeed suggests issues with life-cycle regulation decisions at the end of summer. In

areas where the species went extinct recently, 100% of the individuals developed directly into a third generation without larval diapause, whereas only 43% did so in the areas where the species still occurs. Under unfavourable autumn conditions, the attempted third generation will result in high mortality and eventually a lost or 'suicidal' third generation in this insect with non-overlapping, discrete generations. We discuss the idea of a developmental trap within an integrated framework for assessing the vulnerability of species to climate change and its consequences for species conservation.

GRASSROOTS APPROACH TOWARDS SUSTAINABLE NATURAL RESOURCE MANAGEMENT AND DEVELOPMENT

Chris Magero

BirdLife International

Mercy KARIUKI, BirdLife International ; Albert Schenk, BirdLife International

Lake Victoria in Africa, the second largest freshwater surface area in the world, together with its basin, comprise an ecosystem with extraordinary biodiversity and ecosystem service values, supporting the livelihoods of over 500,000 people. However the lake basin is threatened by unsustainable consumption and production patterns, including hunting, over-exploitation of natural resources, large-scale agriculture and pollution, exacerbated by weak coordination and governance, invasive species and climate change. This negatively affects particularly local communities who rely most directly on natural resources for their livelihood. However at the same time, local communities are the chief stewards of the world's ecosystems, and the vast majority of daily environmental management decisions depends on their local knowledge and how they use land and other natural resources. This creates great opportunities by empowering local communities to play a key role in the management of those vital natural resources. To this end, BirdLife International is implementing the Local Champions Project at six Important Bird and Biodiversity Areas across four countries: Burundi, Kenya, Rwanda, and Uganda. The project aims to strengthen the capacity of community-based Local Community Groups to conserve biodiversity and sustain ecosystem benefits for human well-being. This is being achieved through institutional capacity building of Local Community Groups in governance, natural resource management, advocacy, fundraising, networking, and building strategic partnerships with local government and the private sector. Subsequently the local communities themselves have developed Community Plans which lay out a clear road map and plan of action for the community to effectively address the identified challenges, and to sustainably manage their natural resources. The project demonstrates that local communities, as key stakeholders, can and should be empowered to sustainably manage their natural resources.

WHAT EVIDENCE IS THERE TO SUPPORT THE CREATION OF A PREDATOR FREE 'MAINLAND ISLAND' IN MAURITIUS TO PREVENT THE EXTINCTION OF A CRITICALLY ENDANGERED PASSERINE?

Gwen Maggs

Zoological Society of London

Malcolm NICOLL, Zoological Society of London ; Nicolas ZUËL, Mauritian Wildlife Foundation ; Patrick WHITE, Edinburgh Napier University ; Vikash TATAYAH, Zoological Society of London ; Carl JONES, Durrell Wildlife Conservation Trust ; Ken NORRIS, Zoological Society of London

Invasive species are a major threat for island biodiversity, causing species decline and extinction globally. Of all invasive mammals rats are one of the most detrimental and have been the target of numerous eradication programmes; a successful conservation tool for many taxa. However, for endangered species situated on large populated islands, where eradication is prevented, rat control remains a challenge. The local extirpation of rats through the establishment of large-scale, rat-free areas known as 'Mainland Islands' has been developed successfully in New Zealand using various rat management techniques and is one possible solution. However, large-scale rat management is a long-term investment with huge financial implications; therefore, robust evidence is required to support such an investment. For endangered species obtaining this information is often problematic due to small population sizes hindering experiments. Research conducted on a declining population of Mauritius olive white-eye (*Zosterops chloronothos*), a critically endangered endemic passerine, has explored this issue by combining small-scale field experiments with demographic models. We investigated the impact of rat management on nesting success by establishing rat poison and trapping grids within breeding territories. Results show that rat management significantly decreased rat abundance and increased nesting success, leading to a potential 5-6 fold increase in annual productivity, which in turn could be sufficient to stabilise the current population decline. In the absence of rat management, this analysis suggests the olive white-eye population will continue to decline by about 14% per annum. This research provides compelling evidence that rat-free areas are a viable management option for this declining population and supports further investigation into the development of a mainland island on Mauritius; identifying the most cost-effective technique.

HUMAN-WILDLIFE INTERACTION IN SERENGETI AND NGORONGORO DISTRICTS OF TANZANIA: A CASE STUDY ON SMALL MAMMALS

Flora Magige

University of Dar es Salaam

In the Serengeti and Ngorongoro Districts, small mammals are said to provide protein and income to the local people. However, they are simultaneously reported to conflict with farming activities. These conflicting aspects have not been investigated there. The present article considers human-small mammal interactions in six villages adjacent to the protected areas. Data were obtained through questionnaire administration to the local people in the districts. Small mammals were hunted in the two districts for food purposes and some villagers declared that they were earning income from selling small mammals products. Seventy percent of the respondents in Serengeti District claimed that among the hunted small mammals, the rabbits were the most preferred animals whereas <5% of the respondents in Ngorongoro Districts declared to prefer rabbits. In terms of gender, there was no significant difference between males and females in the preference of rabbits in both districts. However, the frequency of hunting was higher in Serengeti District than in Ngorongoro District and dogs were significantly more used for hunting than were other means of hunting. Some small mammals, such as rodents, were a nuisance in raiding crop fields and food stores. In attempting to protect their crops and other properties against small mammal destruction, villagers used various strategies including trapping and poisoning although these methods were often ineffective. Some villagers suggested extermination of the small mammals as a control measure. Despite the fact that small mammals were destructive, about 26% (n = 150) of respondents disagreed with the proposal of animal extermination, instead they suggested establishment of conservancies or seeking for the government intervention. Domestication of small animals for reptile farms, ecologically focused small mammal management techniques and improved storage structures might reduce the conflict.

49-SPECIES INTERACTIONS SHOW VARIED RESPONSES TO THE DIFFERENT COMPONENTS OF FOREST FRAGMENTATION.

Ainhoa Magrach
ETH Zurich

Forest fragmentation dramatically alters species persistence and distribution and affects many ecological interactions among species. Recent studies suggest that mutualisms, such as pollination and seed dispersal, are more sensitive to the negative effects of forest fragmentation than antagonisms, such as predation or herbivory. We applied meta-analytical techniques to evaluate this hypothesis and quantified the relative contributions of different components of the fragmentation process (decreases in fragment size, edge

effects, increased isolation, and habitat degradation) to the overall effect. The effects of fragmentation on mutualisms were primarily driven by habitat degradation, edge effects, and fragment isolation, and, as predicted, they were consistently more negative on mutualisms than on antagonisms. For the most studied interaction type, seed dispersal, only certain components of fragmentation had significant (edge effects) or marginally significant (fragment size) effects. Seed size modulated the effect of fragmentation: species with large seeds showed stronger negative impacts of fragmentation via reduced dispersal rates. Our results reveal that different components of the habitat fragmentation process have varying impacts on key mutualisms. We also conclude that antagonistic interactions have been understudied in fragmented landscapes, most of the research has concentrated on particular types of mutualistic interactions such as seed dispersal, and that available studies of interspecific interactions have a strong geographical bias (arising mostly from studies carried out in Brazil, Chile, and the United States).

A 5-YEARS INTEGRATED PROJECT FOR THE CONSERVATION OF LIMODORUM TRABUTIANUM BATT. (ORCHIDACEAE): THE EXAMPLE OF THE MARTURANUM PARK (LATIUM, ITALY)

Sara Magrini

Tuscia University, Germplasm Bank

Sergio BUONO, GIROS, Etruria meridionale Section ;

Emanuele GRANSINIGH, GIROS, Etruria meridionale Section ;

Massimiliano REMPICCI, GIROS, Etruria meridionale Section ;

Laura ZUCCONI, Tuscia University, Department DEB

Limodorum trabutianum is a steno-Mediterranean orchid with a highly fragmented distribution area that includes Morocco, Algeria, Portugal, Spain, France, and Italy where it is threatened with extinction. In 2010, a population within the Marturanum Park (Barbarano Romano, Viterbo - Italy), unique to Latium, experienced a strong demographic decline (about 80%), highlighting the urgent need to take serious preservation measures. Therefore, an integrated conservation strategy was performed and the Marturanum Park was chosen as testing-area where in situ/ex situ actions could be experienced before spreading them to the whole distribution area. The following in situ measures were carried out: 1) present and potential threats assessment; 2) fencing the population area, only during the anthesis/fruited phases, in order to prevent damages caused by trampling, grazing, and by massive wild boars presence; 3) tourism limitation in the area; 4) population census and monitoring; 5) Red List assessment IUCN. Furthermore, the following ex situ actions are thought to be necessary for an effective conservation strategy: 6) seed banking to preserve its genetic diversity over time; 7) evaluation of the reproductive success (germination, growth, and development capability) to

highlight potential intrinsic risk factors; 8) in vitro reproduction for conservation and possible reintroduction. Several educational activities were carried out to raise awareness about orchid conservation. After the first in situ actions, a clear improvement in conservation conditions was observed, with an extremely significant increase both in population size (from 2 to 27 plants, with a maximum of 36 in 2013) and in the percentage of mature individuals that have reached the fruiting phase. Results of the first 5 years of this project can provide useful indications for the management and conservation of *L. trabutianum* and other threatened orchids.

CUMULATIVE IMPACTS OF HUMAN ACTIVITIES ON CORAL REEFS IN BRAZIL

Rafael Almeida Magris

JAMES COOK UNIVERSITY

Alana GRECH, Macquarie University ; Robert Leslie PRESSEY, JAMES COOK UNIVERSITY

Effective management of marine ecosystems requires strategies that reduce the cumulative impact of multiple human activities and stressors. Our goal was to inform conservation planning in Brazil by assessing the cumulative impact to coral reefs from multiple human activities. We collated publicly-available satellite data on the following stressors: fishing intensity (based on a decay-factor function that combines information on vessel transits and fisher behaviour); thermal stress (derived from an indicator of coral-bleaching events); coastal development (formulated based on the proximity to night-time light); sedimentation input (based on an indicator of water clarity); and marine mining (obtained from a government database). Our spatial domain was a gridded map of 2,276 cells (spatial resolution of 1 km²) containing all known coral reefs in Brazil. We calculated a cumulative exposure score for each cell using two approaches: (i) the vulnerability of coral reefs to stressors was equally weighted; and (ii) impact weights were used to reflect vulnerability of coral reefs to each human stressor. We found that 2% and 12% of coral reefs were heavily impacted (score > than 0.75), with or without information on vulnerability respectively, and 6.5% of reefs were relatively unaffected in both approaches. We developed hypothetical future scenarios to assess the sensitivity of our cumulative impact scores to changes in the footprint and intensity of stressors. This work is the first comprehensive spatial dataset of cumulative impact to coral reefs in Brazil and we demonstrate how it can be used to explore strategies for planning and management at multiple spatial and temporal scales.

BEHAVIORAL SOLUTIONS TO MISMATCHED HUMAN/ECOLOGICAL TIMESCALES THAT HURT CONSERVATION

Lynn Maguire

Duke University

Kathryn COTTINGHAM, Dartmouth College ; Rebecca EPANCHIN-NIELL, Resources for the Future ; David HARDISTY, University of British Columbia ; Alan HASTINGS, University of California Davis ; Peter MUMBY, University of Queensland ; Debra PETERS, US Forest Service ; Michael RUNGE, US Geological Survey ; Dean URBAN, Duke University ; Robyn WILSON, Ohio State University

Ecological systems often operate on timescales significantly longer, or shorter, than the timescales typical of human learning, decision-making, and action, which can cause substantial difficulty for conservation. Invasive species, such as the white-nose syndrome affecting some North American bats, may move faster than humans can diagnose problems and initiate solutions. Large-scale climate and hydrologic systems may exhibit both long-term inertia and short-term fluctuations that obscure learning about the efficacy of restoration. For instance, efforts to restrict nitrogen to restore an estuary plagued by algal blooms were hampered by both short-term variation in water quality in response to rain events and by long-term release of nutrients from river sediments. We have developed a management decision framework that distinguishes institutional from individual actors, calls attention to the ways that individual actors and ecological systems respond to management actions, and notes institutional learning that accrues from observing these responses. We use this framework to classify timescale mismatches that arise both within and between the human and the ecological components of coupled natural-human systems. Because the timescales of ecological systems typically cannot be altered, solutions to these problems must come from modifying human behavior at the individual and institutional levels. Drawing on the behavioral economics and psychology literature, we propose behavioral interventions to help solve timescale issues that cause conservation failures. Such interventions include framing conservation decisions to enhance the salience of long-term consequences and using structured decision processes that make timescales of actions and consequences explicit. We demonstrate these tools for diagnosing and resolving threats caused by timescale mismatches using restoration of western Lake Erie, a great lake imperiled by agricultural run-off, as a case study.

RECOVERY TIME AFTER REFORESTATION DEPENDS ON THE MOBILITY AND FEEDING HABITS: CASE STUDY FOR GROUND-DWELLING ARTHROPODS

Tibor Magura

University of Debrecen

Dávid BOGYÓ, Hortobágy National Park Directorate ; Szabolcs MIZSER, MTA-DE Biodiversity and Ecosystem Services Research Group, University of Debrecen ; D. Dávid NAGY, MTA-DE Biodiversity and Ecosystem Services Research Group, University of Debrecen ; Bence TAJTHI, University of Debrecen ; Béla TÓTHMÉRÉSZ, University of Debrecen

We explored the recovery of ground-dwelling arthropods after reforestation with native trees. We studied ground beetles (Coleoptera: Carabidae) and millipedes (Myriapoda: Diplopoda) from mature (130-year-old) oak forest, and recently established (5-year-old), young (15-year-old), and middle-aged (45-year-old) reforestation with native English oak to assess the recovery dynamics of their diversity and composition. The overall number of the ground beetle individuals and species were significantly the highest in the 5-year-old reforestation, while the overall number of millipede individuals and species were significantly the lowest in the recently established reforestation. The elevated overall number of ground beetle individuals and species in the 5-year-old reforestation were due to the colonization of good disperser open-habitat species. The number of forest-associated ground beetle individuals and species were significantly the lowest in the 5-year-old reforestation. From 15 years after the reforestation, there was no significant difference in the number of forest-associated ground beetle species. The number of forest-associated millipede individuals and species were significantly the lowest in the 5-year-old reforestation; however, they were significantly the highest in the natural mature oak forest. The diversity and composition of ground beetles with high dispersal ability and less specific feeding habit recovers quickly after the closure of the canopy, while there is no similar quick recovery of millipedes with low dispersal ability and specific feeding habit. This research was supported by the TÁMOP-4.2.2.B-15/1/KONV-2015-0001 project.

THE ETHNO BOTANICAL REVIEW OF SOME PLANT USES BY VHAVENDA, VHEMBE DISTRICT, LIMPOPO PROVINCE, SOUTH AFRICA

Khathutshelo Magwede

University of Venda

Ben - Eric VAN WYK, University of Johannesburg

The Vhavenda people had a rich social culture intrinsically embedded to the natural environment, with their livelihood dependent on its sustainable utilization. The Vhavenda plant uses had been well documented through several studies that had reported on different categorical uses ranging from medicinal, vegetables, fruits, beverages, firewood, art and craft, and building construction. Some of the plants species had been recorded to be utilized in more than one category. To access the information on Vhavenda plant uses several

literatures were consulted followed by an ethno botanical rapid appraisal survey within the Vhembe District Municipality. Data collected was used to analyse the family and category trends of plant species usage. The overwhelming majority of plants are used as medicine for humans and animals healthcare, more than 40 plant species are used as vegetables, with hard wood plants mainly used for construction as well as art and craft. Six categorical uses were recorded for families; Anacardiaceae and Euphorbiaceae with Capparaceae, Celastraceae, Rhamnaceae, Papilionoideae as well as Rubiaceae used in five categories. The ethnobotanical rapid appraisal survey revealed an informative data trend on plant uses from earlier times to present. It also gave indication on plant use dynamics through time. Keywords: Vhavenda, sustainable utilization, and ethnobotanical rapid appraisal.

LARGE-SCALE TEMPERATURE VARIABILITY PREDISPOSES CORAL COMMUNITIES' TO VARIED RESPONSES TO EXTREME TEMPERATURES

Joseph Maina

University of Queensland

Darling EMILY, Wildlife Conservation Society ; Messie MONIQUE, MBARI

Corals species ranges are expected to contract to climate refugia with the intensified global warming, consequently there is a considerable interest in identifying locations where taxa has survived periods of regionally adverse climate, and the environmental attributes that confer this status. This interest is motivated by reports of selective impacts and mixed responses to extreme SST anomalies and of contrasting recovery trends towards pre-disturbance live coral states. So far, however, in spite of suggestions of projected widespread future thermal stress and possible coral extinction, there is considerable uncertainty on how large-scale climate variability has structured coral communities' physiological responses to extreme events and the scope for adaptation to change. We present results from the first global exploration of the association between severe coral bleaching occurrence records over the last ~3 decades and the components of large-scale historical temperature variability: predictability or orderliness of SST time series, frequency, periodicity, intensity, and duration of significant anomalous events. We show that, severe coral bleaching predominantly occurred in regions with a history of prolonged high intensity anomalous events, and are less likely to occur in regions that have experienced highly predictable and frequent anomalous events. Our findings provide a rare empirical support to theoretical deduction that temperature variability of the past has organized coral communities with varied responses to extreme events, leaping forward the current efforts to identify climate refugia.

PREDICTING IMPACTS OF FOREST MANAGEMENT AND CLIMATE CHANGE ON DEAD-WOOD DEPENDENT FUNGI DISTRIBUTIONS USING CITIZEN SCIENCE DATA AND A RANGE OF MODELING APPROACHES

Louise Mair

Swedish University of Agricultural Sciences
Philip HARRISON, Swedish University of Agricultural Sciences ; Mari JÖNSSON, Swedish University of Agricultural Sciences ; Jenni NORDÉN, University of Oslo ; Juha SIITONEN, The Finnish Forest Research Institute ; Tord SNÄLL, Swedish University of Agricultural Sciences

Understanding how species' distributions will be affected by forest management and climate change is an important conservation goal, which can be achieved through the application of species' distribution models (SDMs). SDMs require spatially extensive species observation datasets, and as such, citizen science recording schemes provide an excellent resource. However, such datasets are accompanied by problems of geographical and environmental bias introduced through recorder behaviour. A range of modeling approaches have therefore been developed to deal with such biased data, and I will present the results of applying several such models to dead-wood dependent fungi species in Sweden. The fungi studied are important indicator species of the quality and naturalness of forest stands. They are wood-decaying fungi which rely on an availability of dead wood and perform an important role in nutrient cycling in forest ecosystems. I will present the predicted impacts of forest management and climate change scenarios on these species distributions, showing how predictions made using different SDMs (and therefore different assumptions about the data) agree and differ amongst species. Such an approach allows a consensus to be drawn (and uncertainties to be identified) on the most appropriate forest management strategies for species conservation in the face of climate change.

HOW TO ADAPT PROTECTED AREA MANAGEMENT TO CHALLENGES OF CLIMATE CHANGE?

Akos Malatinszky

Szent István University
Szilvia ÁDÁM, Szent István University

Nature protected areas are seriously affected by climate change, and a main challenge for agriculture, conservation and water management is adaptation planning. We planned the process of implementing adaptation through a stakeholder dialogue in a SE-Hungarian area, to integrate interests into management plans. Major impacts of climate change that affect the agricultural use of wetlands and grasslands were explored. Ecological aspects should be combined with social

and economic factors during the stakeholder dialogue. Mowing techniques, frequency and exact date should be observed as well as grazing species and their breed, due to different grazing, group forming and trampling habits. The integration of landscape history and historical land development into the planning process (especially in case of water management works in the past) is also useful. Identification and engagement of key stakeholders should be followed by an informative meeting, providing information about climatic impacts, on natural and human systems, discussion of objectives, community based assessment of impacts, then elaboration of adapted strategies and measures. There is strong need to differentiate between stakeholders, and customize communication strategies for different groups. The benefits of intense stakeholder involvement are enhanced awareness, willingness to taking action, inclusion of local knowledge, strengthened habitat resilience through guidance of autonomous adaptation and reduction of land use pressures, information exchange among affected parties that might help finding common solutions, and building trust in authorities.

A SOCIO-ECOLOGICAL EXPLORATION OF HUMAN-WILDLIFE CONFLICT IN THE CONTEXT OF OIL PALM PLANTATION DEVELOPMENT IN CAMEROON

Cynthia Malone

Columbia University

Large-scale industrial agricultural expansion is a significant driver of biodiversity loss, increased carbon emissions, and substantial livelihood disruption for communities in tropical ecosystems. Although less documented, the influence of this expansion on encounters between wildlife and human communities is intimately related to these conservation issues. Local communities and wildlife are simultaneously shifted or fully displaced from intact protected areas and human-modified agro-forests, altering traditional modes of interaction. This study employs a socio-ecological systems approach to examine human-wildlife encounters that have escalated into conflict in the Ndian Division of southwest Cameroon, home to a number of protected areas alongside extensive smallholder and industrial oil palm plantations (both extant and planned concessions). The state of human-wildlife conflict, particularly in the form of crop raiding, and the broader socio-ecological system context is examined in three villages with 108 household interviews and fine-scale spatial surveys of village farms across a land use gradient from protected areas to oil palm plantations. To predict how conflict might change once planned oil palm concessions are realized, underlying causes of reported crop-raiding patterns and responses to raids are explored alongside village perceptions of land use change and oil palm development. Results indicate that farm attributes, such as crop diversity and farm age, are significant predictors

of presence for reported crop-raiding species across villages. However, demographic variables such as gender and socio-economic status provide a more nuanced understanding of both raiding patterns and farmer responses to raids. Ultimately, this study provides insight into how conservation practitioners might use a more inter-disciplinary approach towards achieving multi-functional agro-forest mosaic landscapes in Cameroon and similar tropical landscapes.

91: A FRAMEWORK TO USE CONSERVATION EVIDENCE IN A NATIONAL MANAGEMENT ORGANISATION: EXPERIENCES FROM THE NEW ZEALAND DEPARTMENT OF CONSERVATION

Richard Maloney

Department of Conservation

Lynn ADAMS, Department of Conservation ; Rhys BURNS, Department of Conservation ; Troy MAKAN, Department of Conservation

Like most conservation agencies, the New Zealand Department of Conservation strives to use the best available practice for undertaking conservation management actions, and in deciding which future conservation projects deserve attention. Its aim has been to provide information and advice on species, ecosystems, environmental issues and conservation threats, and to base this advice on best practice methodologies. Despite more than 100 years of conservation action, and nearly 30 years as a unified national conservation agency, a recent review indicated that we have failed to adequately provide best practice advice for much of our biodiversity work. To rectify this, we developed an improved best practice framework that: included links to policy and standard operating procedures; determined processes such as who builds, updates, maintains and disseminates best practice information; and ensured that best practice information was based on best available and correctly interpreted evidence, including data, published evidence and expert opinion. We describe our experiences in incorporating and implementing a conservation evidence pathway into a best practice framework for the flora and fauna-related biodiversity work the New Zealand Department of Conservation undertakes.

EFFECT OF HABITAT AND RESOURCE AVAILABILITY ON AVIAN NEST SURVIVAL IN YARDS AND ADJACENT FOREST PARKS

Jennifer Malpass

The Ohio State University

Amanda RODEWALD, Cornell University

Although residential areas comprise a large component of the urban landscape, avian conservation in urban areas usually emphasizes managing habitat remnants with limited human

development, such as forest parks. Part of this emphasis reflects a common assumption that residential yards act as reproductive sinks due to high levels of nest predation. We tested this assumption by comparing nest survival in adjacent forest and yard habitats. We also investigated how yard management practices influence nest survival. During 2011-2014, we monitored American Robin (*Turdus migratorius*) and Northern Cardinal (*Cardinalis cardinalis*) nests at 7 paired suburban neighborhoods and forest parks in Columbus, Ohio, USA, and recorded availability of bird feeders in neighborhoods. Daily nest survival (DSR) of robins was significantly higher in yards (0.970 ± 0.004) versus forest parks (0.946 ± 0.005) and robin nests in yards were twice as likely to fledge young compared to robin nests in forest parks. However, availability of bird feeders mediated survival of robin nests in yards: DSR decreased $0.004 (\pm 0.001)$ for each feeder present in the neighborhood and $<10\%$ of robin nests were expected to fledge in neighborhoods with 5 or more feeders. In contrast, cardinal DSR was similar between paired yard (0.960 ± 0.003) and forest (0.947 ± 0.005) habitats and there was no relationship between cardinal DSR and bird feeders. Our results show that assumptions about the relative value of natural versus developed landscapes and the effects of supplemental food may not be easily generalized across species. Additional research about the mechanisms responsible for these patterns is warranted to better inform conservation efforts for urban birds.

PHYSIOLOGICAL STRESS IN REINTRODUCED TIGER POPULATIONS: HOW DOES IT AFFECT CONSERVATION OUTCOMES?

Manjari Malviya

Wildlife Institute of India

Krishnamurthy RAMESH, Wildlife Institute of India ; Kalyanasundram SANKAR, Wildlife Institute of India ; Govindhaswamy UMAPATHY, Laboratory for the Conservation of Endangered Species Centre for Cellular and Molecular Biology

It is difficult to determine the causal factors for success of a reintroduction program. Each site and animal is unique and would respond to the reintroduction efforts in different manner. When local extinction of tiger (*Panthera tigris*) occurred in Sariska and Panna Tiger Reserves in India, it led to reintroduction of wild tigers there. Subsequently, Panna registered breeding of the founder population, with all but one female yielding multiple litters. In contrast, the Sariska founder population registered its first successful breeding after four years of reintroduction and of the five females only two have successfully littered. This study was undertaken to explain the potential reasons for differential breeding success between the two reserves. Many studies on wild animals have established a link between high physiological stress and low reproductive

potential. It was thus hypothesized that stress caused by anthropogenic pressures and other physiological factors, was a plausible cause for the differential breeding status of tigers. Tiger scat samples were collected and faecal hormone metabolite extraction and analyses were done to understand their stress and reproductive status. Data on stressors viz. prey and anthropogenic disturbance were collected using line transect method, circular plots and camera traps. Hormone analyses results suggested that tigers in Sariska were fertile although far more stressed than that in Panna. To explain which, we examined the status of stressors and found that prey density was high in Sariska, ruling out nutritional stress. However, anthropogenic disturbance was higher in Sariska than Panna, suggesting human induced stress. Moreover, stress levels in different tigers were found to be correlated to different types of anthropogenic disturbances within their home ranges.

LINKING CURRENT STATE OF FISH POPULATIONS AND THEIR DIVERSITY TO CHANGES IN ENVIRONMENTAL CONDITIONS OCCURRING IN THE MIDDLE FLOW OF SYRDARYA RIVER (CENTRAL ASIA)

Nadir Mamilov

Institute of biology and biotechnology, al-Farabi Kazakh National University

Eleonor KOZHABAEVA, Institute of biology and biotechnology, al-Farabi Kazakh National University ; Fariza AMIRBEKOVA, Institute of biology and biotechnology, al-Farabi Kazakh National University ; Nailya IBRAGIMOVA, Institute of biology and biotechnology, al-Farabi Kazakh National University ; Tatyana VANINA, Institute of biology and biotechnology, al-Farabi Kazakh National University ; Anvar MAMILOV, Institute of biology and biotechnology, al-Farabi Kazakh National University ; Farkhad KHABIBULLIN, Institute of biology and biotechnology, al-Farabi Kazakh National University ; Zhasar ADILBAEV, Karatau state wildlife reservation

Ecological disaster in the main part of the Syrdarya River basin in the last decades of XXth century applied some governmental measures after that, in order to stabilise hydrological regimes of the Syrdarya River. In 2002-2014 we have conducted a series of field studies evaluating the state of habitats and diversity of fish populations in the part of the Syrdarya River situated within borders of the Republic of Kazakhstan. There were observed strong interannual variations in water salinity, concentration of biogenic elements (C, N, P, S) and metals (Cu, Fe, Pb) in water samples. Ionic composition of sediments in Syrdarya River was also differed substantially from the inflows and rivers in basin of the Balkhash Lake. Diversity of fishes was much lower than it was expected according to the known lists. There were not detected fringebarbel sturgeon, Syrdarya sturgeon, Aral salmon, pike asp and sharpray. The main species in commercial fishery are roach, sabrefish, carp, asp, pike perch,

snakehead and wels. Histological studies on fish detoxication systems such as liver, gills and kidneys have revealed different levels of damages suggesting significant level of environmental heterogeneity. Indigenous for the Syrdarya River species such as bearded stone loaches, aral spined loach, and ruff were not able to adopt to changed habitats, and thus were substituted in the river with some alien species. Water resources in most of the inflows are used completely by rural populations and cities and do not reach the main stream of Syrdarya River. It explains substantial differences in composition of ichthyofauna between Syrdarya River and its inflows. The main background species inhabiting inflows of the river are sattu snowtrout, Turkestan gudgeon, Tashkent riffle bleak, terskyi stone loach, Kuschakewitsch loach, Aral spined loach. Current level of the use of water resources in the region threatens sustainability of many indigenous fish species and their conservation.

SICILY AS THEORETICAL MODEL TO STUDY THE POTENTIAL IMPACT OF GENETICALLY MODIFIED PLANTS IN A HOTSPOTS OF BIODIVERSITY

Barbara Manachini

University of Palermo

Giuseppe BAZAN, University of Palermo ; Rosario SCHICCHI, University of Palermo

In Europe, especially in Italy, different considerations are necessary when potential GMPs are to be grown. In particular high biodiversity areas such as Sicily should have a more detail plans of potential benefits and risks assuring the conservation of biodiversity and endemic species. Sicily is one of the most relevant biodiversity hotspots in the Mediterranean area, with a vascular flora of 3252 species and 321 endemic taxa. Considering the latest IUCN categories and criteria, 401 taxa (12.4% of Sicilian flora) are under threat (categories "CR", "EN", "VU"), and 220 more taxa (6.8%) are "Near Threatened". Sicily is also known to have a rich butterfly and coleopteran fauna including endemic and rare species. Agricultural systems, 66% of the area, mainly cereal crops (40%) olive groves (7%), vineyard (6%), citrus groves (5%) and orchards (2%). 25% of these are within the Natura 2000 Network sites. Semi-natural systems account for about 21% of the area. The genus Brassica, Cichorium, Dianthus, Medicago, Prunus e Trifolium have a higher number of rare, endemic species, some of which have a high risk of extinction. Moreover, cultivated trees, as Prunus, have rich heritage of some hundreds ethno-varieties, results of centuries of selection practices of farmers. Sicilian territory will likely continue to have among its characteristics an entirely agricultural vocation, with a greater extension of organic agriculture, even in the presence of forms of integration with other sectors such as tourism and protection. For the above reasons Sicily was chosen as a pilot area to study the potential impact of PGMs on biodiversity. Model is based on the potential GMPs, their, traits, areas grown, potential gene flows,

distance from natural areas. Moreover an ecological approach for selection of non-target Lepidoptera species for ecological risk assessment of PGMs in Sicily, using data collected over a 3-year period, is reported.

RELIABILITY AND REFINEMENT OF THE HIGHER TAXA APPROACH FOR BEE RICHNESS AND COMPOSITION ASSESSMENTS

Yael Mandelik

The Hebrew University of Jerusalem
Itai VAN RIJN, The Hebrew University of Jerusalem ; Thomas NEESON, The Hebrew University of Jerusalem

Limited resources and taxonomic expertise in biodiversity surveys often lead to the application of the Higher Taxa Approach (HTA), i.e. the identification of specimens to genus or higher taxonomic levels rather than to species. The reliability of the HTA varies significantly among studies, yet the factors underlying this variability have rarely been investigated. Bees are an ideal model taxon for testing the HTA because they are highly diverse, challenging to identify and there is widespread interest in their role as native pollinators, driving demand for efficient diversity assessment tools. Using extensive bee data sets collected across three biomes and various habitats, we assessed the performance of the HTA in reflecting bee species richness and composition patterns at local scales, factors affecting this performance, and ways to improve it. The performance of the HTA varies considerably among biomes, taxonomic levels (genus and sub-families) and diversity measures (species richness and composition). The number of species per higher taxon was a main factor influencing this performance, while to co-occurrence of taxonomically related species had no significant influence on the performance of the HTA. Further subdividing genera by body size contributed to the performance of the HTA. The considerable variability found in the performance of the HTA in representing local-scale richness and composition patterns of bee species dictates caution in implementing this tool in bee surveys. When possible, an a priori evaluation of the expected performance of the HTA should be done, focusing on species distributions within higher taxonomic levels and the species/higher taxa ratio. Integrating morphological characteristics (such as body size) that consistently sub-divide genera will improve HTA's performance. Our results are likely applicable to other small-bodied and species-rich groups and contribute to the cost-effectiveness of biodiversity surveys.

RESPONSE OF TREE COMMUNITIES AND ABOVEGROUND CARBON STORAGE TO RAINFOREST FRAGMENTATION

Anand Mandyam Osuri

Tata Institute of Fundamental Research

Mahesh SANKARAN, Tata Institute of Fundamental Research

Fragmentation is among the most pervasive forms of human disturbance to forests across the tropics. While fragmentation is known to drive marked shifts in the composition of biological communities, there is limited understanding of resultant effects on ecosystem functioning and services. Here, we examine the effects of fragmentation on rainforest tree communities and aboveground carbon storage in a landscape comprising fragmented and contiguous rainforests in the Western Ghats of peninsular India. Using analyses of plant functional traits, we identify potential mechanisms by which fragmentation affects carbon storage, and assess the relative importance of these different mechanisms in governing aboveground carbon storage in forest fragments. Our results reveal that fragments store ~40% less carbon per unit area than contiguous rainforests, with reduced forest stature emerging as an important factor contributing to carbon losses. First, there were shifts in tree allometry, with trees in fragments not growing as tall for given basal diameter as conspecifics in contiguous forests. Additionally, fragmentation favoured tree communities dominated by small-seeded species, presumably due to shifts in the assemblage of seed dispersers. Because small-seeded species tend to be shorter than larger-seeded species – a pattern we observed not just in the tree community in this study but also more generally across other tropical forest tree species – such compositional shifts may generally be expected to reduce forest stature and carbon storage. These results imply that the ability of tropical forests to store carbon may be influenced by processes such as seed dispersal, and reduce when large vertebrate seed dispersers decline in forests which are fragmented or otherwise disturbed. Thus, conservation efforts to prevent defaunation and improve connectivity at broader landscape scales are also likely to enhance aboveground carbon storage in fragmented tropical forests.

133-ENGAGEMENT OF MUSLIM LEADERS FOR CONSERVATION AND SUSTAINABILITY ACTIONS IN INDONESIA

Fachruddin Mangunjaya

Universitas Nasional

Muslim activists have been leading biological conservation efforts in Indonesia and urging influential Islamic scholars and clerics to collaborate with them. The Indonesian Clerics Council (Majelis Ulama Indonesia [MUI]) was established a special unit called the Institute of Honoring Environmental and Natural Resources (PLH-SDA) MUI in 2011. Since that time, the PLH-SDA MUI have been working together with government and environmental conservation NGOs to raise environmental awareness and promote conservation activities through edicts and aid. MUI has released four edicts related

to the environment: (1) the fatwa for environmentally friendly mining; (2) edict on the misuse of formalin and harm material in the production of fish; (3) edict on protection of wildlife for the balance of ecosystem; and (4) edict about wastes. Lessons learned from this “soft power movement” of interacting religious MUI and government, conservation NGOs and academia will be shared and hopes for future success toward ecological sustainability will be expressed.

EXTRAPOLATING CETACEAN DENSITIES IN THE OFFSHORE NORTH ATLANTIC: TOWARDS A BASIN-WIDE MANAGEMENT APPROACH

Laura Mannocci

Duke University

Jason ROBERTS, Duke University; Patrick HALPIN, Duke University

Extrapolating beyond the range of environmental variables is very risky; however, geographical extrapolation is acceptable when parsimonious habitat models are built from meaningful environmental predictors and survey datasets. We were contracted by the U.S. Navy to estimate the densities of 29 cetacean species in the Atlantic fleet testing and training (AFTT) area, extending from the shoreline of North America to 45°W and from 21 to 65°N. Most of this area has only been surveyed with line transect protocols within 200 miles from shore. Our objective was to provide reliable extrapolations of cetacean densities in the AFTT area based on available cetacean line transect surveys and environmental predictors. We built generalized additive models from over 1.2 million km of line transect surveys in the U.S. waters and a variety of environmental predictors, favoring those for which a broad range of values was covered in the surveyed area. Since the U.S. surveys mostly covered nearshore waters, we incorporated European surveys which extended farther offshore but in the other side of the North Atlantic basin. The results illustrate the difficulty of providing robust density estimates in offshore waters from surveys mainly conducted in nearshore waters. In addition, our study suggests that, for some species, different environmental variables may drive cetacean distributions on each side of the North Atlantic. For example, when we added European surveys to our fin whale model, different predictors were selected and the abundance estimate for the AFTT area doubled. In contrast, for harbor porpoise, the same predictors were selected and the estimated abundance decreased by a more modest 30%. In both cases, much of the change in abundance occurred beyond the shelf. In conclusion, our study stresses the urgent need of conducting line transect surveys in the offshore North Atlantic in order to provide the most accurate estimations of cetacean densities.

MAPPING ECOSYSTEM SERVICES AT THE SITE LEVEL: A PROXY-BASED APPROACH FOR RIZOELIA NATIONAL PARK, CYPRUS.

Paraskevi Manolaki

Open University of Cyprus

Marios ANDREOU, Frederick University; Charalambos CHRISTODOULOU, Department of Forests, MANRE; Iro KOUZALI, Frederick University; Konstantinos PAPASAVVAS, Department of Forests, MANRE; Louise SUTHERLAND, Open University of Cyprus; Vassilis TRIGKAS, Open University of Cyprus; Ioannis N. VOGIATZAKIS, Open University of Cyprus

Conservation and management of Natura 2000 sites should go beyond simply conserving the biodiversity they support towards managing the multitude of services they provide. This shift in management necessitates the identification and mapping of these services. The National Park of Rizoelia in Cyprus is a Natura 2000 site supporting two priority habitats at the European level, Ziziphus arborescent mattoral (*5220) and gypsum steppes (*1520), which have been well documented and mapped. However, this is not the case for other services supported by the Park. The current study aims to identify, quantify and map the range of ecosystem services (ES) in the park. We develop a framework based on widely used methodologies using tables for regulating, provisioning and cultural ecosystem service linked to related indicators for their quantification. Furthermore, spatial concepts of service providing units, benefitting areas, spatial relations, rivalry, spatial and temporal scales are elaborated. Finally, matrices linking habitat types to ecosystem service potentials, flows, demands and budget estimates are provided. The resulting maps show the spatial distribution of ES in the park, which constitute a practical and easy tool for managers to integrate the concept of ES in decision-making. Nonetheless, integrating more data and validating this approach in the future is still necessary if it is to be adopted and applied as a standard method at regional or national scale.

SYMPOSIA NUMBER 188; NOT ALL SMALL DAMS ARE BENIGN: A STUDY ON THEIR CUMULATIVE IMPACTS IN SOUTH AFRICA

Sukhmani Mantel

Rhodes University

Small dams are generally ignored in impact assessments due to the perception of their benign nature relative to large dams. This may be an oversight in catchments with a high density of small dams. In two South African regions, reduced low flows, deteriorated water quality, and impoverished macroinvertebrate communities (with dominance of opportunistic taxa and reduced abundance for specialist

groups) was previously established in catchments with high density of farm dams that support vineyards, stock farming and exotic timber plantations. An index of cumulative small dams with a threshold of five small dams per square root kilometer of catchment area was identified above which the density of small dams significantly compromises river functionality and impacts on environmental flows. Index values have been calculated at quaternary level (a basic water management unit in South Africa) and it was found that forty-three percent of the 1,946 quaternaries exceed the threshold for high density of small dams above which river deterioration is expected. This estimate of potentially impacted quaternaries is considered to be conservative since the GIS coverage for small dams used in the analysis does not include northern countries with which South Africa shares borders, and thus the index values for quaternaries with transboundary rivers to the north of South Africa might be biased. Secondly, the coverage of small dams dates back to the year 1999 and it is expected that the numbers have changed, possibly increased, since then. Current research is investigating incorporating this small-dams index into a river continuity index, which integrates both lateral and longitudinal discontinuities, for assessing the vulnerability of aquatic biota to climate change effects and for use as a conservation-related decision-making tool for South Africa.

CLIMATE CHANGE MEDIATES RISK OF GLOBAL BIODIVERSITY LOSS DUE TO LAND-COVER CHANGE

Chrystal Mantyka-Pringle

University of Saskatchewan

Piero VISCONTI, University of Rome ; Moreno DI MARCO, University of Rome ; Tara MARTIN, CSIRO ; Carlo RONDININI, University of Rome ; Jonathan RHODES, University of Queensland

Climate change and land-cover change will have major impacts on biodiversity persistence worldwide. While these two pressures are likely to interact, how climate change will mediate the effects of land-cover change remains poorly understood. Here we use an empirically-derived model of the interaction between habitat loss and climate to predict the implications of this for biodiversity loss and conservation priorities at the global scale. Risk analysis was used to estimate the risk of biodiversity loss due to alternative future land-cover change scenarios and to quantify how climate change mediates this risk. We demonstrate that the interaction of climate with land-cover change could increase the impact of land-cover change on birds and mammals by up to 43% and 24% respectively and alter the spatial distribution of threats. Additionally, we show that the ranking of global biodiversity hotspots by threat depends critically on the interaction between climate change and habitat loss. Our study suggests that the global priority hotspots will likely change once the interaction between climate change and land-cover change is

taken into account. We argue that global conservation efforts must take this into account if we are to develop cost-effective conservation policies and strategies under global change.

DEMOGRAPHY AND POPULATION GROWTH OF WORKING ELEPHANTS IN MYANMAR

Khyne U Mar

University of Sheffield

Although the Union of Myanmar is home to the world's largest captive population of Asian elephants (*Elephas maximus*), its demography has never studied in detail. Life history data analyzed in this study are taken from the records and reports archived and maintained by Myanma Timber Enterprise, which is under the charge of the Ministry of Forestry, the Government of the Union of Myanmar. The study population contains 5292 individually identified captive timber elephants, which were born or captured between 1952 and 2000. Overall population structure is in favour of females. A gradual increase in the population size is observable until 1991 followed by a decline until the end of study period in 2000. Projected trends in population size and age- and sex-specific structures are largely affected by the annual rate of capture, births, and deaths. The generation time (T), net reproduction rate (R_0) and the intrinsic rate of increase (r) of captive born and wild caught populations are calculated as 29.49 yr, 1.02, -0.001 and 31.60 yr, 0.47, -0.026, respectively, indicating that the captive born portion of the timber elephant population is self-sustaining while wild caught elephant population, on the other hand, is not self-sustaining, and their population is declining by about 53% each generation.

HUMAN-WILDLIFE CONFLICTS ON PRIVATE LANDS IN BRAZIL: A FAST GROWING ISSUE

Silvio Marchini

University of São Paulo

Katia FERRAZ, University of São Paulo ; Monica ENGEL, Memorial University

Human-wildlife conflicts have grown in Brazil over the past 10 years. There has been a dramatic increase in the number, diversity of species involved, geographic range, and severity of outcomes. This growth is concentrated on farming areas and at the urban-rural interface, and is attributed to several factors: expanding human settlement, changes in agricultural practices (e.g. recently banning of cane burning), growth of outdoor recreation, and increase in the number of species that have adapted to living in human-dominated landscapes. Managing these species is complicated by the growing diversity of wildlife values among different publics. We describe conflicts involving jaguars, pumas, capybaras (associated with agricultural damage, vehicle collisions and transmission of

zoonotic disease) and wild boars (a spreading exotic species involving issues of hunting/anti-hunting). Three critical needs are identified. 1) Move from a conservation to a management paradigm, where there may be need to reduce populations at some places, rather than the conventional situation where the population was always expected to increase, 2) Emphasize coexistence rather than conflict, addressing factors that can be precisely specified, objectively measured, and positively communicated to the different publics (e.g. tolerance or acceptance instead of conflict), and 3) Apply interdisciplinary approaches to research, management, planning and policy - with particular attention to bringing in the social sciences - by integrating natural, social and behavioural data from multiple species, multiple stakeholders and multiple spatial scale analysis.

SHAKEN, NOT STIRRED": STAKEHOLDER MAPPING AND SOCIAL NETWORK ANALYSIS OF A PROTECTED AREA BUFFER ZONE IN THE TEMPERATE RAINFOREST OF SOUTHERN CHILE

Gonzalo Mardones
University of Otago

One of the main challenges for a buffer zone of protected area is to achieve a successful integration of biodiversity conservation and development needs of local people. In this zone converges a wide range of social, political and economic actors, whose interests need to be integrated. This research presents a stakeholder mapping and a social network analysis of relevant actors in the buffer zone of a protected area in the temperate rainforest of southern Chile. The study identify nearly 200 institutions and organizations with interest and/or influence on conservation and/or development, from local communities organizations, public agencies, local governments, private companies, educational institutions and NGOs. The stakeholders are classified according to type of organization, geographical level of intervention, socio-ecosystem and degree of interest and/or influence, reflecting the multidimensional character should have a good governance of protected areas and their buffer zone. The social networks analysis suggests: a) weak linkage between conservation agency and local communities; b) limited links between conservation agency with other public agencies; c) the social network as a whole has little cohesion and there are a significant number of subgroups; d) the cross-scale links (regional-local) area based on subsectors (agriculture, forestry, fishery, education, health, etc.) without an overall vision; e) the connections at regional level between public agencies and private sector are almost absent; f) the ties between stakeholders are primarily for communicational purposes. All these situations have important consequences for the protected area governance, such as difficulties of sharing

information and knowledge, lower social and political support for conservation, little chance to amplify good experiences and lower resilience to uncertainties.

LIVING KNOWLEDGE ABOUT TRADITIONAL AGRICULTURE IN KALOTASZEG, CENTRAL-EASTERN EUROPE

Katalin Margóczy

University of Szeged, Department of Ecology
Krisztina MOLNÁR, University of Pannonia ; Krisztina GELLÉNY, University of Szeged, Department of Ecology ; Marianna BIRÓ, Institute of Ecology and Botany, MTA Centre for Ecological Research, Hungarian Academy of Sciences

Knowledge about traditional farming system could be crucial in planning conservation management, especially ecosystem management. The book of the Hungarian ethnographer K. Kós: "Traditional agriculture in Kalotaszeg" (in Hungarian) contains detailed description of the local traditional farming system and land use in the middle of the 20th century, and earlier. Kalotaszeg is a traditional farming landscape in Transylvania (in Romania), with a significant Hungarian population, and ethnographical importance. Kós described the three-field rotation of arable land, the importance of livestock in agriculture as power and maintenance of soil fertility, and the essential local integration of different types of land uses, as arable land, fallow, pasture, hayfield, orchard and garden. In 2013 we conducted 24 semi-structured deep interviews with the people living now here in two villages: Sztána and Zsobok. We asked the people about the past and present land use methods. They told us, that the collectivization (1949-1962) did not change considerably the agricultural system but after the collapse of socialism (1989) most of the arable land were abandoned, the number of livestock decreased considerably. Extensive sheep grazing is the main land use form nowadays, but seminatural vegetation occurs thorough the esthetically attractive landscape. Most of the asked people had detailed knowledge about the former land use system, described by Kós in his book in the middle of the 20th century. They think that present situation is only transitional, and the only right and appropriate method of land use in this area is the traditional method. We discuss the ecological and socio-economical sustainability of the past and present land use system in the presentation.

CONSERVATION OF A KEY STONE SPECIES: BLACK TAILED PRAIRIE DOG RECOVERY IN NORTHWESTERN MEXICO

Alejandro Marin

Instituto de Ecología UNAM

Rodrigo SIERRA-CORONA, Instituto de Ecología UNAM ; Sara ARIAS, Instituto de Ecología UNAM ; Gerardo CEBALLOS, Instituto de Ecología UNAM

In 1989 in the Northwest of Mexico a complex of 55000 ha of prairie dogs colonies was rediscovered, this complex was the largest in the country and the beginning of a conservation project in the Mexican grasslands. Since then, research studies in the area accompanied with biodiversity monitoring have shown the role of prairie dogs on grassland ecosystem, supporting associated biodiversity, aerating the soil, promoting the water infiltration and other ecosystem services. Paired with the research studies, a mistakenly conception of prairie dogs as a plague, which led to eradication campaigns and a recent land conversion to agriculture threat the populations and the grassland ecosystem. In 2005 in order to assess the status of prairie dogs populations, the complex was monitored revealing a reduction of 73 percent of the area covered by colonies in 1989 and an estimated population of 100 thousand individuals. In 2013 we conducted the third monitoring of the prairie dog complex and we found an accentuated reduction with only 2284 ha with prairie dogs active colonies and an estimate population of 13660 individuals, representing that only a 5.4 percent of the area remains from the original distribution mapped in 1989. We also found an increase in the fragmentation of the colonies in the complex, passing from 43 colonies units in 1989, 56 colonies in 2005 and 76 colonies on 2013, and this fragmentation associated with an increase of croplands and a decrease of active prairie dogs burrows, which serves to many others species in the grassland ecosystem. With the actualized distribution and population trends we recategorize the black tailed prairie dog as an endangered species in the Mexican law, as a first step of a long term strategy for this key species and as a mechanism to preserve the last grassland in northwest Mexico.

ADAPTIVE CONSERVATION OF ETHIOPIAN WOLF POPULATIONS: LONG-TERM EFFECTS OF SOCIALITY, CLIMATIC VARIATION AND DISEASE

Jorgelina Marino

University of Oxford [INSTITUTE] Ethiopian Wolf Conservation Programme

Claudio SILLERO-ZUBIRI, University of Oxford [INSTITUTE] Ethiopian Wolf Conservation Programme

Successful strategies for the conservation of endangered carnivores rely on a good understanding of the factors and processes that drive their population dynamics. This knowledge, however, is typically constrained by the lack of detailed demographic data over long periods of time, so that the effects of climatic variation and of infrequent events such as sporadic disease epizootics can be captured. In social species with cooperative behaviours, an additional challenge is to

account for the impacts that behavioural decisions may have on population-level phenomena. Close monitoring of Ethiopian wolf (*Canis simensis*) populations over 30 years provides a valuable opportunity to assess these multiple influences, including that of recurrent rabies and canine distemper virus epizootics and reactive vaccination interventions. Demographic analyses and modelling revealed how these factors intermingle to control wolf numbers and their capacity to recover, with implications for their conservation and future population management interventions.

21. TOWARDS JUSTICE AS RECOGNITION: ASSESSING THE POLITICS OF REPRESENTATION IN CONSERVATION GOVERNANCE

Kimberly Marion Suiseeya

Purdue University

Over the past 30 years, scholars, practitioners, and policy makers have sought to transform global conservation efforts from being the source of injustice for forest-dependent communities towards being, at a minimum, initiatives that “do no harm.” As part of this quest, global conservation governance has adopted a set of justice practices aimed at facilitating justice at the community level, primarily focusing on enhancing procedural and distributional justice. In this paper I argue that the pursuit of these two dimensions of justice is insufficient for promoting just conservation. Instead, more attention to justice as recognition is required. Using data collected through two collaborative event ethnographies, coupled with institutional analysis of forest conservation projects in Laos and Southeast Asia, I show how understanding the politics of representation in global conservation governance across multiple scales of governance can open up new pathways towards justice as recognition. In particular, I direct attention to indigenous and local community representation at the Tenth Conference of Parties to the Convention on Biological Diversity, the World Parks Congress 2014, and their related forest conservation projects to highlight the barriers to and opportunities for facilitating justice as recognition.

SYMPOSIUM 116 - NATURE AND WILDERNESS IN THE ANTHROPOCENE

Virginie Maris

CEFE/CNRS

It is often said that we are witnessing the death of nature. Empirically, almost no place on the Earth remains uninfluenced by human activities. Conceptually, the old Nature/Culture dichotomy has been strongly criticized during the past thirty years. In the field of biodiversity conservation, there is less and less reference to the idea of nature, which is diluted in

the technical and economical spheres. From a technical point of view, the intensification of intrusive and technological-dependent means to conserve or restore biodiversity makes it less and less easy to distinguish what is natural from what is artificial, including in those areas traditionally dedicated to nature. From an economical point of view, the trend is made visible in the changing vocabulary of conservation, which increasingly borrows jargon and metaphors from economics, nature protection now having to do with the management of natural capital and the optimization of ecosystem services. The Anthropocene narrative reinforces this process of dissolution. By describing the present time as the one in which the Earth enter the era of humans, it looks like if there is no longer any room left for wild nature. However, a reference to nature is still salutary in order to face the environmental crisis. More precisely, the exteriority, the otherness and the agency of nature and natural entities are key features that offer the necessary background on which to project a peaceful and flourishing way to interact with other living beings. These features are well captured by the idea of wilderness. I will show that this concept, often criticized as an old-school phantasm, can still offer a precious guide for action in conservation, as long as it is re-conceptualized in terms of process rather than in terms of areas.

ARTISANAL AND RECREATIONAL FISHING FOOTPRINT ON CORALLIGENOUS VULNERABLE HABITATS

Vasiliki Markantonatou

Polytechnic University of Marche

Ricardo CATTANEO-VIETTI, Polytechnic University of Marche ; Valentina CAPPANERA, Portofino Marine Protected Area ; Pietro CAMPODINICO, Portofino Marine Protected Area ; Chris SMITH, Hellenic Center for Marine Research (HCMR) ; Giuseppe DI CARLO, World Wide Fund for Nature (WWF) ; Carlo CERRANO, Polytechnic University of Marche

Coralligenous habitats are extremely prone to mechanical disturbance and human activities such as fishing. Even though commercial fishing - and particularly bottom trawling - is considered by far the most destructive activity, recent studies show that small scale and recreational fishing should not be overlooked, as they extract a considerable amount of marine resources and exert significant pressure on benthic key habitats and species. Assessing fishing activity in the Mediterranean requires complicated approaches due to the increased heterogeneity and combination of gears, the variation of target species and the poor availability of data. Even though in most cases these activities are regulated a specific management plan should be developed, particularly in Marine Protected Areas (MPAs), due to the high biodiversity they host and the considerable numbers of fishermen involved in order to ensure their conservation targets. The present

study reveals areas vulnerable to the footprint of small scale and recreational fishing activities in Portofino MPA (Italy), aiming to support monitoring strategy in Mediterranean MPAs and support decision making for conservation objectives. Spatial analysis tools were used to integrate various sources of information from common MPA monitoring frameworks, in order to describe the impact and identify the spatial patterns of destructive fishing gears, such as fixed nets and longlines, on coralligenous habitats. The pressure assessment was based on the features of the gears and the fishing techniques in relation to the sea bottom characteristics. Results reveal an increased fishing footprint in areas where coralligenous habitats occur in 30-50m depth overlapping with elevated diving activity, increasing the risk of impact on this vulnerable habitat. The present study may provide baseline information on ecological, ecosystemic and conservation modelling related to fishing activity and vulnerable habitats in Mediterranean MPAs.

124-AVERTED LOSS OFFSETTING: COUNTERFACTUALS AND WHAT THEY MEAN FOR NNL GOALS

Martine Maron

The University of Queensland

Ascelin GORDON, RMIT University ; Joe BULL, Imperial College London ; Megan EVANS, The Australian National University

The extent and condition of native vegetation and habitat continues to decline in most parts of the world. Despite national and supranational commitments to stabilise biodiversity loss, the end point of these trajectories of decline remain unclear. In recent years, the growing popularity of biodiversity offsetting has helped popularise the concept of 'no net loss' of biodiversity. This outcome could be achieved through directly linking losses and gains (e.g. offsets) or more broadly ensuring we restore at least as much as we destroy. However, even this seemingly-clear goal can be interpreted in multiple ways, and depending on which interpretation prevails, achieving 'no net loss' can counter-intuitively mean that biodiversity continues to decline. We review goals and targets outlined in Australian native vegetation policy. We focus on offset policy, which in Australia is used extensively as a response to development that requires deforestation. Despite referring to 'no net loss' or a requirement to 'improve or maintain' biodiversity, all Australian applications of offsetting were based (implicitly or explicitly) on a declining baseline for biodiversity. In some States, these baselines were steep – up to 4.2% loss (of vegetation extent and/or condition) per annum. Policies that aim to achieve no net loss relative to a declining baseline essentially entrench it across impact-offset trades. Thus, the more that this type of 'averted loss' offsetting is relied upon to negate losses, the more broadly the declining baseline becomes entrenched. We suggest ways in which such perverse

outcomes can be minimised through linking baselines to biodiversity conservation goals.

BIODIVERSITY IN INPUT-OUTPUT ANALYSIS: THE INDIRECT DRIVERS OF BIODIVERSITY LOSS

Alexandra Marques

IDiv

Inês MARTINS, IDiv ; Henrique Miguel PEREIRA, IDiv

In 2010, the European Union established its growth strategy for the ten years ahead, the EU 2020 Strategy. The Resource-Efficient Europe is one of its flagship initiatives, framed under the principle of sustainable growth. One of its key proposals is the EU Biodiversity Strategy to 2020 to halt biodiversity loss and ecosystems degradation. This strategy highlights the importance of reducing the impacts of EU consumption patterns, particularly for resources that have significant negative impacts on biodiversity. Environmentally-extended input-output (IO) analysis has been increasingly used to identify the economic drivers of environmental impacts. Namely, the embodied impacts associated with a consumption activity and the impacts embodied in international trade. In this work, we developed a biodiversity extension to EXIOBASE, a global multi-regional environmentally extended input-output database. We used the countryside species area relationship to measure the number of species lost due to the activity of the land use sectors and analyze how consumption indirectly drives biodiversity loss. This work provides important insights into the linkages between economic activity and biodiversity loss. In an increasingly globalized world there is a spatial disconnection between production activities and the final consumer. Understanding how consumption drives biodiversity loss due to land use change can provide new pathways for biodiversity conservation.

EVALUATION OF A PARTNERSHIP WITH THE WINE INDUSTRY FOR SUSTAINABLE AGRICULTURE AND BIODIVERSITY CONSERVATION IN CHILE'S MEDITERRANEAN ECOSYSTEMS

Marcela Marquez-Garcia

University of Florida

Susan JACOBSON, University of Florida ; Olga BARBOSA, Universidad Austral de Chile

Only 1% of Chile's Mediterranean ecosystems are protected, yet this is a global conservation priority due to high levels of endemism and threats. Private land conservation efforts are needed, especially in partnership with the agricultural industry, which is a major economic driver in the region. The expanding wine industry is a primary target since producers and consumers increasingly value environmental stewardship. Using an organizational application of the theory of planned behavior, we compared the individual and institutional

factors of adopting conservation practices among Chilean winegrowers participating in a multi-year sustainability program with a control group. Semi-structured interviews were conducted with 25 vineyard managers. The program treatment group reported more conservation practices than the control. Ecosystem services, such as erosion control, pest and disease management, and aesthetic and spiritual benefits were the most important advantages of adopting conservation practices for both groups. Other motivations to engage in conservation were a sense of moral obligation and responsibility for future generations, which emerged more frequently in the treatment group. Regarding social pressures, the customers and the company's owner were important drivers of conservation behavior, but the treatment group reported a broader spectrum of internal stakeholder influence. Also, the treatment group seemed to be strongly influenced by conservation leaders within the company and from the sustainability program. The lack of information about the direct benefits of biodiversity conservation on the winegrape production and wine quality constituted an important barrier. This study enhanced our understanding of corporate environmental management, and identified factors beyond winegrowers' financial returns that explain sustainable agriculture and biodiversity conservation behaviors in endangered Chilean Mediterranean ecosystems.

MODELLING FINE SCALE HABITAT ASSOCIATIONS OF MEDIUM-TO-LARGE FOREST MAMMALS IN THE UZUNGWA MOUNTAINS OF TANZANIA USING CAMERA TRAPPING

Emanuel Martin

Sokoine University of Agriculture

Nathalie CAVADA, Tropical Biodiversity Section, MUSE - Museo delle Scienze ; Vedasto NDIBALEMA, Sokoine University of Agriculture ; Francesco ROVERO, Tropical Biodiversity Section, MUSE - Museo delle Scienze

We used camera trap data from the Tropical Ecology, Assessment and Monitoring (TEAM) network, collected in 2013 from 60 camera trap locations, to determine medium-to -large forest mammals' habitat associations at a fine scale level in the Udzungwa Mountains of Tanzania. This is an outstanding area for biodiversity and endemism in Africa, particularly for forest mammals. Our sampling lasted one month and yielded 12,911 images of 26 species of mammals. We used generalized linear modeling to determine relationship between trapping events and vegetation and other habitat variables, and obtained satisfactory model fit for nine out of the 11 most recorded species, with explained deviance ranging from 5.79 to 63.7 %. For rare species such as Abbott's duiker (*Cephalophus spadix*) results showed their trapping events to be positively correlated with the distance to the National Park

border while for Lowe's genet (*Genetta servalina lowei*) it was found to be positively correlated with big trees diversity but negatively correlated with a visibility index and herbaceous-seedlings forest floor cover. Our study validates the usefulness of camera trapping to assess communities of forest mammals and in particular determining their habitat associations, thus providing data which are relevant to their conservation management.

15 - LINKING LANDSCAPE STRUCTURE AND ON-FARM MANAGEMENT TO BIODIVERSITY IN AGRICULTURAL LANDSCAPES

Emily A. Martin

University of Würzburg

Ingolf STEFFAN-DEWENTER, University of Würzburg

Landscape structure and on-farm management are important factors for the richness and abundance of species in agricultural landscapes. Previous studies have shown beneficial effects of the proportion of non-crop habitat, the configurational complexity of landscapes and organic farming on biodiversity in agricultural landscapes. Various organisms including arthropods and birds exhibit higher species richness and abundance in landscapes with high amounts of natural or seminatural habitats that provide additional foraging and nesting resources. In addition to landscape composition, the spatial arrangement of land use types in a landscape can increase the interconnectedness of patches and thereby the richness and abundance of species. Finally, local management has a direct impact on organisms by pesticide application and different availability of food resources. However, the relative importance of landscape composition, landscape configuration and local management for different functional animal groups is still unclear. Due to data limitation, available syntheses lack functional resolution and have included only coarse local and landscape effects. Here, we use a quantitative meta-analytic approach based on the data of previous studies to analyse the interactive effects of local management intensity, landscape composition and configuration on functional groups of pollinators, pests and natural enemies in agricultural landscapes. We hypothesize that (1) Pollinator groups, which mainly depend on the amount of flowering resources, are most affected by landscape composition, whereas natural enemies are most affected by landscape configuration and the proportion of ecotones between habitat types, (2) Effects of local management intensity interact with landscape factors such that management effects are strongest in landscapes with both low amounts and a simple configuration of habitats. We will present and discuss results from the analysis of a large European-wide data set.

DIE-OFF OF LARGE TREES DRIVES FOREST COLLAPSE TO NON-FOREST STATE

Philip Martin

Bournemouth University

Adrian NEWTON, Bournemouth University ; Elena CANTARELLO, Bournemouth University ; Paul EVANS, Bournemouth University ; Edward MOUNTFORD, Joint Nature Conservation Commission

There is great concern different drivers may cause forests to rapidly transition to non-forest states. Such changes may be driven by human use (e.g. logging, grazing of animals), climatic stress (e.g. drought) or interactions between the two. While there have been many case studies indicative of such rapid transitions they tend to be hindered by short sampling periods. Our work uses a 50 year time series from a woodland in Southern England that appears to be switching to a non-forest state. This work shows that die off of large trees has resulted in massive change in forest structure in some areas. Plots that experienced more severe collapse had greater alteration of ecological communities and understories tended to be dominated by grasses. Mortality in the woodland may have been elevated by a combination of storms, drought and fungal pathogens. Regeneration in the woodland is almost nil probably as a result of overgrazing of livestock and deer. Together these different drivers are responsible for shifting the woodland to a largely treeless state in which it is likely to remain without any remedial action.

NATIVE FOREST COVER INFLUENCES SPECIES DISTRIBUTION AND NETWORK STRUCTURE OF ARTHROPOD-PLANT ASSEMBLAGES IN TRADITIONAL CORNFIELDS

Eliana Martinez P

Universidad Nacional de Colombia

Argenis BONILLA, Universidad Nacional de Colombia ; Rafael RAIMUNDO, Universidade de São Paulo ; Paulo GUIMARÃES JR., Universidade de São Paulo ; Rodolfo DIRZO, Stanford University

Understanding processes shaping communities in agroecosystems is essential for the design of strategies promoting long-term sustainability of ecosystem services, such as pest control. We studied the organization of arthropod-plant assemblages in twelve traditional cornfields from the Colombian Andes. We first investigated the association between patterns in species distribution and gradients in native forest cover, altitude, field size, and organic matter in soil. Then, we described the architecture of local species interaction networks. The assemblages of plants associated to corn crops were significantly nested, i. e., species composition of species-poor cornfields represent subsets of species-rich cornfields. Altitude and content of organic carbon in soil accounted for nestedness of the plant meta-community,

whereas forest cover and weed richness accounted for nestedness of the arthropod meta-community. Only the plant meta-community exhibited significant, albeit low, modularity. Local species interaction networks were modular, with plants acting as module hubs with arthropods, particularly herbivores, being peripheral species. The modular structure of arthropod-plant interaction networks suggests herbivores tend to be specialized with regards to their host plants. Forest cover and weed species richness within cornfields were positively related with both the number of arthropod species in networks and average interaction numbers per species, but negatively affected modularity. Thus, clearing native forest in this agroecosystems may induce the loss of predator species and also may lead to the lack of cohesion of overall weed-arthropod interaction networks with negative consequences for pest control. This network approach can be useful to identify environmental factors and species with potential, to play key roles in pest management. Increasing forest cover surrounding crops augments the local diversity of predators, decreasing demands for agrotoxicals.

LAND USE CHANGE SCENARIOS AND ECOSYSTEM SERVICES PROVISION IN CENTRAL CHILE

Maria Martinez-Harms

University of Queensland

Patricio PLISCOFF, Universidad de Chile ; Eugenio FIGUEROA, Universidad de Chile ; Kerrie WILSON, University of Queensland

Scenarios of land use and land cover change provide a platform to predict the possible outcomes of land use decisions on the provision of ecosystem services. This information can then be used to inform the development of policy and minimize unintended consequences. Despite the wide use of scenarios in ecosystem service assessments, there is a lack of clarity on how qualitative expert-derived information on the drivers of land use change can be transparently combined with quantitative analyses on the provision of ecosystem services. In this study we integrate qualitative scenario storylines derived through expert-elicitation with spatially explicit models of land use and land cover change. We quantify the impact of future land use and environmental change on a selection of ecosystem services in Central Chile: carbon storage, wine production, and scenic beauty. Experts identified urbanization sprawl and climate change as the critical drivers affecting the study area. The drivers were compiled into a set of four storylines depicting contrasting assumptions and translated into spatial rules of land use change according to their impacts on the selected services. The resultant scenario maps representing higher greenhouse gas concentration levels and higher levels of urbanization show a potential future decline in the provision of ecosystem services for the year 2050. The information derived from our scenario analysis is useful to inform and guide the development of future land use policy in Central Chile.

CHALLENGES & STRATEGIES WHEN DOCUMENTING INUIT KNOWLEDGE, A VALUABLE TRADITIONAL ECOLOGICAL KNOWLEDGE DATABASE FOR ARCTIC WILDLIFE MANAGEMENT AND CONSERVATION

Laura Maria Martinez-Levasseur

Trent University

Chris FURGAL, Trent University ; Mike HAMMILL, Maurice Lamontagne Institute, Fisheries and Ocean Canada ; Gary BURNES, Trent University

Combining Traditional Ecological Knowledge (TEK) with science has increased in ecology, particularly when working in remote locations such as the Arctic, where harvesters have a close relationship with wildlife. However, there are often limitations and biases in the methods used to gather, analyze and report TEK that not only jeopardize the validity of the data, but can potentially result in negative impacts for wildlife. Here, we discuss the limitations and biases faced during our documentation of TEK on walrus in the Canadian Arctic, and offer strategies to address these issues. Semi-directive interviews with a mapping process were used to collect Inuit Knowledge from 33 walrus experts. The audio-recorded interviews and digitized maps were analysed using NVivo and ArcGIS. Our data interpretation was verified during workshops held with participants. We found that by recording and adding to maps the geographic limits of participants' primary area of knowledge, we were able to distinguish areas that hunters typically visited and did not see walrus from areas that hunters never visited. Furthermore, using a top-down strategy, our statistical models showed that the variability in the quantity of mapped data was explained by the community of residence and the average number of hunting trips per individual but not their age. These results highlight the importance of considering and including key attributes as criteria to select participants. On the contrary, age explained the variability in the quantity of diverse mapped data, suggesting that while Elders do not provide a greater quantity of map information, they provide greater diversity. We hope this careful examination of methods will help to increase rigour in the methods used to gather TEK, and increase confidence in TEK datasets as a valuable source of knowledge for wildlife management and decision making.

MATRIX AND EDGE EFFECTS ON THE MAINTENANCE OF ECOLOGICAL FUNCTION IN AN AFROMONTANE PROTECTED AREA

Robin M. Martino

Antioch University New England

Beth A. KAPLIN, University of Rwanda[INSTITUTE]Antioch University New England ; Norbert J. CORDEIRO, Roosevelt University[INSTITUTE]Field Museum of Natural History

Land use type in the human dominated matrix surrounding tropical forest can influence edge effects on forest ecological processes. Seed dispersal is a key ecological process in tropical forest regeneration dynamics. Our hypothesis was that soft or low contrast matrix types will better support ecological processes than a hard or high contrast matrix. We examined how matrix type, tea plantations (hard) vs. pine plantations (soft), affects seed dispersal effectiveness and vegetation structure and composition in adjacent edges of montane tropical forest. Research was conducted in Nyungwe National Park, Rwanda, located in the Albertine Rift biodiversity hotspot. We conducted focal tree observations and sampled vegetation over a 10 month period. We found significant differences in frugivore assemblages and forest structure adjacent to hard vs. soft matrix types. Large birds made more visits to focal trees and removed more fruit (49%) in forest edge adjacent to soft, low contrast pine plantation, while primates made significantly more visits to focal trees and removed more fruit (90%) in forest edge adjacent to hard, high contrast tea plantations. Forest edges adjacent to tea plantations showed a deeper penetration of edge effects resulting in a greater proportion of small seeded, shade intolerant tree species than in edges adjacent to pine plantations. These findings demonstrate how land use around tropical forests affects forest composition, structure and function, and can contribute to ecological integrity in systems facing pressure from human land use in the surrounding matrix.

CONSERVATION EFFORTS ON HIGH NATURE VALUE FARMLANDS IN CYPRUS

Angeliki Martinou

Cyprus University of Technology
Savvas ZOTOS, Open University of Cyprus ; Marina XENOPHONTOS, Department of Environment, Ministry of Agriculture, Natural Resources and Environment ; Lefkios SERGIDES, Terra Cypria, the Cyprus Conservation Foundation ; Ioannis VOGIATZAKIS, Open University of Cyprus ; Menelaos STAVRINIDES, Cyprus University of Technology ; Ioannis VOGIATZAKIS, Open University of Cyprus

The growing recognition that the conservation of biodiversity in Europe depends on the continuation of low-intensity farming systems resulted in the concept of High Nature Value farming (HNVF). In the Mediterranean in particular, HNVF includes some of the most traditional agricultural crops such as cork oaks, olives, carobs and vineyards. In Cyprus carob groves and vineyards are among the crops which are inextricably linked with the economic and cultural character of the island. At the same time these crop systems when farmed

at low-intensity, support species of fauna and flora which are important at the National or European level, while providing a number of other ecosystem services. Despite their importance, these HNHF types on the island are now threatened by intensification, abandonment or lack of awareness about their role. This demonstration project puts into practice, tests, evaluates and disseminates actions/ methodologies that are unfamiliar to the Cyprus geographical, ecological and socio-economical context. The objectives of the project are to: a) Conserve biodiversity in vineyards and carob groves, with a strong focus on species listed in the Birds and Habitats Directives, b) Support and promote sustainable agricultural practices that increase ecosystem services, c) Identify strengths and weaknesses of bioindicators for evaluation of HNHF in small scale agriculture and d) Encourage stakeholder involvement and increase public awareness regarding HNHF issues through active participatory learning. Although this work is still under progress we anticipate that the knowledge generated from it would provide important guidelines for the sustainable management of vine and carob HNHF in Cyprus.

USING COUNTRYSIDE SPECIES-AREA RELATIONSHIP TO QUANTIFY THE IMPACTS OF LAND USE ON BIODIVERSITY

Inês Martins

German Centre for Integrative Biodiversity Research (iDiv)
Halle-Jena-Leipzig
Alexandra MARQUES, German Centre for Integrative Biodiversity Research (iDiv) Halle-Jena-Leipzig ; Henrique PEREIRA, German Centre for Integrative Biodiversity Research (iDiv) Halle-Jena-Leipzig

Land use is one of the main drivers of biodiversity loss. The response of species richness to habitat area loss is often assessed using species area relationships (SAR) models. The classic SAR or power model assumes that the number of species is mainly determined by habitat area, projecting that all species go extinct after all native habitat is lost. However, the conversion of natural habitats to human-dominated habitats, for example the conversion of forests to agricultural areas, may lead to the increase in some species and decline in others. Alternative forms of the SAR, such as the countryside SAR, have been developed in order to address this problem. The countryside SAR model accounts for land use information and for species affinity to the different types of habitat. In this work we perform a global spatially explicit analysis to determine the impact of 14 land use activities on species extinctions of birds, mammals and amphibians. Using the habitat preferences and geographic range data from the IUCN we assessed the affinity of each species to a certain land use type. Our global analysis calculates, for each WWF ecoregion and biome, the species loss associated to each individual land use activity. Then this loss is allocated to each country taking into consideration the area

occupied by each land use sector in each country as well as the affinity of the species to that land use activity. At the national level our results provide important insights for sector driven policies to halt biodiversity loss.

THE SOCIAL IMPACTS OF PROTECTED AREAS: INSIGHTS FROM 100 VILLAGES IN INDONESIA

Michael Mascia

Conservation International

Fitryanti PAKIDING, Papua State University ; Louise GLEW, WWF

Protected areas are an integral component of local, national, and international strategies for biodiversity conservation, but their contributions to sustainable development goals (SDGs) remain contested. To inform this debate, we examined the impacts of marine protected areas (MPAs) on household well-being in >100 villages across the Bird's Head Seascape (BHS) of Indonesia. Using a quasi-experimental design and drawing upon nearly 5,000 interviews, we examine social well-being across five social domains: economic well-being, health, political empowerment, education, and culture. Preliminary impact data from eight MPAs and matched control sites provide insights into the short-term impacts of protected area establishment on household well-being. We find that MPA social impacts vary widely, with the magnitude and direction of impacts differing within and among social groups, across social domains, and between sites, resulting in complex arrays of impacts. In addition to providing insights for site-level adaptive management, the heterogeneous social impacts of MPA establishment in the BHS highlights the need for a more nuanced approach to evaluating the social impacts of conservation interventions as the foundation for analyzing protected area–poverty linkages and advancing sustainable development goals. This manuscript is part of a set of contributed papers organized by L. Glew, M. Mascia, and D. Miller. If accepted, please include this presentation in the program immediately following the presentation by Dan Miller and immediately prior to the presentation by Lauren Persha. If you have any questions, please contact me directly. Thanks.

THE GEOGRAPHICAL RANGE OF BRITISH BIRDS EXPANDS DURING 15 YEARS OF WARMING

Dario Massimino

British Trust for Ornithology

Alison JOHNSTON, British Trust for Ornithology ; James W PEARCE-HIGGINS, British Trust for Ornithology

Climate change is affecting the distributions and populations of many species and it is projected to lead to range contractions and extinctions. Previous assessments of distribution change have relied on presence-absence or presence-only data, and therefore only assess species entering new areas or leaving old areas. Furthermore, expansions

are easier to detect with presence data than contractions, so there may be biases in the data. Changes in abundance within an existing range are a more powerful way of assessing distributional change and they may be an early-warning of changes to range extent. We examine change in abundance within species ranges and assess whether range limits and range optimums are moving in response to climate change. We use 15 years of bird data from Great Britain, where there has been substantial northward movement of climate. Species northerly distribution margins moved northward for a wide range of species, but the southerly edges of the species distributions were largely static. This suggests the mechanisms defining the northerly and southerly distributional limits may differ. The northerly movement of the northerly edge of the distributions, without the concurrent contraction in the south has led to many species expanding their distribution. The magnitude of northerly distribution shifts lagged behind the equivalent shifts in temperature, suggesting that species may be accumulating a climatic debt and may find it increasingly difficult to track the moving climate. Contrary to the generally expected long-term consequences of climate change of range contraction and population decline, we show that the short-term response of birds to recent warming in Great Britain has been range expansion.

177-WETLAND SOCIAL-ECOLOGICAL DYNAMICS, BIODIVERSITY CONSERVATION AND DIALOGUE PROCESS: LESSONS-LEARNED FROM THE BUTORSTAR COMPUTER-BASED ROLE-PLAYING GAME

Raphael Mathevet

CNRS UMR 5175 CEFE

Brigitte POULIN, Tour du Valat ; Gaetan LEFEBVRE, Tour du Valat

With computer simulations and/or role-playing games, agent-based models (ABM) can support participatory modelling approaches in which stakeholders involved in biodiversity management projects collectively construct and/or reflect together on land use and land planning scenarios. Ten years ago we created ButorStar, a role-playing game based on an ABM that allows the simulation of the impacts of multiple uses of a wetland on habitat and fauna dynamics and their feedback on land cover changes and social-economic dynamics. This tool serves in training students in negotiation and participatory-management of both protected and unprotected natural areas. The analysis of gaming sessions with postgraduate students in social science, conservation science and environmental management shows that (i) students learned more about social dimensions of biodiversity conservation planning than about ecological interdependencies; (ii) students from social science were more able to find social-ecological trade-offs; (iii) students from conservation sciences were likely to create more

dikes to manage threatened species, increasing the man-made influence on the landscape. Also used with local stakeholders in several wetlands, and with managers of NGOs and protected areas, the results demonstrate that this approach contributes to increasing stakeholders' ability to adopt methods of interaction that promote adaptive management of natural areas. Overall our results show three key social effects within the context of integrated conservation and development projects: (1) the creation of social-ecological knowledge that may feed integrated conservation policy ; (2) the use of social learning to resolve practical problems ; (3) the rising awareness of social-ecological interdependencies during the game session increase the capacity of players to collaborate and to participate in the social change that any integrated conservation project may need.

IMMEDIATE BIRD RESPONSES TO WINDSTORM DISTURBANCE: A CASE STUDY FROM BUSSACO NATIONAL FOREST, CENTRAL PORTUGAL

Milene Matos

Department of Biology & CESAM, University of Aveiro
André AGUIAR, Department of Biology & CESAM, University of Aveiro ; Carlos FONSECA, Department of Biology & CESAM, University of Aveiro

On 19 January 2013, a windstorm named Gong, which observed wind gusts of 140 km/h, hit the Portuguese coast and was responsible for the downfall of thousands of trees in some Portuguese forests and cities. Bussaco National Forest (BNF), an old-growth heritage forest, was affected in about 40% of its area, with over 2500 fallen trees. Acoustic and visual bird censuses were conducted from June to December, before and after the storm, in 35 sampling points distributed by the three main landscape units amongst BNF: Pinhal do Marquês Pinus pinaster pinewood, relict forest and the arboretum. The pinewood and the arboretum were highly damaged, whereas the relict forest, a climax woodland composed exclusively by native species, was the less affected landscape unit. Overall and in all landscape units, birds' species richness diminished, but birds' abundance increased. Diversity and evenness indices presented significant differences in the pinewood and in the arboretum, but no differences in the relict forest. The assemblage composition of the most abundant species was altered only in the pinewood, for instance with *Corvus corone*, that was not registered there before the storm, becoming the most abundant species afterwards. In all landscape units rare species recorded before the storm virtually disappeared afterwards. We discuss that windstorm disturbance may cause short-term immediate bird responses that only favour more common and resilient species and hypothesize that treefall gaps may however contribute to the structural heterogeneity of the forest and benefit the composition and richness of the bird community in the long run. Sound forest management

preventing ecological invasions and favouring native species is crucial for accelerating the restoration of the ecosystem. Some conservation perspectives are also discussed.

FORECASTING FUTURE DIVERSITY AND DISTRIBUTIONS OF BUTTERFLY SPECIES UNDER CLIMATE CHANGE IN JAPAN

Misako Matsuba

University of Tokyo

Tadashi MIYASHITA, University of Tokyo

Future climate change is a major threat to biodiversity through habitat degradation or species geographic range shifts. The alteration of habitats under climate change could cause the current nature reserves less valuable to conserve species in the future. Butterflies are flagship species for conservation, and more than 25% of them are listed in Red Data Book in Japan. Forecasting their future distributions would enable us to identify priority species and areas, leading more effective conservation planning. First, we constructed species distribution models for 179 butterfly species with a presence only modelling, Maxent. We then forecasted their future distributions for three time slices (2020, 2050, 2080), and under three climate change scenarios (RCP2.6, RCP4.5, RCP8.5). The future climate variables were averaged over four climate models (MIROC5, MRI-CGCM3, GHDL-CM3, HadGEM-ES) to consider model uncertainties. Based on the future distribution maps, we identified vulnerable species to future change, which rapidly and severely decline in their range size. We also identified robust areas that will stand as hotspots until 2080 under different climate scenarios as candidate priority areas, which had a higher proportion of landscape heterogeneity than existing nature reserves. Landscape heterogeneity is enhanced by mixture of open lands or agricultural fields with secondary forests, which are significant refuges for grassland species, accounting for 70% of Red Data Book of Japanese butterflies. Considering complementary with existing nature reserves which mainly consist of forested areas, we propose conservation strategies to prioritize the management of open lands or agricultural fields to maintain landscape heterogeneity under the future threat of climate change.

ANALYSIS OF THE DEFORESTATION DYNAMICS IN PRATIGI'S ENVIRONMENTAL PROTECTED AREA, BRAZIL, AND THE IMPLICATIONS FOR CLIMATE CHANGE

Bruno Matta

IPÊ

Clinton JENKINS, IPÊ ; Eduardo DITT, IPÊ ; Alexandre UEZU, IPÊ

The study of deforestation dynamics is extremely important for a better understanding of the processes and phenomena that determine land use change. In the region of the Atlantic Forest

biome along the coast of Brazil (a biodiversity hotspot), such an analyses allows the design of effective actions to conserve the remaining forest fragments. Even with the existence of specific laws to protect and preserve the Atlantic Forest (Federal Law n°11.428/2006), deforestation still exists in the biome and is considered a common practice in many regions. In Pratigi's Environmental Protection Area (EPA) in the Central Corridor of the Atlantic Forest, deforestation increased 9% between 2000 and 2011, representing around 14 thousand hectares and a mean rate of 1273 hectares/year. The goal of our study was to understand the historic processes of these deforestation dynamics in Pratigi's EPA and to estimate the amount and location of deforestation until 2041. Between 2000 and 2006, the mean annual deforestation rate was 1.21%, while in the second period between 2006 and 2011 the rate was a slightly higher 1.55%. In the year 2000, the deforested area was approximately 38,312 ha, which represents 22% of the Pratigi area. In 2011, there was an increase in the deforested area, reaching 31% of the EPA and 52,319 ha. The projected deforestation for the Pratigi's EPA in the period 2011-2041 was 31,322 ha, being an annual mean deforestation rate of 1.2%. This would represent a total emission of 10,443,422 tons of CO₂. The possibility to develop a forest conservation project (REDD+), aiming to generate carbon credits from reduced deforestation, could potentially represent a gross revenue of 43 million dollars in 30 years of a project.

SUCCESSES AND CHALLENGES FROM FORMATION TO IMPLEMENTATION OF ELEVEN BROAD-EXTENT CONSERVATION PROGRAMS

Brady Mattsson

University of Natural Resources and Life Sciences (BOKU)
Erik BEEVER, U.S. Geological Survey, Northern Rocky Mountain Science Center ; Matthew GERMINO, U.S. Geological Survey, Forest and Rangeland Ecosystem Science Center ; Max POST VAN DER BURG, U.S. Geological Survey, Northern Prairie Wildlife Research Center ; John BRADFORD, U.S. Geological Survey, Southwest Biological Science Center ; Mark BRUNSON, Utah State University, Department of Environment and Society ; Harald VACIK, University of Natural Resources and Life Sciences (BOKU)

Integration of conservation partnerships across geographic, biological, and administrative boundaries is increasingly relevant because drivers of change, such as climate shifts, transcend these boundaries. We explored successes and challenges of established conservation programs that span multiple watersheds and consider both social and ecological concerns. We asked representatives from a diverse set of 11 broad-extent conservation partnerships in 29 countries 17 questions that pertained to launching and maintaining partnerships for broad-extent conservation, specifying

ultimate management objectives, and implementation and learning. Partnerships invested more funds in implementing conservation actions than any other aspect of conservation, and a program's context (geographic extent, United States vs. other countries, developed vs. developing nation) appeared to substantially affect program approach. Despite early successes of these organizations and benefits of broad-extent conservation, specific challenges related to uncertainties in scaling up information and to coordination in the face of diverse partner governance structures, conflicting objectives, and vast uncertainties regarding future system dynamics hindered long-term success, as demonstrated by the focal organizations. Engaging stakeholders, developing conservation measures, and implementing adaptive management were dominant challenges. We describe an approach to overcome these challenges using two case studies on large, cross-border national parks of central Europe.

ECOSYSTEM SERVICES AS A RATIONALE FOR ECOLOGICAL RESTORATION IN AUSTRALIA

Virginia Matzek

Santa Clara University

Marit KRAGT, University of Western Australia ; Kerrie WILSON, University of Queensland

Habitat restoration has long been motivated by conservation of biological diversity, but increasingly, it is also called on to restore or protect the flow of ecosystem services (ES) to humans. We examined perceptions of the relative importance of ES and biodiversity as a rationale for ecological restoration projects in Australia, where government funding priorities have alternately favored biodiversity and ES goals for restoration on public and private lands. First, we queried the MERIT database of Commonwealth-funded natural resource management projects, to quantify the frequency of ES and biodiversity goals in >250 restoration and revegetation project summaries. Second, we did 30 semi-structured interviews with land managers charged with implementing restoration projects all over Australia, to understand the role that ES provision and biodiversity conservation played in justifying projects to landowners, funders, and other stakeholders. Third, we developed a survey for members of the general Australian public, to understand what value they place on ecosystem services and biodiversity as goals of restoration. The data analyzed so far quantify a trend of increasing importance of ES goals in motivating restoration projects in Australia. However, the largest and best-funded projects appear to have conservation of endangered species as their principal goal.

BAYESIAN NETWORKS AS A TOOL FOR RECONCILING THE ECOLOGICAL, SOCIAL AND ECONOMIC DIMENSIONS OF CONSERVATION: A CASE STUDY ADDRESSING THE SUSTAINABILITY OF WHALE-WATCHING

Giada Maugeri

Plymouth University [INSTITUTE] Galway-Mayo Institute of Technology

Simon BERROW, Galway-Mayo Institute of Technology ; Steve FLETCHER, Plymouth University ; Simon N. INGRAM, Plymouth University

Conservation, acting at the interface between natural and social sciences, requires a dynamic, holistic and multidisciplinary approach. However, in spite of the growing awareness of the need to cross disciplinary borders, effective integration of knowledge originating from different disciplines such as ecology, economics and psychology remains an open challenge. In fact, the tendency towards overspecialization and the lack of common frameworks, languages and tools between disciplines has often undermined attempts to adopt a more integrated approach. Bayesian Networks (BNs) have shown to be a powerful tool for retrieving “the bigger picture”, in a visually accessible and mathematically robust way. By combining graph theory, which effectively represents the relationships between variables, and probability theory, which explicitly incorporates uncertainty, BNs are models able to predict future scenarios and the outcomes of certain actions through complex causal chains. Our work offers an overview on the use of BNs as a framework for integrating the ecological, social and economic dimensions of conservation. As an example, we illustrate the ongoing development of a BN model examining the complex system underpinning the sustainability of whale-watching. Through our case study we show how BNs can potentially integrate any kind of qualitative or quantitative information available, from the outcomes of existing models to expert opinion, from popular knowledge to raw datasets. Once the model is developed, we illustrate how it can be used to identify monitoring and research priorities, to give insight into future scenarios under different management regimes, and to optimise action according to the best available information. Our study demonstrates that BNs represent a viable tool for successfully meeting the challenge of interdisciplinary and holistic management, thus having the potential to contribute to global conservation outcomes.

ELEPHAS MAXIMUS ECONOMICUS : MODELLING THE POPULATION OF LAO CAPTIVE ELEPHANTS USING A BIO-ECONOMICS APPROACH.

Gilles Maurer

Centre d'Ecologie Fonctionnelle et Evolutive

Benjamin RASHFORD, University of Wyoming ; Jean-Dominique LEBRETON, Centre d'Ecologie Fonctionnelle et Evolutive ; Olivier GIMENEZ, Centre d'Ecologie Fonctionnelle et Evolutive

Asian elephant populations (*Elephas maximus*) are in overall decline and classified as endangered by the International Union for Conservation of Nature. Captive populations represent a third to a quarter of the total population, which makes them of paramount importance in terms of species conservation. Interrelationships between wild and captive populations persist in most countries, typically through reproduction between captive cows and wild bulls. However, very few studies have considered captive individuals, and their role in the persistence of elephant populations. As a case study, we focused on Laos that has a tradition of raising Asian elephants for centuries. Yet the captive population has plummeted over the past twenty years due to the intensification of work in the logging industry with the recent opening to the market economy. Elephant owners thus refrained their cows to breed preferring the high incomes generated by their work. We aimed at describing the dynamics of an exploited population of Asian elephants in Laos, paying particular attention to the determinants of fecundity. Using population demography modeling, we demonstrate that fecundity is impacted i) by the dynamics of the wild elephant pool through mating of captive females by wild males and ii) by the financial inducement of elephant owners to breed their animal. As a result, we predict that fecundity will raise again gradually in response to the rapid increase in elephants' prices, confirming the hypothesis of elephant owners profit maximization. The captive population will tend towards an asymptotic limit determined by the dynamics of the wild pool. Overall, our bio-economic approach allows producing new ecological-economic equilibria that will serve as a basis for designing recommendations on a sustainable management strategy for the species.

MAINSTREAMING PROTECTED AREA CO-MANAGEMENT IN BANGLADESH: TWO DECADES OF USAID EXPERIENCE

Azharul Mazumder

USAID/Bangladesh

Karl WURSTER, USAID/Bangladesh ; Mary MELNYK, USAID

Natural capital continues to be a major source of wealth and power around the world and evidence of this reality remains compelling in Bangladesh. In Bangladesh, poverty is mainly rural, and mainly among natural resource dependent and landless communities. The important role of biodiversity in the economy of Bangladesh is quite evident and irreplaceable. Sustainable management of the biodiverse natural capital is; therefore, central to poverty reduction. Once endowed with a rich biological patrimony, vast portions of the major ecosystems have now been lost or degraded. With more

than 160 million people, a population growth rate of 1.8%, and a population density of 2,600/mile², the pressure on the nation's natural resources is already tremendous. Regardless of the national economic growth rate, for at least the medium term, the ultra-poor will continue to depend on natural capital, further affecting biodiversity, food security, nutrition and incomes of the poor. The fundamental question of why a country so rich in natural resources finds itself in such a dire ecological situation is, ultimately, a question of policy, governance and capacity. USAID has been playing a pioneering role in addressing these issues. Working for about two decades with the Government of Bangladesh (GOB), USAID helped establish a formally recognized network of terrestrial and aquatic protected areas (PA) that are being co-managed with natural resource dependent communities at the center of a multi-stakeholder process. USAID's efforts aimed at establishing a pragmatic conservation finance mechanism to establish communities' rights to manage the resources and benefit from the revenues. USAID focused on establishing sustainable community organizations to manage the process and deployed a market-driven alternate livelihood strategy for livelihoods improvement. The experience in working with the co-management model for PA co-management, its opportunities and challenges are worth sharing.

HABITAT ASSOCIATIONS DRIVE SPECIES VULNERABILITY TO CLIMATE CHANGE IN BOREAL FOREST

Adriano Mazziotta

University of Jyväskylä, Department of Biological and Environmental Science

Maria TRIVIÑO, University of Jyväskylä, Department of Biological and Environmental Science ; Olli-Pekka TIKKANEN, Finnish Forest Research Institute, Joensuu Unit ; Jari KOUKI, University of Eastern Finland, School of Forest Sciences ; Harri STRANDMAN, University of Eastern Finland, School of Forest Sciences ; Mikko MÖNKKÖNEN, University of Jyväskylä, Department of Biological and Environmental Science

Species climate change vulnerability has been assessed for a limited portion of biodiversity. Our knowledge of climate change impacts is often based only on exposure, even if species sensitivity plays a key role in determining vulnerability. We analyse the role of species habitat associations in explaining vulnerability for two poorly-known but species-rich taxa in boreal forest, saproxylic beetles and fungi, using three IPCC emissions scenarios. We found a habitat quality improvement towards the end of the 21st century associated with an increase of deadwood, an important resource for species, as a consequence of the high tree growth under high emissions scenarios. However, climate change will potentially reduce habitat suitability for ~30-36% of the threatened

deadwood-associated species. This loss is likely caused by the future higher timber extraction and decomposition rates causing higher deadwood turnover which have a strong negative effect on boreal forest biodiversity. A projected high level of spatial turnover in habitat availability will further reduce potential species climatic adaptation. Our results are species and scenario specific. Diversified forest management and restoration ensuring deadwood resources in the landscape would allow the persistence of the species whose capacity of delivering important supporting ecosystem services can be undermined by climate change.

THE EFFECT OF RESOURCE ABUNDANCE AND DISPERSION ON THE RANGING BEHAVIOR OF AFRICAN LIONS (PANTHERA LEO)

Moreangels Mbizah

University of Oxford

Marion VALEIX, University of Oxford ; Andrew LOVERIDGE, University of Oxford ; David MACDONALD, University of Oxford

The range of any animal is associated with the spatial abundance and distribution of limiting resources, and these resources determine the size and utilization of the animal's range. Increases in resource abundance leads to smaller ranging areas, but, when resource availability is heterogeneous, larger areas may be needed to encompass the spatial and temporal variability of these resources. We explored the role of spatial and temporal variation in resource abundance and dispersion in the shaping of African lion home ranges. The Resource Dispersion Hypothesis (RDH) predicts that resource dispersion determines territory size, whereas patch richness independently influences group size. Hwange National Park ecosystem provides an unusual opportunity to test the predictions of the RDH in a system where prey abundance and resource patch dispersion and richness are characterized by high variability and are relatively easy to quantify. A two year detailed data set of both lion seasonal movements and the seasonal variation in abundance and dispersion of their ungulate prey in Hwange National Park, was used to: 1) explore the effects of prey abundance on lion home range size, and 2) explore the effects of resource patch dispersion on lion home range size. Our results showed that lion home range size increased with a decrease in prey abundance and that home range size increased with an increase in resource patch dispersion. This supports the first prediction of RDH that territory size increases, as resource patches are more dispersed in the landscape. Our study therefore demonstrates that landscape ecology is a major driver of ranging behavior in lions. Low prey abundance and more dispersed resource patches can therefore force wide-ranging species (such as lions) beyond current reserve boundaries and into communal areas, which often results in conflict with humans.

THE EFFICACY OF THE ONE PLAN APPROACH TO AFRICAN PENGUIN CONSERVATION

Grainne McCabe

Bristol Zoological Society

Margaret ROESTORF, Southern African Foundation for the Conservation of Coastal Birds ; Richard SHERLEY, Environment and Sustainability Institute, University of Exeter[INSTITUTE] Bristol Zoological Society ; Christoph SCHWITZER, Bristol Zoological Society

The population of African penguins (*Spheniscus demersus*) has seen a rapid and ongoing decline in recent decades, caused by a severe food shortage due to overfishing and to movement of sardine and anchovy stocks away from the penguins' breeding colonies. The Chick Bolstering Project (CBP) was set up by the Bristol Zoological Society and the Southern African Foundation for the Conservation of Coastal Birds (SANCCOB) to investigate the efficacy of using hand-reared penguin chicks, abandoned by their parents in the Western Cape, to bolster declining colonies, as well as to develop the infrastructure and knowledge required to artificially establish new penguin colonies on South Africa's south coast, closer to the current spawning areas of their prey. The CBP has two main aims: addressing the ongoing population decline by reinforcing extant wild colonies with locally hand-reared birds; and investigating the factors that determine breeding site fidelity in African penguins through monitoring translocated birds, thus enabling the artificial establishment of new breeding colonies of African penguins in places more suitable for their long-term survival. The international zoo and aquarium community is contributing technical expertise and practical help with hand-rearing chicks in South Africa, and it is envisaged that the captive populations will eventually contribute to stocking penguin colonies and reinforcing the wild population. We will discuss the success and the challenges of the CBP, an example of the One Plan approach to integrated species conservation promoted by the IUCN SSC Conservation Breeding Specialist Group whereby captive and wild populations are managed as a larger meta-population. This management is guided by one overarching goal, the conservation of the African penguin in its natural habitat.

ESTIMATING POPULATION SIZE AND TREND IN THE THREATENED GREATER SAGE-GROUSE USING N-MIXTURE MODELS

Rebecca Mcaffery

University of Montana

Josh NOWAK, University of Montana ; Paul LUKACS, University of Montana

The greater sage-grouse is a charismatic species of conservation concern in western North America that is

experiencing ongoing population declines due to habitat loss, energy development, disease, and other factors. It is therefore imperative to have robust estimates of population size and trend in this species across its range as part of monitoring, management, and conservation efforts. Greater sage-grouse are typically monitored by conducting counts of males at breeding leks, but the relationship between this index and true population size is unknown. We tested the performance of N-mixture models to evaluate population size, detection probability, and trend in greater sage-grouse using lek count data collected over space and time. We used simulations to test how well the models recovered abundance and growth rate parameters with increasingly sparse survey data. We found that the models recovered parameters for scenarios with both constant and variable detection probability, even with up to 90% of the data missing, where 94% of population growth parameters fell within the 95% credible interval. We then applied the model to 13 years of lek count data from northern Montana, USA. We determined that the population was decreasing by 5% per year on average, and that mean annual detection probability ranged from 0.31 to 0.95. In contrast, regressions of naïve counts over time showed a 6.2% annual decrease in population size. High interannual variability in detection probability demonstrates that naïve counts do not accurately measure interannual variability in population size, and may lead to misleading trends in population size over time. N-mixture models are thus a promising approach for conducting robust analyses of population trends for species that aggregate at discrete breeding sites, even when datasets are sparse or uneven, and can be applied across large areas in a cost-efficient manner.

GENETIC CENSUSING SUGGESTS AN UNEXPECTEDLY LARGE POPULATION OF CHIMPANZEES (*PAN TROGLODYTES SCHWEINFURTHII*) IN A FOREST FRAGMENT CORRIDOR OF WESTERN UGANDA

Maureen Mccarthy

University of Southern California[INSTITUTE]Max Planck Institute for Evolutionary Anthropology

Jack LESTER, Max Planck Institute for Evolutionary Anthropology ; Mimi ARANDJELOVIC, Max Planck Institute for Evolutionary Anthropology ; Eric HOWE, University of St. Andrews ; Craig STANFORD, University of Southern California ; Linda VIGILANT, Max Planck Institute for Evolutionary Anthropology

Many threatened animal populations increasingly inhabit fragmented and degraded forests outside protected areas. Across their range, chimpanzees are often distributed among largely unprotected forest fragments in human-dominated landscapes. In western Uganda, a potential wildlife corridor for chimpanzees and other species has been identified

between the Budongo and Bugoma Forest Reserves, but little is currently known regarding the distributions of unhabituated primate populations in this area. Over a two-year period, we noninvasively collected more than 800 fecal samples for 15 months over more than 600 km², and successfully genotyped 662 (77%) at 14 microsatellite loci. These genotypes were attributed to approximately 200 chimpanzees, with a mean of over 3 captures per individual. Associated estimates of population size more than tripled a previous estimate based on nest count surveys, a result in accordance with the reported tendency of nest counts to underestimate population sizes. The spatial clustering of co-sampled genotypes suggests at least 10 communities in the area, with community sizes varying between a minimum of 5 and 63 individuals. These putative communities are further supported by the geographic distribution of 14 Y-chromosome haplotypes defined by genotyping of 8 Y-chromosome microsatellites. Specifically, haplotypes are often shared by geographically proximate males, while closely related haplotypes typically appear in geographic proximity. These findings illustrate the power of noninvasive genetic censusing to assess the status of elusive primates and demonstrate that, despite habitat fragmentation, a relatively sizeable population of chimpanzees remains widely distributed in this region. Their continued persistence remains uncertain, however, if habitat loss and fragmentation continue unabated.

BIOGEOGRAPHY VERSUS RESOURCE MANAGEMENT: HOW DO THEY COMPARE WHEN PRIORITIZING CONSERVATION OF CORAL REEF FISH DIVERSITY?

Tim Mcclanahan

Wildlife Conservation Society

Diversity is broadly influenced by historical, physical, and geographic factors that are often the basis for global prioritization of conservation investments. However, within-region patterns of diversity are often influenced by a number of site-specific factors including abundance, habitat features, and resource management. Conservation programs often prioritize geography or specific types of management systems or specific management systems within specific geographies. Consequently, in order to better understand the potential of these policies to influence biodiversity, I simultaneously evaluated the variance attributable to within-region geography and fisheries management influences after accounting for local habitat effects using an extensive field sample of common coral reef fishes in the southwest Indian Ocean countries. This evaluation allowed an estimate of the contribution of biogeographic and local-factor variance to evaluate site, geography, and management effects. Local diversity was most strongly predicted by an asymptotic relationship with fish biomass, followed by habitat variables, and lastly by the

geographic positions of latitude and longitude. A diversity center or "hotspot" was found between Madagascar and the African coastline but the geographic variance was low after removing biomass and habitat effects, suggesting a tepid hotspot. Evaluation of diversity among existing fisheries management categories indicated that biomass was the main mechanism for controlling diversity and high compliance closures had 17% more diversity than management systems with few gear restrictions. Nevertheless, variable biomass among resource management categories indicated a high potential for maintaining fish diversity through various restrictions. While the diversity center indicates a potential climate refugia – a priority for regional climate change planning, managing to maintain biomass >600 kg/ha is the highest priority for conserving fish diversity.

MARSH RABBIT MORTALITIES TIE PYTHONS TO THE PRECIPITOUS DECLINE OF MAMMALS IN THE EVERGLADES

Robert McCleery

University of Florida

Adia SOVIE, University of Florida ; Kristen HART, U.S. Geological Survey

To address the ongoing debate over the impact of invasive species on native terrestrial wildlife, we conducted a large-scale experiment to test the hypothesis that invasive Burmese pythons (*Python molurus bivittatus*) were a cause of the precipitous decline of mammals in Everglades National Park (ENP). Evidence linking pythons to mammal declines has been indirect and there are reasons to question whether pythons, or any predator, could have caused the precipitous declines seen across a range of mammalian functional groups. Experimentally manipulating marsh rabbits, we found that pythons accounted for 77% of rabbit mortalities within 9 months of their translocation to ENP and that python predation appeared to preclude the persistence of rabbit populations in ENP. On control sites, outside of the park, no rabbits were killed by pythons and 71% of attributable marsh rabbit mortalities were classified as mammal predations. Burmese pythons pose a serious threat to the faunal communities and ecological functioning of the Greater Everglades Ecosystems that will likely spread as python populations expand their range.

EXTINCTION RISK IN ANIMALS WORTH MORE THAN THEIR WEIGHT IN GOLD

Loren Mcclenachan

Colby College

Nicholas DULVY, Simon Fraser University ; Andrew COOPER, Simon Fraser University

Preventing extinction of animal species hunted for international luxury markets has been one of the most

significant conservation challenges of the past half-century. Many of these species have high intrinsic risk of extinction due to their large body size and low rates of reproduction, and also face elevated risk due to the high value of their non-perishable products, which can be stockpiled for global markets. For a taxonomically diverse group of large-bodied animals traded in international luxury markets, we identify (1) factors associated with elevated extinction risk and (2) differences between marine and terrestrial species that can inform conservation. For both marine and terrestrial animals, we find that threatened species are more valuable across three types of economic value (first sale, mean retail, and maximum potential values) and that penalties for poaching these animals are disproportional to the economic value gained from sale of preserved parts. We find that marine species face an additional management challenge because their ranges span a significantly greater area and more countries than those of terrestrial species, making national and regional conservation less likely to be effective. Finally, we find that unlike for terrestrial species for which large ranges are associated with reduced risk, large range sizes are associated with elevated risk in marine species. Together these results suggest that a more diverse suite of strategies than has been employed for terrestrial species hunted for international luxury markets will be needed to successfully manage marine species.

COMMUNITY BENEFITS OF RESTORING HISTORICAL ECOSYSTEMS AND FISHERIES: ALEWIVES IN MAINE

Loren Mcclenachan
Colby College

Restoration of coastal ecosystems provides opportunities to simultaneously restore historical fisheries and ancillary ecosystem and social benefits that were historically derived from functioning ecosystems. In Maine, dam removal and other ecosystem restoration efforts have positively impacted anadromous fish, with local populations of alewives (*Alosa pseudoharengus*) recovering to near historical population abundances in some locations. This research investigates the social benefits conferred by the restoration of habitat connectivity, fish populations, and local small-scale fisheries. Using municipal fisheries data and interviews with stakeholders in coastal Maine, it describes a suite of both direct and indirect benefits: a reversal of the “shifting baselines syndrome” and a motivation to manage fisheries sustainably, diversification of local economies and fisheries, community building and an increased sense of local pride, a demographic broadening of the conservation community, and enhanced ecosystem services and recreational opportunities. Placing restoration efforts into this larger social and historical context—rather than simply evaluating them based on immediate economic benefits—provides a broader framework to assess overall benefits derived from restoration efforts.

PARTIAL IDENTIFICATION IMPROVES THE CREDIBILITY AND TRANSPARENCY OF CONSERVATION IMPACT

Matthew Mcconnachie

Centre for Invasion Biology, Stellenbosch University
Claudia ROMERO, Department of Biology, University of Florida ; Paul FERRARO, Andrew Young School of Policy Studies, Georgia State University ; Brian VAN WILGEN, Centre for Invasion Biology, Stellenbosch University

Measuring conservation impact is extremely difficult because researchers must measure the difference between the outcome where an intervention occurred and what the outcome would have been without it, called the counterfactual. Because the counterfactual is unobservable, researchers must make an untestable assumption that some untreated units can be used as a surrogate for the counterfactual (aka the control group). The conventional “top-down” approach is to present a point-estimate (i.e. single number estimate) of impact, using for example regression methods. Point-estimates provide powerful conclusions, but in non-experimental contexts depend on strong assumptions about the counterfactual that often lack transparency and credibility. An alternative “bottom-up” approach, called partial identification, is to first estimate what the counterfactual bounds would be if the least possible assumptions were made. After doing this the researcher narrows the bounds by using weak but credible assumptions based on knowledge of why units were selected for treatment and how they might respond to it. We demonstrate this approach by measuring the cost-effectiveness of clearing invasive trees in the Cape Floristic Region by the Working for Water program. We found that our most cost-effective estimate was 2.5-times less cost-effective than what previous studies predicted. Partial identification holds promise for applications in conservation science because: (1) it encourages researchers to identify and account for selection biases; (2) it can be used to test the robustness of conventional point-estimates; (3) it could reduce the problem of advocacy science where researchers “cherry-pick” assumptions that fit the conclusion they desire; (4) where conservation impacts are contentious, it might be easier for stakeholders to agree on bounded-estimates than a point-estimate; (5) it only requires knowledge of basic arithmetic.

MOLECULAR IDENTIFICATION OF THE WOOD THRUSH DIET AND VALIDATION OF A PROTOCOL FOR STUDIES OF AVIAN DIETS

Dana Nicole Mccoskey
George Mason University

Rebecca FORKNER, *George Mason University*; Masoumeh SIKAROODI, *George Mason University*; Patrick M. GILLEVET, *George Mason University*

DNA barcoding markers and next-generation sequencing (NGS) show great promise in applications to food web studies. By extracting mixed community DNA from an animal's scat or stomach contents and then using polymerase chain reaction (PCR) and NGS with public reference databases, this method can identify prey species DNA while overcoming limitations of traditional foraging studies. For example, field observations are both time and labor intensive and biased by the detectability of focal species. Likewise, scat and stomach content analyses are labor intensive, require expert knowledge of prey morphology, and can be biased by differences in digestibility of prey. We tested the efficacy of these methods to quantify diet diversity and breadth for a declining neotropical migratory bird, the wood thrush (*Hylocichla mustelina*). We compare species detected in partially digested remains to those found with an NGS molecular method. We then compare molecular results from scat samples and stomach contents from the same individuals, to determine how much information is lost during digestion. The success of this approach strongly depends on data generated by universal molecular markers, the processing of samples, and if information is lost during digestion. Our data help to validate a low impact molecular method that will improve our understanding the wood thrush's niche and which can be applied to studies of other bird species.

ERADICATION OF INVASIVE MAMMALS ON ISLANDS COULD PREVENT 40% OF ISLAND VERTEBRATE EXTIRPATIONS GLOBALLY

Erin McCreless

University of California Santa Cruz
David HUFF, *NOAA Southwest Fisheries Science Center*; Donald CROLL, *University of California Santa Cruz*; Bernie TERSHY, *University of California Santa Cruz*; Dena SPATZ, *University of California Santa Cruz*; Nick HOLMES, *Island Conservation*; Stuart BUTCHART, *BirdLife International*; Chris WILCOX, *CSIRO Marine and Atmospheric Science*

Introduced human-commensal mammals pose severe and ongoing threats to global island biodiversity. However, the relative severity of threats from different mammals, and the influence of island geomorphological and climatic attributes on native-invasive interactions, remain unknown. These knowledge gaps hinder our ability to identify and protect island populations and species facing imminent threat of extirpation or extinction due to invasive mammal impacts. We used the first comprehensive global dataset of threatened island vertebrates and invasive mammals to characterize global island extirpation patterns for threatened and extinct island vertebrates. Most variability in extirpations was explained by a

logistic regression model with covariates that included native taxonomy, island size and precipitation, and the presence of human populations, invasive rats, cats, pigs, mustelids, and mongooses. Our model predicts that under current conditions, 45% of extant globally threatened vertebrate populations will be extirpated from their breeding islands. The group most at risk is volant birds, with extirpation predicted for 67% of populations, followed by non-volant mammals (44%), amphibians (43%), bats (34%), reptiles (21%), and flightless birds (17%). However, the control or eradication of invasive mammals (i.e. rats, cats, pigs, mustelids, and mongooses) on these islands would prevent 40-75% of these extirpations. Global island conservation efforts should therefore include focused research on improving control and eradication methods for these species, particularly on large and inhabited islands that pose unique technical and social challenges to eradication efforts. Our analysis strengthens conservation prioritization efforts by providing robust, quantitative estimates of the benefits of invasive mammal removal.

STRATEGIC PRIORITIZATION OF ISLANDS FOR INVASIVE MAMMAL ERADICATIONS TO PROTECT GLOBALLY THREATENED VERTEBRATES

Erin McCreless

University of California Santa Cruz
Donald CROLL, *University of California Santa Cruz*; Bernie TERSHY, *University of California Santa Cruz*; Dena SPATZ, *University of California Santa Cruz*; Nick HOLMES, *Island Conservation*; Stuart BUTCHART, *BirdLife International*; Chris WILCOX, *CSIRO Marine and Atmospheric Science*

Islands are crucial to the conservation of biodiversity. A leading threat to island species is invasive mammals, and invasive mammal eradication is a powerful tool for protecting island species and ecosystems. However, the global scope of mammal invasions greatly outweighs resources available for eradications. Eradication efforts therefore must be prioritized. We quantified the benefits and costs of eradications on islands globally, and implemented an optimization model to identify the most cost-effective sets of islands for eradications. Specifically, we estimated the extinction risk caused by invasive mammals to each IUCN-listed Critically Endangered and Endangered terrestrial vertebrate species. We then identified sets of islands on which invasive mammal eradication would achieve a series of increasingly ambitious conservation thresholds, in terms of the number of island populations of each threatened species, for the minimum cost. Our results indicated that eradications on 135 islands would lead to substantial reductions in extinction risk for 132 of the most threatened island species globally. This approach builds on previous island prioritization efforts by: 1) explicitly, quantitatively evaluating biodiversity benefits, 2) integrating robust benefit and cost estimates across islands to identify

cost-efficient islands for eradication, and 3) treating the island prioritization problem systematically by considering islands as sets rather than as individual, independent entities. In addition to identifying sets of high-priority islands that should be a focus for global eradication efforts, our study illustrates a flexible approach to conservation prioritization that can be easily adapted to other conservation decision-making situations. This type of strategic return-on-investment approach is critical for achieving the greatest possible conservation gains in a world of limited resources.

THE INFLUENCE OF SCALE ON DELINEATING REGIONAL FLOW PATTERNS FOR RESILIENT LANDSCAPES

Jane Mccurdy

Dalhousie University

Karen Beazley, Dalhousie University

Delineating regional flow patterns is critical to identifying directional movements and areas where species are likely to become concentrated, diffused, or rerouted due to the structure of the landscape at large scales. We assessed the influence of scale on delineating regional flow patterns for resilient landscapes. Both the pixel resolution of the input data and size of the calculation area were assessed using four combinations of scale-analyses. Two scales (270 m and 100 m cells) of resistance surfaces were created as a representation of landscape permeability to species movement using land-cover and road data. Two different sized (400 km and 40 km) calculation units were established. The two resistance surfaces were analyzed with each of the calculation areas using Circuitscape. Current was passed across the two resistance surfaces within each calculation area, in four directions. The current maps for each of the four analyses were then mosaicked together to create four omnidirectional connectivity maps. The final output maps were first evaluated by comparing their similarities and differences. Overlaying a protected areas layer in order to simulate known populated and, likely, high-traffic areas assisted with the assessment of the maps perceived level of accuracy. The advantages and disadvantages offered by each output scale-analysis surface were evaluated and weighed. The results indicate that in lieu of increased processing time, finer-scaled land-cover data and resistance surfaces are preferable over more generalized data that can exclude important landscape details. Complications associated with connectivity mosaics created using the tiling method reveal that the use of a larger-scaled calculation area is more likely to enhance the seamlessness of regional scale connectivity modeling.

118 A CONCEPTUAL FRAMEWORK FOR UNDERSTANDING THE INTER-RELATIONSHIP OF EQUITY, POVERTY AND WELL-BEING

Constance Mcdermott

University of Oxford

Melanie MCDERMOTT, Rutgers University ; Sango MAHANTY, Australian National University ; Schreckenberg KATE, Southampton University

This presentation explores the use of an Equity Framework as an overarching conceptual tool for understanding how conservation efforts impact poverty and well-being at multiple scales and among diverse actors. The framework first distinguishes among three dimensions of equity that shape its content or definition. These are 1) distributive, referring to the distribution of material benefits; 2) procedural, referring to equity of decision-making; 3) contextual, referring to the pre-existing conditions that limit or facilitate people's access to decision-making procedures, resources and benefits. The framework then considers three overarching parameters that determine the scope and scale to which conceptions of equity are applied, including 1) the scale and target group of concern (i.e. who is considered a subject of equity), 2) the framing of goals with respect to equity (i.e. whether equity is a goal and to what extent), and, finally, 3) how decisions are made about the content, target and goals of equity. We argue that such an overarching framework is important for situating "poverty" and "well-being" within a broader social landscape involving complex trade offs across actors, objectives and scales.

WHAT THE MATRIARCHS OF THE SEA TAUGHT THEIR DAUGHTERS: JAPANESE AMA DIVERS TRADITIONAL APPROACHES TO MARINE MANAGEMENT AND CONSERVATION

Anne Mcdonald

Sophia University

Nobuyuki YAGI, University of Tokyo

Hereditary fishing rights and community-based management are integral to resource use and social structure of all fishing communities in Japan. Most are patriarchal, but among the female ama diver communities these rights have matriarchal foundations. Harvesting seasons, grounds and species are all determined by fishing rights. Decisions to modify current rules that guide harvesting activities and other resource management decisions, such as enforcing no-take zones in their communal harvesting grounds, are discussed and decided by the collective whole. Community-level collective structures regulate the use of the commonly owned coastal resources. An example is the collective decision to designate no-take zones and the mechanisms such as financial penalties and ostracism, to protect these collectively managed protected areas. Another

examples to explore in their resource management approaches are the decisions to adopt or reject newly introduced technologies - from adopting goggles and the wet suit, to the rejection of scuba tank diving technology. Cultural identity and a non-utilitarian view of their ecosystem were considered in collective deliberations, and took precedence over short-term gains in time or financial efficacy. Such decisions, it may be argued, have led to better outcomes socially and environmentally. This community's path to reconcile tradition and modernity may potentially be an insightful example that compels more research on the use of cultural identity and traditional knowledge for sustainability in a modern context. This paper will explore traditional knowledge and how it is applied to resource use and management through the lens of matriarchal hereditary rights based fisher communities in Japan to try and gain further insight on female approaches to marine resource management and conservation, nature views and technological innovation.

AN ADAPTIVE ASSESSMENT AND MANAGEMENT TOOLKIT FOR DATA-LIMITED FISHERIES WITH A CASE STUDY FROM KARIMUNJAWA NATIONAL PARK, INDONESIA

Gavin Mcdonald

Sustainable Fisheries Group, UCSB
Stuart CAMPBELL, *Wildlife Conservation Society*; Helen FOX, *Rare*; Raymond JAKUB, *Rare*; Kendra KARR, *Environmental Defense Fund*; Tasrif KARTAWIJAYA, *Wildlife Conservation Society*; Janelle MUELLER, *Rare*; Katherine SIEGEL, *Sustainable Fisheries Group, UCSB*; Lennon THOMAS, *Sustainable Fisheries Group, UCSB*

Data-limited fisheries often go unmanaged or are managed with little or no scientific guidance. This often results in poor fisheries performance and a failure to achieve stakeholder goals. There are an increasing number of data-limited assessment and management approaches being introduced in the literature. However, there are relatively few user-friendly resources at the disposal of fisheries managers who need practical tools to help make on-the-ground decisions. We present an adaptive assessment and management toolkit designed to fill this gap. The toolkit is a step-by-step guide designed to help managers and stakeholders implement an adaptive assessment and management framework appropriate for their goals and available data. Managers and key stakeholders use the toolkit on a periodic adaptive cycle during which they: 1) determine the assessment and management tier that their fishery falls under based on data availability; 2) determine appropriate fisheries management control(s); 3) select multiple data-limited performance indicators and reference points appropriate for the available data and stakeholder goals; 4) define harvest control rules

that will adjust fisheries management controls according to performance indicators; 5) perform the appropriate data-limited assessment methods for their fishery; 6) interpret the assessment results alongside local ecological knowledge to determine if a management response is necessary; and 7) adjust fisheries management controls accordingly using pre-defined harvest control rules. The toolkit is designed to be user-friendly and only requires that users have a general fisheries background and a familiarity with Microsoft Excel. We present a case study from Karimunjawa National Park, Indonesia where the toolkit is being used to inform their fisheries assessment and management process.

185 - USING FOOD WEB THEORY TO CONSERVE ECOSYSTEMS

Eve Mcdonald-Madden

University of Queensland
Regis SABBADIN, French National Institute for Agricultural Research; *Edward GAME, The Nature Conservancy*; *Peter BAXTER, Queensland University of Technology*; *Iadine CHADES, CSIRO*; *Hugh POSSINGHAM, University of Queensland*

Food web theory has the potential to guide the management of ecosystems. However, species importance in a food web, based on Jenga[®]-style species removal, is not necessarily akin to a species management priority. We show that management prioritized based on indices of species importance that are commonly used in food web and network theory can be a poor guide to ecosystem management, resulting in significantly more extinctions than necessary. We demonstrate this by using Artificial Intelligence techniques to deriving optimal management strategies for six real and 40 hypothetical food webs. While no single index provides an appropriate guide to management for all food webs, a modified version of Google's PageRank[™] algorithm reliably minimizes the chance and severity of negative outcomes. Our analysis shows that by prioritizing ecosystem management based on the network wide impact of species protection rather than species loss, we can substantially improve ecosystem management decisions and outcomes.

185 AVOIDING PERVERSE OUTCOMES FROM SPECIES INTRODUCTIONS: ECOSYSTEM-WIDE MODELLING AT BOODEREE NATIONAL PARK

Eve Mcdonald-Madden

Australian National University ; Sean MAXWELL, The University of Queensland ; Michael BODE, The University of Melbourne

Translocations are a critical and increasingly used part of the conservation toolkit. However, they must proceed with care because each introduction will have impacts on other species in the recipient ecosystem, and there is growing evidence that translocations can have unanticipated outcomes that arise from ecosystem-level interactions. For example, the re-establishment of wolves in Yellowstone National Park, had dramatic and unexpected indirect impacts on vegetation and water flow via the wolves' predation on Elk. Predicting these ecosystem-level outcomes is notoriously difficult because they depend on a very accurate and quantitative understanding of the ecosystem dynamics. Here, we present a novel modelling approach where we use generalised Lotka-Volterra equations to model the uncertain, coupled dynamics of a large group of species. We use these methods to systematically explore the possible outcomes of reintroductions in Australia's Booderee National Park, an iconic protected area that supports key populations of endangered species. The park has previously experienced unexpected outcomes of management actions – most notably, a feral fox control program resulted in the local extinction of an arboreal mammal, the greater glider. The large number of parameters in our model (over 400) makes direct experimental parameter estimation impossible. Instead we use a 'backcasting' method, where we generate candidate parameter values at random and accept only those which re-create a set of past ecosystem dynamics observed at Booderee. Using the acceptable parameter sets allows us to scope out possible outcomes from different species re-introductions. Between 1998 and 2005 there was a two-fold increase in the number of global conservation translocations, and our project offers the first ecosystem-wide risk assessment approach for informing such decisions.

3.10 COMPARISON OF CARBON SEQUESTRATION METHODOLOGIES FOR USE BY ACADEMIC INSTITUTIONS IN TEXAS

Christina Mcglew

St. Edward's University

Suzanne GAMBOA, St. Edward's University ; Erica JOELSON, St. Edward's University ; Gwendolyn BAILEY, St. Edward's University ; Thomas LAPOINT, St. Edward's University ; Michael WASSERMAN, St. Edward's University ; Amy BELAIRE, St. Edward's University

As natural areas continue to be converted for anthropogenic use, it is important to quantify the loss of ecosystem services. Until recently, the study of these services in urban areas has been limited. Specifically, carbon sequestration is critical to climate regulation and universities have shown increased interest in obtaining carbon credits in order to compensate for

their carbon emissions, which ensures protection of natural areas owned by universities through economic benefits. For this process to be effective, appropriate methodology must be readily accessible to universities. Therefore, our objectives were: 1) to compare two sets of methodology for quantifying carbon sequestration and carbon credits based upon ease of use, cost, time requirement, and accuracy: data provided by remote Lidar technology and field measurements incorporated into iTree software, and 2) to provide recommendations to other Texas universities to increase the use of benefits of ecosystem services, such as carbon sequestration, to promote biodiversity protection on land owned by academic institutions. We quantified carbon sequestration for St. Edward's University at Wild Basin Wilderness Preserve in Austin, Texas. Using 30 plots across the preserve we measured for diversity, DBH, and for soil C analysis. These data were then entered into iTree for an estimate of carbon sequestration. These field-based estimates were compared to estimates provided by remote Lidar data. Results indicated that across 12 universities in Texas, only two currently preserve property to offset their carbon emissions with carbon credits. Access to and promotion of effective carbon sequestration methodology to universities has potential for conserving local biodiversity in Texas. By improving access to these methodologies, more universities will choose to conserve and restore existing undeveloped land, which will protect urban biodiversity and enhance the health and well-being of students and city residents.

SEA SHARING OR SPARING: SHOULD WE FOCUS ON MORE HABITAT PROTECTION OR NO-TAKE MARINE AREAS?

Jennifer McGowan

The University of Queensland

Michael BODE, The University of Queensland ; Maria BEGER, The University of Queensland ; Katrina DAVIS, University of Western Australia ; Sylvaine GIAKOUMLI, The University of Queensland ; Nils KRUECK, The University of Queensland ; Tessa MAZOR, CSIRO ; Katherine YATES, Flinders University ; Hugh P POSSINGHAM, The University of Queensland

Unsustainable exploitation of the oceans has led to widespread degradation of marine ecosystems. To maintain the primary benefits humans derive from the sea, namely food supply and biodiversity that generates other ecosystem services, the ocean is divided into three general management regimes: open-access, managed, and reserved areas. Using a theoretical example of a fish stock that depends on habitat type, we explore the conditions by which it is better to spare the sea, by investing more in marine reserves or to share the sea by investing in management to maintain habitat quality. We model the fraction of the seascape in each management regime given a fixed budget and a minimum food supply. Our objective is to create a plausible model with a simple analytic

answer for the purpose of guiding broad policy options. We explored the range of parameters where marine reserves are favored over managed areas and vice versa. The relative costs of reserves vs. management, the growth rate of the fish population, effectiveness of habitat protection and the amount of self-recruitment all influence this decision. Preliminary results suggest that intermediate levels of self-recruitment favor a mixed strategy of both reserves and managed areas. When the cost of reserving area increases in relation to managing for habitat loss, we prefer a management regime that protects habitat. We are working on a simple rule of thumb that determines the optimal management strategy given our constraints.

COMBINED USE OF POINT COUNTS AND AUTOMATED RECORDERS TO MONITOR AVIAN DIVERSITY AND PHENOLOGY ALONG A MONTANE MEGA-TRANSECT

Michael Mcgrann

William Jessup University

Brett FURNAS, California Department of Fish and Wildlife

Climate change is expected to disrupt the distribution and phenology of birds. By providing access to remote areas, hiking trail networks provide an opportunity to efficiently monitor the effects of climate change on avian diversity along elevation gradients. We evaluated the combined use of point counts and automated recorders along a 697-km segment of the Pacific Crest Trail (PCT) in northern California, USA, to inventory species occurrences and breeding phenology of montane avian communities. We conducted 5-minute point counts of birds at 404 sites along the trail on 2 mornings, 4 days apart. At approximately half the sites, we left automated recorders to make 5-minute recordings (for later interpretation of bird sounds) for 3 times each morning, repeated over 3 consecutive days. Using a multi-species occupancy model of the detection/non-detection data, we found that species richness exhibited a unimodal distribution, peaking at an elevation of 1142 m [90%CI: 1000-1280 m]. We assumed that detection probability was an indicator of singing/breeding phenology and found that average detection probability among 6 warbler (Parulidae) species was greatest on 12 June [90%CI: 9-14 June]. The precision of our species richness and detection probability estimates was greatly improved by the automated recorders for little additional cost. Furthermore, the elevation at which species richness was greatest was lower than what we would have found if we had just conducted point counts, which we attribute to temporal differences in detection probability with elevation. A power analysis ($\alpha=0.1$, $\beta=0.2$) suggests that repetition of these surveys annually should be sufficient to observe an average climate-change-induced advancement of the singing phenology of warblers of 5 days over 20 years. Expansion of surveys to a mega-transect along the entire PCT

from Mexico to Canada would allow conservation planners to monitor regional climate-change effects throughout the Pacific Cordillera.

GRASPING ALBATROSS DIET WITHOUT GRASPING ALBATROSS: A NON-INVASIVE DNA DIET ANALYSIS METHOD TO ENCOMPASS THE WHOLE DIET.

Julie Mcinnes

University of Tasmania

Rachael ALDERMAN, Tasmanian Department of Primary Industries, Parks, Water and Environment ; Mary-Anne LEA, University of Tasmania ; Simon JARMAN, Australian Antarctic Division

Albatross are one of the most threatened seabird groups, yet diet information fundamental to their management is absent for many species. One reason for the paucity of diet data is the invasive nature of current dietary analysis techniques, such as stomach flushing, induced chick regurgitation or blood sampling. DNA-based dietary analysis, which identifies prey DNA sequences, is proving to be a highly effective, alternative analytical approach for many seabird species. The aim of our research is to develop the dietary analysis of scat DNA into a powerful, non-invasive ecosystem-scale monitoring tool for seabird populations worldwide. Shy albatross (*Thalassarche cauta*) scats were collected from Albatross Island in NW Tasmania, Australia, during the austral summer 2014/15. We tested two PCR-based DNA analysis approaches on these samples: 1. Analysis with 'Universal' primers that amplify from any eukaryote, but only identify prey to family or higher level; and 2. A range of taxon-specific PCR primer sets that identify prey to species level, but can only identify prey within one pre-defined group. We identified the strengths and weaknesses of each PCR approach. The diet preferences of shy albatross were ascertained from the scat samples without any handling, making this dietary technique ideal for threatened species where minimising disturbance is critical. By using method one we were able to identify all prey groups, including soft-bodied organisms (e.g. jellyfish), that are rarely detected using other methods. The second approach had a more narrow focus, but gave valuable species information and identified potential foraging overlaps with fisheries. If possible, incorporating both methods into a study provides the best overall dietary information. Understanding seabird dietary needs will further define ecosystem linkages, permitting the institution of improved management and conservation programs.

EVALUATING CONSERVATION PLANNING SUCCESS: ADDRESSING THE SOCIETAL AND GOVERNANCE FACTORS BEHIND EFFECTIVE CONSERVATION ACTIONS

Emma Mcintosh

University of Oxford

Systematic conservation planning (SCP) is continuing to gain popularity with conservation scientists and policy makers worldwide. This is partly due to the suitability of this approach for providing transparency in value-laden decision making and in assisting to bridging the 'knowledge-implementation divide'. Despite this, several retrospective analyses have suggested conservation plans can easily slip back into academic pursuits rather than practical tools. Regional evaluations are starting to be produced, including several examinations of how effectively specific conservation planning initiatives have influenced decisions around the implementation of related policies. However, what is lacking is a global assessment of 'what works' in translating complex conservation plans into on ground action. Several decades on from the widespread application of systematic approaches to designing protected area networks, is it possible to tell how well those networks are helping to meet the conservation goals they were initially intended to achieve? The societal and governance factors behind effective (and ineffective) conservation planning initiatives remain particularly poorly understood. What is the relative importance of, for example, strong stakeholder engagement versus robust scientific information in the planning phase? A global dataset of protected area planning exercises will be discussed, including material not previously published in the peer reviewed scientific literature. I will present a meta-analysis of SCP effectiveness, focusing in particular on socio-political markers of long term effectiveness, and discuss trends and common factors between plans.

TOWARD A HUNTING FOOTPRINT: REGIONAL PATTERNS OF WILD GAME DEPLETION AND DEPENDENCE IN EASTERN AND SOUTHERN AFRICA

Alex McInturff

University of California Berkeley

Justin BRASHARES, University of California Berkeley; Tristan NUNEZ, University of California Berkeley; Kaitlyn GAYNOR, University of California Berkeley; Briana ABRAHMS, University of California Berkeley; Lauren WITHEY, University of California Berkeley; Kathryn FIORELLA, University of California Berkeley; Ryan MARSH, University of California Berkeley; Katherine SETO, University of California Berkeley

The consumption of wild game, or "bushmeat," has received heightened attention in the past decade, both as a major threat to biodiversity conservation and as a critical resource for human nutrition and income. As human population growth and expanding infrastructure have increased access to dwindling game habitats, many conservationists have assented that we are in the midst of a "bushmeat crisis" that threatens both wildlife species and the communities that rely

on them. Many studies have explored patterns of hunting surrounding individual human settlements, but the social and ecological forces that ultimately drive the dynamics of game utilization and species extirpation operate at large spatial scales. At these scales, our understanding of patterns of wild game harvest remains glaringly incomplete. Here we present a first-of-its-kind, spatially explicit model estimating hunting offtake in Eastern and Southern Africa, a region where game species declines have been pronounced and where many communities rely heavily on game resources. We completed an extensive literature review to select and weight socioeconomic data – including human population density, poverty level, and livestock density – to estimate potential reliance on wild game across space. We combine this assessment with environmental factors – land cover and a novel model of ungulate biomass – to identify areas where both wildlife and human livelihoods are at risk due to dependence on wild game. A spatial representation of hunting across this region will facilitate effective conservation efforts at a scale fitting the drivers of species decline and help identify communities most vulnerable to the loss of this resource.

191: MARKETING MPAS: LESSONS FROM THE LAND?

Emma Mckinley

University of Chichester

Marine and coastal policy has undergone considerable change in recent years, with increasing emphasis placed on the importance of engaging the public in protecting and managing the use of marine resources. In response to this, Marine Protected Areas have secured their place as an important mechanism for conserving and managing marine ecosystems across the globe. However, the relationship between society and their surrounding environment is complex. Therefore, in order to be successful, MPA planners and managers must not only evaluate their impact on the environment, biodiversity, socio-economics and culture of communities. They must also have an understanding of the public response and sense of public buy in relating to the implementation of MPAs. In comparison to terrestrial protected areas, such as National Parks, MPAs are relatively new as a widespread designation and management strategy, and remain something of an unknown entity. Historically, terrestrial protected areas have succeeded in engendering a strong sense of connection and responsibility amongst society, supported by strong messages of public wellbeing and conservation value. While the contemporary objectives of terrestrial protected areas, to support sustainable tourism and business, balanced with the environmental and socio-economic needs of the local community, may not match exactly to those of MPAs, their use of easily recognisable branding and marketing provides audiences with a focal point, and attracts people to these

protected sites in support of the efforts to conserve. This paper reviews existing literature on branding, marketing and promotion of terrestrial protected areas, identifying success stories which can be used to highlight lessons and best practice that can be applied to the on-going efforts to implement a coherent network of marine protected areas, both in the UK and on a global scale.

PENN STATE CHANCE: IMPACTING STUDENT LEARNING, ATTITUDES, BEHAVIORS, AND CAREER CHOICES THROUGH REAL-WORLD CONSERVATION EXPERIENCES

Jacqueline McLaughlin
Pennsylvania State University

We are drowning in information, while starving for wisdom. The world henceforth will be run by synthesizers, people able to put together the right information at the right time, think critically about it, and make important choices wisely. Edward O. Wilson Today humanity faces this reality - the environment is broken on local, state (provincial), national, and global scales most of which is a result of human impact on natural resources and ecosystems. CHANCE (Connecting Humans And Nature through Conservation Experiences) is an environmental education, professional development and outreach program, whose overarching goal is to teach conservation (the science and practice of conserving the Earth's biological diversity) and global sustainability (the pursuit of social, environmental, and economical balance) at the front line. To do this, CHANCE creates unique learning environments which immerse its participants, students and science teachers, in nature. Participants work online or directly in the field with scientists to EXPLORE species diversity, RESEARCH ecology, and CONSERVE the biological structure of select and threatened ecosystems around the world. The ultimate goal: to prepare global minded citizens, who can analyze, create and implement solutions to maintain biological diversity, and as such, face the challenges of our time such as energy clean air, water quality, food, and climate change. CHANCE's work in Central America and China with several of its key partners exemplifies how innovative, interdisciplinary, and informal (outdoor and international) teaching and learning strategies can effectively teach sustainability while impacting student learning, attitudes, behaviors, and career choices.

DISENTANGLING SAMPLE SIZE AND GEOGRAPHIC EXTENT WHEN MODELING SPECIES DISTRIBUTIONS: A CASE STUDY FROM GUYANA, SOUTH AMERICA

Tsitsi Mcpherson
State University of New York at Oneonta (SUNY Oneonta)

Species distribution modeling (SDM) continues to gain prominence as a tool to facilitate biodiversity conservation. In SDMs, specimen (point) data from museums and herbaria are used in conjunction with environmental data to project current and future species distributions. Model output can then be used to propose various conservation measures. Model uncertainty is dependent on sample size or number of specimens per species and how well those samples capture the environmental preferences of the species. The minimum number of specimens per species used in SDM often ranges from 25 to 50. However, for many species, especially in tropical locations, the number of specimens in collections is significantly less than 25. If the aim of conservation is to protect the rarest species we must ask how effective conservation measures are at capturing critical sites for rare species. Using Guyana, South America, as a case study, species distributions for seven taxon groups were modeled using MaxEnt, a machine-learning SDM method frequently used for specimen data. Model output for species represented by 5-20 specimens are compared with those for species with >50 specimens. Due to issues of location bias, model output for species represented by >5 distinct locations, based on the analysis grid, are also evaluated. Results show that the number of grid cells the species are represented in is more influential to model output than the number of specimens per species. While the size of the analysis grid should reflect the spatial extent of the rarest species, obtaining compatible environmental data may be problematic.

101 BAT CAVES AS RESERVOIRS OF BIODIVERSITY AND PROVIDERS OF ECOSYSTEM SERVICES

Rodrigo Medellín
Institute of Ecology, UNAM
Laura LOPEZ-HOFFMAN, University of Arizona

Cave ecosystems are grossly underrepresented in conservation planning and implementation around the world. This has become one of the great flaws of conservation. Caves contain great levels of biodiversity – from fungi to invertebrates to vertebrates. Caves also harbor a remarkable degree of microendemism, primarily of invertebrates, but also fish and fungi. In addition, caves often serve as roosts to some of the largest concentrations of warm-blooded animals on earth, bats. Finally, caves act as direct routes to aquifers and groundwater resources. As such, caves provide extremely important ecosystem services to vast areas surrounding them; their influence extends three-dimensionally via subterranean water bodies and the aerial nightly dispersal of the bats. Bats, in turn, provide a host of services from seed dispersal to pollination to pest control, while the nutrients they bring back into the cave fuel the entire cave ecosystem. In a further service to humans, bats create guano, one of

the richest organic fertilizers in the world. Many caves are extremely attractive as ecotourism destinations and provide unique opportunities to educate the public about unexpected biodiversity values and ecosystem services. Many caves have been severely impacted by human activities triggering declines in bat populations and overall cave biodiversity. The main threats to caves include vandalism, solid waste, and misunderstood tourist use. While many caves have been affected beyond repair, conservation measures such as education, land acquisition, and legal protection have proven effective tools. It is time to call the attention of authorities and the public about the urgent need to launch a worldwide cave conservation initiative

CONSERVATION AND MANAGEMENT OF CALIFORNIA'S CHINOOK SALMON: USING GENOMICS TO DEFINE POPULATIONS AND IDENTIFY INDIVIDUALS

Mariah Meek

Cornell University

Melinda BAERWALD, University of California, Davis ; Molly STEPHENS, University of California, Davis ; Alisha GOODBLA, University of California, Davis ; Michael MILLER, University of California, Davis ; Katharine TOMALTY, University of California, Davis ; Bernie MAY, University of California, Davis

Most populations of California's Central Valley Chinook salmon (*Oncorhynchus tshawytscha*) are listed as federally threatened or endangered under the U.S. Endangered Species Act due to a variety of stressors: harvest, habitat alteration, dam construction, and hatchery influence. Our limited understanding of the current genetic structure of these populations hinders our ability to accurately assign individuals back to their natal populations for monitoring and research purposes. This is particularly problematic given the different listing statuses among seasonal runs (Winter, Spring, Fall, and Late-fall). Newly developed genomic tools allow us to better assess the genetic diversity of non-model organisms and the factors driving population differentiation by sampling across the genome and examining signatures of selection. We use restriction site associated DNA sequencing (RAD-seq) technology to discover over 20,000 new Single Nucleotide Polymorphism (SNP) markers distributed throughout the Chinook salmon genome and constructed a high density SNP linkage map. We found fine-scale population structuring in the Central Valley, and discovered a panel of markers that accurately identifies unknown individuals to run. We interpret these results in the face of current Chinook salmon conservation and restoration efforts being implemented in the Central Valley of California.

HABITAT QUALITY IS A KEY FACTOR TO MAINTAIN FARMLAND BIODIVERSITY

Kim Meichtry

Swiss Ornithological Institute

Simon BIRNER, Swiss Ornithological Institute ; Markus JENNY, Swiss Ornithological Institute

In the last decade many European countries developed agri-environment schemes AES with the aim to halt and reverse the loss of biodiversity. In Switzerland farmers have to implement ecological compensation areas (ECAs) as part of the Swiss AES, like extensively managed meadows of low or high quality, litter meadows, wildflower strips, hedgerows, high-stem trees and orchards and so on. However, positive effects of ECAs on species richness and abundance at landscape level have been rather moderate so far. In our opinion this is due to the low ecological quality of most ECA options. We reveal in three different studies that farmland bird species and brown hare do benefit from ECAs, if they are of high ecological quality and quantity. All three studies were conducted in ecologically highly improved regions owing to extensive advisory support of farmers. The first study was done in the mainly arable farmed Klettgau and shows that the densities of six out of 10 studied species were positively related to the amount of high-quality ECAs (wildflower areas and high-quality meadows). The second study was conducted in a part of the grassland dominated Rhine valley. There the brown hare seems to favour high-quality meadows in early-spring nights, when he is foraging and mating. In the third study, five out of six studied farmland bird species preferred habitat of high quality in the mainly arable farmed champagne genevoise. Compared to other habitat types, the proportion of fallow land and of the ECA option "wildflower strip" was significantly higher in the territories than in the entire region. Our results point out the importance of habitat quality for farmland birds and brown hare in Switzerland. However, high-quality options currently compose only a small proportion of the ECAs in the Swiss lowland. The Swiss AES and its options have to be tailored towards a far higher amount of high-quality ECAs in order to halt the loss of most farmland species of conservation concern.

INTEGRATING POTENTIAL FOR MICROREFUGIA IN PROJECTIONS OF CURRENT AND FUTURE SPECIES DISTRIBUTIONS OVER LARGE GEOGRAPHIC EXTENT

Eric Meineri

Stockholm University

Kristoffer HYLANDER, Stockholm University

Microrefugia are small areas with favourable environment in which populations can survive outside their main distribution area. Microrefugia are mainly caused by topographic variations as microclimate is driven by several climate forcing factors such as elevation, insolation, distance to sea and

major water bodies, soil moisture and relative elevation. Many review papers have stressed the importance of microrefugia for assessing climate change impact on potential species loss. However this recommendation has only been followed by a few studies. These studies i) often use downscaled climate grids that rely on elevation only to predict current species distributions and future species loss and ii) focus on rather small geographic extent. We aim to bridge these two gaps. First, we used a regression approach to produce national scale (Sweden) 50m grained microclimatic grids accounting for the known effects of topography (topogrid). Using these topogrids, we will project fine scale distribution of northern plant species and assess potential future species loss in Sweden. These species distribution models (SDM) will account for potential microrefugia since they will be fitted using fine scale climatic grids accounting for most topographic effects described in the literature. For comparison, we will also repeat the analyses using microclimatic grids based on geostatistic and elevation (elevgrid), as commonly done in the literature. All models are validated using external datasets. The preliminary results show that the two climate downscaling approaches produced good microclimatic grids. However, the topogrids (validation R^2 : 0.85 to 0.95) outperformed the elevgrids (validation R^2 : 0.75 to 85). Thus, we expect to obtain better SDMs using the topogrids than the elevgrids. We also expect that the SDMs based on the topogrids will predict lower species loss for the coming years because of better capturing potential microrefugia than the elevgrids.

A NEGLECTED OPPORTUNITY FOR BIRD CONSERVATION: THE VALUE OF A PERENNIAL, SEMIARID AGROECOSYSTEM IN MEXICO'S CENTRAL PLATEAU

Eric Mellink

Centro de investigación Científica y de Educación Superior de Ensenada, B.C.

Mónica RIOJAS-LÓPEZ, CUCBA, Universidad de Guadalajara ; Patrick GIRAUDOUX, Université de Franche-Comté/CNRS et Institut Universitaire de France

As elsewhere in the world, the semi-arid regions of the southern part of Mexico's central plateau have been heavily transformed due to agriculture and grazing. No protected areas exist here, and setting aside large tracks of natural vegetation for conservation is unfeasible. Hence, other conservation strategies must be employed. Perennial, low-input, dry-farmed agroecosystems, especially those focused on fruit production, offer an important opportunity for this. In the region, nopal (*Opuntia* spp.) orchards are widely present, and are economically and culturally important. They are also used heavily by wild vertebrates. We studied the use of nopal orchards by birds and the effect of neighboring vegetation

(shrubland, grassland, and annual rain-fed cropland) at 12 locations throughout one year. We concluded: (1) nopal orchards offer a variety of resources for birds, and are used by about 40% of the potential species for terrestrial habitats in the region; (2) some bird species were more frequent in orchards and shrublands, but there was no typical orchard-shrubland bird assemblages, as there were no grassland or cropland assemblages; (3) nopal orchards, although variable, have bird assemblages richer than those of grasslands or croplands, and as rich as and akin those of shrublands, which whom they integrate when they are adjacent; (4) nopal orchards appear to contribute importantly to the conservation of birds in the region, independently from their surrounding matrix patches; they reflect, in addition to physical conditions (soil, rainfall of a particular year), the idiosyncrasies of the owners regarding orchard and edge constitution and management, attributes that can be managed to achieve specific conservation goals and; (5) the attributes that make nopal orchards a potential venue for bird conservation are likely of similar value in other semi-arid, fruit-oriented agroecosystems.

ECOLOGICAL RETROSPECTIVE OF THE UPPER BASIN OF THE QUEBRADA GRANDE, MUNICIPIO OF SAN ANTONIO DE TEQUENDAMA CUNDINAMARCA, COLOMBIA.

Germán Melo

University of Santo Tomas

As a result of deforestation, pollution, degradation and fragmentation of the ecosystem, the upper reach of Quebrada Grande has triggered secondary succession processes covering pre-existing conditions, which for decades have affected not only plants, but also amendments to high ground. It is remarkable to state that depending on the intensity of disturbance and the nature of ecosystems that dominate the area, the succession has taken an unexpected turn that generates the loss of native species and high-value ecosystems. Firstly, a taxonomic characterization of plant species was conducted, finding that nowadays some wildlife groups make a retrospective ecological system, before human intervention processes. From the previous system, the episodes of disturbance, its current condition can be modified through the replacement of species through time and space in the future. About the information obtained, bibliographic support in the area and/or similar ecosystems, major key species were determined of the watershed, reaching the definition of the reference ecosystem; thus the system was evaluated through their ecological relationships, this generated a reading of post disturbio stress of high micro round. This research contributed to the understanding of ecological relationships in areas with a high degree of human intervention, identification of scales ecological stress disorder and considering the conserved and

transferred areas. Keywords: Vegetation, avifauna, disturbance, taxonomy

LANDSCAPE GENETICS OF JAGUARS FROM BELIZE

Angelica Menchaca

Bristol University

Jaguars are the only species of the genus *Panthera* that can currently be found in the American continent. During the last 50 years populations have declined dramatically due to habitat fragmentation, poaching of their natural prey and direct killing. They are considered "near threatened" by IUCN and are included on CITES Appendix I. The species represents the largest carnivore in the American continent acting as an important umbrella species. Traditional techniques to study jaguars have provided valuable information on the species, however, more accurate estimates of population density and abundance across a variety of habitats is necessary to properly implement conservation efforts that adequately protect the remaining populations of jaguars. Ecological information alone cannot contribute enough in the long-term survival of the species if its evolutionary potential is not analysed. Non-invasive genetic techniques have only been addressed in the last 15 years but have enabled a more accurate estimation of population size and density; furthermore, they take into consideration diverse genetic parameters such as population structure and demographic history that have more robust implications in wide-range conservation efforts of landscape species such as *P. onca*. Here I present a study on the genetic diversity and population structure of jaguars from Belize using 366 scat samples assessed through amplification of 12 microsatellite loci. And a Landscape Genetics analysis on the most probable habitat utilised for movement across the study area. These results contribute in the characterization of the genetic diversity of the species and provide a phylogenetic approach to its conservation. Furthermore the results presented here could be use in future studies to draw inferences on historical processes, clarify taxonomic issues and provide insight about genetic flow and evolutionary potential of *P. onca*.

UNCOVERING THE WORLD'S BIGGEST FISH, THE WHALE SHARK, NOW IN PERU

Alejandra Mendoza

EcOceánica

Rossana Maguiño, EcOceánica ; Shaley KELEZ, EcOceánica ; Ximena VELEZ-ZUAZO, EcOceánica ; Dení RAMÍREZ, Whale Shark Mexico

The whale shark is epipelagic with a circumtropical distribution. This shark has a K-selected life history whose characteristics make them more vulnerable to exploitation. It is a highly

migratory shark, and because of this, sustainable use of this threatened species depends on international collaboration. The knowledge of its life history is poorly understood, and the information about its ecology is most advanced in the Indian Ocean, with only a little research in the Pacific Ocean. Although Peru has been a member of CITES since 1975, a member of CMS since 1997 and has seven IUCN members, it has no local, regional or national protection laws. The lack of information about the whale shark population from Peru limits the generation of a proper management plan of the species at local level. In order to generate knowledge about the whale shark from the region we conducted interviews of fishermen and dive companies. From 84 interviews a total of 107 whale shark reports were noted. Initial evidence suggests that there are two whale shark seasons in Peru - one in summer and the other in winter - with the highest quantity in summer. Having this information we started a crucial baseline research of the whale shark from Peru in order to determine basic information such as seasonality, abundance, and population structure. We will present the findings of the preliminary investigation of the whale shark population monitoring study. Gathering this information, and working closely with the Peruvian government and fishermen, will help to implement the first management plan for this species and its habitat. Key words: Whale Shark, baseline research, management.

NEW POPULATION ASSESSMENT AND VARIATION IN BREEDING PARAMETERS OF MOGODOR ISLAND COLONY OF ELEONORA'S FALCON, *FALCO ELEONORAE* THROUGH DIGITAL TERRAIN MODELS

Malki Meryem

University Chouaib Doukkali, Faculty of Sciences

Juan ARIZAGA, Urdaibai Bird Center, Aranzadi Society of Sciences ; Adnane HABIB, University Chouaib Doukkali, Faculty of Sciences ; Houda HADI, University Chouaib Doukkali, Faculty of Sciences ; Hamid Rguibi Idrissi, University Chouaib Doukkali, Faculty of Sciences

Eleonora's Falcon, *Falco eleonorae* has been identified as "Rare for Europe" species and its decline is related to habitat loss. Morocco appears to receive number of birds of this species in breeding season. The aim of this study was to provide a reliable estimate of current population size of Eleonora's Falcon in Morocco according to distance-sampling technique. This census was the first of its kind and part of a global population survey in Morocco and the population size at certain colonies was significantly underestimated in 1996 and 2014, as well as at national level in 2014, up 30% the global Mediterranean population size. We gathered data for a two-year period (2013–2014) on the nesting ecology and reproductive performance of Eleonora's falcon in the Mogador Islands. A total of 1,745 individuals were counted in the entire study area. A correction

factor for the detectability of the birds in all transects is calculated. The results indicated a new breeding population estimate of 1.428 breeding pairs in Morocco. By the way, we investigated in an indirect way the relation between clutch size and pre-laying food availability, the significance of site and pair quality on productivity, and the effects of habitat and intraspecific competition on breeding success. We study the nesting-site preferences in Eleonora's falcon *Falco eleonorae* by means of geographic information systems and high-quality high-resolution digital terrain models. Breeding parameters varied significantly between the years, exhibiting a strong spatial yet local effect. The results of this survey provided guideline for reviewing the conservation status of Eleonora's Falcon in Morocco and also help to set an effective national conservation plan for future population monitoring.

ON THE WAY TO BETTER PEST CONTROL: HOW WE COULD IMPROVE THE DIFFICULT BATTLE AGAINST INVASIVE SPECIES.

Rose-Anne Merz

Victoria University of Wellington

Invasive species are the second biggest threat to biodiversity worldwide. The loss caused by invasive species has devastated many ecosystems and the damage is likely to go beyond what we can study and observe. Many remaining species, especially on off shore islands would have likely fallen victim to extinction if it wouldn't be for pest control measures. Nevertheless, today's pest control measures are still remarkably basic and require large amounts of human effort and resources which most countries cannot afford. This talk will give an insight into current pest control measures by outlining their weakest points based on my own research examples. My research focuses on invasive mammalian and invertebrate species on islands, and their behavior and interactions with trapping devices. The aim of my research is to better understand those invasive species which could allow us to achieve more innovative, sustainable, and effective pest control measures worldwide. In this talk I offer a short introduction to these problems and propose key directions to achieve a new path for conservation.

HABITAT MANAGEMENT VARYING IN SPACE AND TIME: THE EFFECTS OF BURNING AND GRAZING ON WETLAND AMPHIBIANS

Béla Mester

Hungarian Academy of Sciences, Centre for Ecological Research, Department of Tisza Research

Miklós PUKY, Hungarian Academy of Sciences, Centre for Ecological Research, Department of Restoration and Animal

Ecology ; Szabolcs LENGYEL, Hungarian Academy of Sciences, Centre for Ecological Research, Department of Tisza Research

Amphibians have declined globally recently due to contamination, degradation, fragmentation and loss of their habitats, and the management of aquatic ecosystems has become a priority in their conservation. Despite numerous reports on conservation actions for amphibians in forests and grasslands, there is limited information on the proper management of wetlands specifically for amphibians in Europe. Our aim was to examine whether and how management by controlled late-summer burning of reed and year-round low-intensity cattle-grazing affect the species richness and abundance of anurans in the Egyek-Pusztakócs alkali marsh system, Hungary. Management was implemented in a 600-hectare, previously homogeneous reedbed between 2006 and 2009 and we surveyed anurans and sampled vegetation in a quasi-experimental design consisting of five transects each in six different treatment levels in 2010-2011. Prescribed fire caused the almost complete loss of reed and increased the diversity of the vegetation. The species richness of anurans and the abundance of Pelophylax species, Common and Green Toads the next spring were highest in areas burned the previous year. While the Fire-bellied Toad, a habitat generalist, was less affected by treatment, it was more abundant in managed than in control areas. By the second spring, the effect of reed burning vanished. However, grazed areas had lower reed cover and higher total anuran abundance compared to other treatments. In conclusion, grazing and burning can effectively remove homogeneous reedbeds and create breeding sites for anurans in the next spring. However, burning leads to quicker, but fast-disappearing results, whereas low-intensity grazing has slower but more lasting results.

INCREASING HABITAT ISOLATION CHANGES THE COMPOSITION OF A SAPROXYLIC BEETLE COMMUNITY AND NEGATIVELY IMPACTS DEAD WOOD DECOMPOSITION

Laia Mestre

Swedish University of Agricultural Sciences (SLU)

Nicklas JANSSON, Linköping University ; Thomas RANIUS, Swedish University of Agricultural Sciences (SLU)

Saproxylic insects depend on dead wood and many of them are endangered due to forest management practices that cause habitat loss or fragmentation. Because saproxylic insects are believed to play a significant role in dead wood decomposition, loss of saproxylic insect diversity is likely to have a negative effect on ecosystem functioning in forests. However, the ecosystem services provided by saproxylic insects have rarely been studied. We set up a field experiment in sites with oak pastures in south-eastern Sweden where we examined the effect of habitat isolation on colonization patterns of saproxylic

beetles and on decay of dead wood. We mounted boxes filled mainly with saw dust to emulate tree hollows with wood mould, which are habitat for specialized saproxylic beetles, on 120 trees across 8 sites and we sampled the beetle fauna and the remaining amount of wood mould in each box at different times. A box belonged to either of two habitat isolation treatments depending on whether it was placed in an oak pasture on a tree with hollows with natural wood mould ("low isolation") or about 100-200 m from the pasture, where only trees without hollows were present ("high isolation"). A year after, "high isolation" boxes hosted a different saproxylic beetle community with fewer species than "low isolation" boxes. Two years later, these biodiversity changes led in turn to a reduction in wood mould decay in the boxes with fewer species of obligate saproxylic beetles. Altogether, our results show that habitat fragmentation negatively affects dead wood recycling, and emphasizes the importance of preserving the diversity of saproxylic species in order to maintain ecosystem functioning.

SENTINELS OF GLOBAL CHANGES: THE FRENCH PACIFIC ISLAND TERRITORIES AS EXCEPTIONAL SITES FOR RESEARCH AND MANAGEMENT OF INVASIVE ALIEN SPECIES

Jean-Yves Meyer

Délégation à la Recherche, Gouvernement de la Polynésie française

Hervé VIDAL, Institut Méditerranéen de Biodiversité et d'Ecologie marine et continentale (IMBE), Aix-Marseille Université, UMR CNRS-IRD-UAPV, France & IRD ; Hervé JOURDAN, Institut Méditerranéen de Biodiversité et d'Ecologie marine et continentale (IMBE), Aix-Marseille Université, UMR CNRS-IRD-UAPV, France & IRD ; Atoloto MALAU, Service territorial de l'Environnement

Islands are often celebrated as laboratories of evolution because of their strong isolation, restricted areas, small populations and simplified communities, allowing the study of evolutionary patterns and processes (e.g. colonization, extinction, speciation and adaptive radiation). Though, in the context of the current biodiversity crisis under global change pressures, thousand of species have already been vanished from Pacific islands in the last five centuries, and many more endemic birds, skinks, insects, snails and plants are experiencing an on-going contemporary extinctions or decline because of introduced invasive species. The French Pacific island territories (French Polynesia, New Caledonia, and Wallis et Futuna), formed by hundred of tropical and subtropical islands (ranging from 1 to 17,000 km²) stretched over a distance of 7,000 km from West (Melanesia) to East (Polynesia), provide a unique experimental ground and excellent model system for both research and management of invasive alien species. Through few examples chosen among conducted programs

(miconia tree, predatory rodents and cats, alien ants), we will introduced some relevant conservation issues that would be better addressed in such high biodiversity insular context, including the rise of novel or hybrid ecosystems, the new relationships between alien and native species (e.g. predation, competition, mutualism), the shift of species altitudinal ranges with climate change, and restoration initiatives to recover endangered species and habitats. We believe that there are strong opportunities to make the difference in conservation in these territories where "the house is still burning"...

TERRESTRIAL MAMMAL COMMUNITIES IN FORESTS OF CENTRAL PANAMA, BOTTLENECK OF THE ISTHMUS OF PANAMA: AN ASSESSMENT USING CAMERA TRAPS

Ninon Meyer

El Colegio de la Frontera Sur/Smithsonian Tropical Research Institute

Helen ESSER, Wageningen University ; Ricardo MORENO, Yaguara Panama ; Frank VAN LANGEVELDE, Wageningen University ; Yorick LIEFTING, Wageningen University ; David ROS OLLER, Wageningen University ; Chantal VOGELS, Yaguara Panama ; Andrew CARVER, Asociacion Panamericana para la Conservacion ; Clayton NIELSEN, Southern Illinois University ; Patrick JANSEN, Wageningen University

The rise of the Isthmus of Panama 3 million years ago facilitated the Great Biotic Interchange between North and South America. Today, the interchange is hampered, as the isthmus has lost more than half of its forests due to economic development, and the remaining forest is fragmented and subject to poaching. Here, we use camera-trap surveys to assess whether forests in Central Panama – the narrowest and most disturbed portion of the Isthmus – still have intact communities of medium- and large-bodied terrestrial mammals. During 2005-2014, we conducted camera-trap surveys in 15 national parks and forest fragments on both sides of the Panama Canal, and compared these to survey data from two sites in the intact Darién National Park in Eastern Panama, the nearest available reference. We found that the communities in two national parks that are still connected to the Darien forest complex resembled those in the reference sites. In contrast, all other sites in Central Panama – including the national parks along the Panama Canal Zone – had lower mammal species richness and evenness, and less structurally-complex mammal communities than the reference sites. Forests in Central Panama had little or no apex predators and large terrestrial frugivores. The national parks along the Panama Canal were biased towards game species, suggesting release from predation, while forest fragments in agricultural landscapes were biased towards culture followers, suggesting heavy disturbance. Our results indicate that the terrestrial

mammal community in forests of Central Panama is currently degraded, even inside national parks, and probably poorly connected to intact forest complexes. These data provide a baseline for evaluating the success of conservation efforts to restore connectivity in Central Panama.

THE EFFECT OF DIFFERENT MOWING REGIMES ON HOVERFLY COMMUNITIES IN LOWLAND GRASSLANDS

Sandro Meyer

University of Bern

Debora UNTERNÄHRER, University of Bern ; Pierrick BURI, University of Bern ; Raphaël ARLETTAZ, University of Bern ; Jean-Yves HUMBERT, University of Bern ; Wolfgang NENTWIG, University of Bern ; Myles MENZ, University of Bern

In an increasingly dominated agricultural landscape in Western Europe, an improved management of extensive grassland ecosystems has the potential to benefit several pollinator groups, such as wild bees, butterflies, and hoverflies. Hoverflies have been shown to be important pollinators of native plants and crops, and have the added benefit of providing biocontrol of crop pests. Unfortunately, the current agri-environment schemes (AES) designed to promote pollinator diversity have yet to show clear positive impacts on pollinators. We investigated if slight alterations of the mowing regimes in the Swiss lowlands would have a positive impact on hoverfly abundance, richness, and diversity. We did this by applying a randomized block design with 12 replicates of each treatment: 1. Control: first cut not before 15 June (the conventional Swiss AES management of extensive meadows); 2. Refuge: first cut not before 15 June, but leaving 15% of grassland as a refuge uncut; 3. Delayed: delaying cutting for a month to 15 July. Two sampling methods were applied: sweep netting and pan trapping. Hoverflies were collected once before first cut (15 June) and once after the first cut, but before 15 July. We found the sampling method greatly influenced the hoverfly community that was caught. Pan traps exhibited a higher species richness in control than refuge meadows, as a result of a higher abundance of the saprophagous species. In contrast, sweep netting resulted in a higher abundance and species richness in delayed and refuge meadows compared to control meadows. This can be explained by the abundance of small aphidophagous species that occurred in the unmown (delayed) meadows in July, which feed on the pollen of grasses for egg maturation. Overall, delayed meadows exhibited a higher species richness and abundance than refuge and control meadows, indicating that delayed management could have a positive impact on hoverfly communities in lowland grasslands.

FIELD SURVEYS AND RED LIST ASSESSMENT OF BORNEO'S SLOW LORISES (NYCTICEBUS MENAGENSIS AND N. KAYAN) USING LOCAL KNOWLEDGE IN SARAWAK, BORNEO.

Priscillia Miard

Oxford Brookes University

K.a.i. NEKARIS, Oxford Brookes University ; Hatta RAMLEE, Sarawak forestry department

Slow lorises (*Nycticebus* spp.) are small, cryptic nocturnal primates found throughout SE Asia that are threatened by habitat loss and the illegal wildlife trade. Over the last decade, revisions in taxonomy mean that five of the eight species are listed by the IUCN as Vulnerable or Critically Endangered, with three new taxa in Borneo currently Data Deficient. In this research project, I aimed to provide the first systematic field data from Sarawak (Malaysia) focusing two species of lorises: *Nycticebus menagensis* (VU) and *N. kayan* (DD). My preliminary work in the area has already shown that these species occur in both protected forests and in anthropogenically disturbed habitats. In order to gain knowledge on the range and potential overlap of these taxa, as well as their use by humans, I focused on the local knowledge, conducting a series of interviews with local people in remote areas as well as with staff running tourist hotels in forested areas. Abundance estimates of species have been made through forest surveys via occupancy modeling, and observations with the aid of an infrared video camera. Examinations of locally caught pet lorises have also been undertaken. Hopefully, my data provides a strong basis for a conservation assessment for the new species *N. kayan* as well as gain vital population data regarding remaining lorises in these regions of Borneo. The data presented in this poster are the result of a three-month field study to understand how the local beliefs affect slow loris conservation. Results show that ancient taboos about slow lorises are decreasing because of an expanding globalization, and that this issue needs to be addressed with more intensive education projects in the field. Our survey using occupancy modeling allows for a clear idea of the range of the two different species but further investigation is needed to estimate population densities.

POPULATION CENSUS OF HOUSE MARTINS IN SWITZERLAND: A WEB BASED CITIZEN SCIENCE PROJECT

Stephanie Michler

Swiss Ornithological Institute

Shona RÜESCH, Swiss Ornithological Institute ; Jael HOFFMANN, Swiss Ornithological Institute ; Nadine APOLLONI,

Swiss Ornithological Institute ; Reto SPAAR, Swiss Ornithological Institute

House martins are in decline in many western European countries, as well as in Switzerland. The reasons for the decline are poorly understood. One probable cause is a diminishing acceptance of homeowners and inhabitants for house martin nests on buildings and a lack of material around buildings to build own natural nests where the birds are still welcome. As part of a long term species recovery project for the house martin, the Swiss Ornithological Institute started a web based citizen science project in 2013. Aim of the project was firstly to collect information on exact addresses of house martin colonies to protect larger colonies. Secondly, we collected information on the amount of natural and artificial nests the birds bred in, the types of buildings the nests were located on and the availability of material for nest construction close to the colonies to learn more about current breeding circumstance of house martins. Thirdly, the project aimed at informing the Swiss public about the status of the house martin and at sensitising to the problems the species faces nowadays. The results of the census show that more than half of the occupied nests were artificial, thus house martins in Switzerland depend to a large extent on human provided breeding facilities. Furthermore, the proportion of artificial nests occupied and also the availability of open ground for nest material differ strongly between regions, thus conservation strategies need to take into account regional factors. Another important result is that about half of the artificial nests remained unoccupied, while many natural nests were reported as damaged or destroyed. We thus need to adapt current conservation strategies to these findings.

UNDERSTANDING THE RESILIENCE OF AFRICAN RAINFOREST TREES, APPLYING NEW GENOMIC TOOLS TO PHYLOGEOGRAPHY

Jérémy Migliore

Université Libre de Bruxelles, Evolutionary Biology & Ecology
Esra KAYMAK, Université Libre de Bruxelles, Evolutionary Biology & Ecology ; Cédric MARIAC, IRD - UMR DIADE ; Yves VIGOUROUX, IRD - UMR DIADE ; Thomas L. P. COUVREUR, IRD - UMR DIADE ; Gilles DAUBY, IRD - UMR DIADE ; Rosalia PINEIRO, Evolutionary Genomics, Centre for GeoGenetics, Natural History Museum of Denmark ; Kasso DAÏNOU, Université Libre de Bruxelles, Evolutionary Biology & Ecology [INSTITUTE] Université de Liège, Gembloux Agro-Bio Tech, Laboratoire de Foresterie des Régions tropicales et subtropicales ; Olivier J. HARDY, Université Libre de Bruxelles, Evolutionary Biology & Ecology

Long-term stability has been considered for long as a prime cause of the remarkable biodiversity of tropical rainforests. However, paleoecological evidence of substantial change in the vegetation of tropical regions resulting from global climate

fluctuation call for a reassessment of the temporal dynamics of biodiversity. Through the AFRIFORD program we aim to understand how past environmental changes have shaped the current distribution and composition of African rainforests and the genetic diversity of their constituent trees. Knowing the past to understand the present and forecast the future can rely on the integration of paleoecology, phylogeography and species distribution modelling to characterize the complex spatiotemporal trajectories of species and populations. In this context, we are developing next generation sequencing tools to analyze the genetic polymorphism of rainforest trees at the intra-specific level. The capture and sequencing of chloroplast genomes at deep multiplexing levels have been undertaken on 96 individuals of the rainforest tree *Greenwayodendron suaveolens* (Annonaceae), representative of Central African mature forests. A higher level of polymorphism and a more reliable phylogenetic signal allow inferring the evolutionary history of African rainforest populations. A critical view of this approach will then be possible, comparing this new phylogeographical pattern to those reconstructed by sequencing some cpDNA regions and genotyping microsatellites. Taking into account the evolutionary dimension of tropical ecosystems remains a key challenge to develop conservation strategies, and preserve the resilience and/or adaptation potential of rainforest trees to rapidly accelerating human impact. Maintaining biodiversity at all its levels and provisioning a broad array of ecosystem services in this global biodiversity hotspot imply therefore a close collaboration between ecologists, conservation biologists and natural resource managers.

SETTING AND REALIZING A CONSERVATION RESEARCH AGENDA FOR HUNGARY: OUTCOMES OF A PARTICIPATORY APPROACH

Barbara Mihók

MTA Centre for Ecological Research
Bálint BALAZS, Szent István University, Institute of Nature Conservation and Landscape Management, [INSTITUTE] Environmental Social Science Research Group (ESSRG) ; Eszter KOVÁCS, Szent István University, Institute of Nature Conservation and Landscape Management, [INSTITUTE] Environmental Social Science Research Group (ESSRG) ; György PATAKI, Environmental Social Science Research Group (ESSRG) [INSTITUTE] Department of Environmental Economics and Technology, Corvinus University of Budapest ; András BÁLDI, MTA Centre for Ecological Research

Participatory research prioritizing exercise in conservation proved to be a useful tool in providing a review of critical challenges based on stakeholder engagement, possibly contributing to, among others, a more effective allocation of research funding. In order to realize the optimal resource

allocation and the research priorities, however, research agendas need to be developed at an operative administrative and management level and need to be successfully channelled into research finance and strategic development. The present paper discusses the results and outcomes of a participatory exercise conducted in Hungary aiming to compile the most important conservation research questions at the national level and provide a set of further tools for dissemination. During the process 792 research questions were collated from conservation practitioners and natural resource managers via interviews and an online questionnaire. Of the 792, the final 50 most important questions were ranked by practitioners and policy makers during a participatory expert workshop. The list of questions indicate country-specific highlights regarding endangered habitats such as the Pannonic wooded steppe and floodplain forests. Many questions address issues significant in contributing to policy- and decision-making processes regarding habitat management, land-use and regional development. Numerous questions highlights conflicting issues between natural resource management and conservation. In addition to the question list as a thematic review of conservation challenges, enhanced collaboration and interaction between stakeholders is also an important result. Outcome derived in the process is therefore assigned with a "lobbying power", which can be used and directed towards academic and research financing institutions. Thus we argue that special emphasis should be put on identifying the target audience of dissemination and the channels of effective information transfer towards them.

CHALLENGES AND LESSONS FROM PREDICTIVE ECOLOGICAL MODELING FOR DESIGNING AN INTEGRATIVE BIODIVERSITY MONITORING PROGRAM

J-B. Mihoub

Helmholtz Centre for Environmental Research - UFZ
Neil BRUMMITT, *The Natural History Museum*; Denis COUVET, *Muséum national d'Histoire naturelle*; Karine PRINCÉ, *University of Wisconsin-Madison*; Benjamin ZUCKERBERG, *University of Wisconsin-Madison*; Dirk SCHELLER, *Helmholtz Centre for Environmental Research - UFZ*

Reliable assessments and future projections of biodiversity responses to environmental and anthropogenic changes are keys to improving biodiversity conservation enforcement and management. Yet, important mismatches between predictive ecology requirements and biodiversity monitoring might potentially limit the development of relevant and realistic forecasts. We reviewed recent predictive ecology literature in line with available biodiversity monitoring information and we identified some key limitations. Mechanistic process-based models (MPBMs), in which predictions on ecological patterns

are emergent properties of the system, usually offer more reliable predictions than correlative approaches. However, while ecologists may have gathered sufficient information to design generic MPBMs integrating multiple-ecological components at various scales, the necessary information required to accurately parameterize realistic models and to validate their outcomes is lacking. Current biodiversity monitoring generally skews biodiversity information by collecting a few types of data, for particular taxa or biodiversity levels and with limited temporal and geographic coverage. Whereas biodiversity monitoring provide essential information about patterns in species distribution, population abundances and potentially community composition, most quantitative information about traits, mechanisms and processes required as input parameters in MPBMs come from a few monitoring schemes conducted at small spatial and / or temporal scales. Failure to anticipate changes in biodiversity in response to global changes might therefore be partly due to insufficiently comprehensive biodiversity monitoring. Referring to the developing Essential Biodiversity Variables concept, we advocate for urgently re-prioritizing biodiversity monitoring at global scale, targeting data collection on traits, mechanistic and functional interactions between and within EBVs.

CHANGING SENSITIVITY TO A GLYPHOSATE-BASED HERBICIDE DURING THE TADPOLE STAGE IN THE COMMON TOAD (BUFO BUFO)

Zsanett Mikó

Plant Protection Institute, Centre for Agricultural Research, Hungarian Academy of Sciences

János UJSZEGI, *Plant Protection Institute, Centre for Agricultural Research, Hungarian Academy of Sciences*; Attila HETTYEY, *Plant Protection Institute, Centre for Agricultural Research, Hungarian Academy of Sciences*

The worldwide application of pesticides emphasizes the need of investigating the harmful effects that pesticides may have on non-target organisms. Previous studies showed that pesticides can harm aquatic organisms, and that toads are more sensitive to herbicides than other amphibians. However, there is little information about how sensitivity changes during early ontogeny, and how the duration of exposure is linked to the magnitude of malign effects. Without this knowledge, it remains notoriously difficult to formulate recommendations regarding the timing of pesticide application. We exposed tadpoles of the common toad (*Bufo bufo*) to three concentrations (0, 2 and 4 mg a.e. / L) of a glyphosate-based herbicide at seven regimes (never, during the 1., 2., 3., 4., 5. week of larval development, and during the whole experiment). We measured survival, time until metamorphosis and metamorph body mass. Sensitivity changed during development in accordance with our expectations; younger tadpoles were more sensitive to the herbicide in all measured

traits, than older ones, and the older the tadpoles were at the first contact with the herbicide, the less effect was observed. Furthermore, while tadpoles exposed to the herbicide during their entire larval period developed slower than tadpoles exposed only early on, we did not observe a similar difference either in body mass or survival. Our results suggest, that postponed pesticide application would be highly favourable for early-breeding amphibians: tadpoles would be exposed to pesticides for a shorter time during their aquatic life-stage, and would not get into contact with the herbicide during their most sensitive early development.

LOCAL PEOPLE COUNT: USING CITIZEN SCIENTISTS TO MONITOR FRUIT BAT POPULATIONS

Tammy Mildenstein

Cornell College

L. Scott MILLS, North Carolina State University; David PATTERSON, University of Montana

Three quarters (143/196) of the world's megabats (Old World fruit bats; Pteropodidae) are found on islands, where they are ecological keystones as seed dispersers and pollinators. Although nearly half of the species are considered threatened, the conservation status of most Pteropodids remains largely unknown because of the lack of researchers on remote islands. We studied how local community members could be engaged as citizen scientists to monitor and detect trends in populations. We conducted fruit bat exit counts across the Mariana Islands and the Philippines to measure sampling error due to differing levels of counting experience and to demonstrate the impact of observer error on trend detection. As expected, field experience was inversely correlated with observer error; average error was 70% among observers with no field experience, 11% among fieldworkers, and 5% among experienced counters. However, even the largest error (from inexperienced observers) did not greatly compromise trend detection. In a projection model incorporating observer error from our field data, we found estimates of exponential trend to be robust to the measured levels of observer error. There were no misidentifications of trend direction after 20 years of counting even for amateur counters, and few trend misidentifications after only 5 years of counting. Fruit bat conservation in Oceania and insular Southeast Asia is dependent on regular monitoring of populations of concern. Our modeled success in detecting trends from citizen scientist data suggests that community-based fruit bat monitoring programs may be scientifically valid in addition to being cost-effective, sustainable, and relevant to local management.

THE RELATIONSHIP BETWEEN WHITE-TAILED DEER (ODOCOILEUS VIRGINIANUS) POPULATION DENSITY, FORAGING PRESSURE ON VEGETATION, AND FECAL CORTISOL LEVELS

Pamela Millan

St. Edward's University

Amanda MAXON, St. Edward's University; Stacia SHEPUTA, St. Edward's University; Christopher JOHNSON, St. Edward's University; Gregory WASHINGTON, St. Edward's University; Amy BELAIRE, St. Edward's University; Michael WASSERMAN, St. Edward's University

The overpopulation of white-tailed deer (*Odocoileus virginianus*) in North America has led to vast effects on vegetation growth and diversity, as well detrimental human-wildlife interactions, such as automobile accidents. Therefore, the goals of our study were twofold: (1) we determined how deer density, activity, and browsing pressure varied across an urban nature preserve, and (2) quantified spatial variation in stress levels of deer across the nature preserve in relationship to roads, neighborhoods, and a field station. We used camera traps to estimate deer population density and activity across Wild Basin Wilderness Preserve in Austin, Texas, by measuring the distance of the individual(s) to the camera when a picture was taken and the angle at which they approached the camera, along with data on average velocity of the deer and average group size in the preserve. To estimate browsing pressure on the plant community, we established vegetation plots around the camera traps and identified plant species, percent coverage, and grazing pressure using the falling plate method. To estimate stress levels we measured fecal cortisol levels across the preserve. Seasonality was observed in number of sightings of deer with the highest activity occurring in November. We also found a significant positive correlation between deer sightings and temperature ($R^2 = 0.32$, $p = 0.05$). These results are vital for understanding temporal and spatial variation in the movement and distribution of white-tailed deer, which influences the plant community through grazing effects. Our results can be used to improve management practices, particularly in urban landscapes where deer density is high. As many urban areas are currently increasing the protection of green space within the city, an understanding of how the dominant large mammalian herbivore in North America can be effectively managed in these systems is critical for both the well being of ecosystems and human society.

THE MISSING MIDDLE: LOCAL GOVERNMENT, INTERNATIONAL BIODIVERSITY AID, AND THE POLITICS OF PROPERTY AROUND BENIN'S W NATIONAL PARK

Daniel Miller

World Bank

Research on the social and ecological impacts of protected areas and conservation aid interventions has tended to focus either at the local (village or protected area) or national (protected area system) level. It has largely skipped over the meso-level, which includes political units such as municipalities, districts, and provinces. Yet politics and policy at this level can be decisive in shaping the outcomes of conservation efforts in protected areas. Understanding the role of this “missing middle” is especially important given that decentralization processes continue to unfold in more than 60 countries across the world. This paper examines the interaction of an international conservation project (ECOPAS - Ecosystèmes Protégés en Afrique Soudano-Sahélienne), the national parks agency, and sub-national political elites around the W National Park in Benin. Using a mixed methods approach based on a quasi-experimental research design, it explains how access, use, and management rights shifted over time in the periphery of the park due to the implementation and subsequent close of the ECOPAS project. Resultant uncertainty over property rights led to negative effects on local livelihoods and undermined sustainable conservation and natural resource governance in the region. Results of this study demonstrate the importance of effective engagement with sub-national political actors and processes for conservation policy and practice and also show how changing property rights can act as a mechanism linking conservation interventions with social and ecological impacts. Note: This manuscript is part of a set of contributed papers organized by L. Glew, M. Mascia, and D. Miller. If accepted, please include this presentation in the program immediately following the presentation by Louise Glew and immediately prior to the presentation by Michael Mascia. If you have any questions, please contact me directly. Thank you.

THE IMPACT OF BRIDGING THE SCIENCE-POLICY BOUNDARY IN ASSESSING RISKS TO ECOSYSTEMS

Rebecca M. Miller

International Union for Conservation of Nature (IUCN)
Aurélien CARRÉ, Comité français de l’UICN ; Marcos VALDERRABANO, Centro de Cooperación del Mediterráneo UICN-Med ; Taibou BA, Centre de Suivi Ecologique ; Edmund G. BARROW, International Union for Conservation of Nature ; David A. KEITH, University of New South Wales ; Jon Paul RODRÍGUEZ, Instituto Venezolano de Investigaciones Científicas

Understanding risks to biodiversity is a pre-requisite for effective action to slow rates of loss, secure ecosystem services and effectively manage ecosystems. However, too often conservation results and recommendations get lost in the gap between science and policy, particularly in the

context of wider socio-economic and political challenges. Bridging the science-policy boundary is crucial for effective communication and uptake of conservation findings. In 2014, the International Union for Conservation of Nature (IUCN) adopted a set of categories and criteria for assessing risks to ecosystems, thereby establishing a new global standard for biodiversity assessment and monitoring. After broad consultation, development and testing, the Red List of Ecosystems is now being implemented at the local, national and regional level around the world, forming the basis for natural resource decision making and investment. This talk focuses on Red List of Ecosystem initiatives carried out to date on the African continent (Madagascar, Morocco, Senegal). Political support of Red List of Ecosystems initiatives through engagement with governments and policy-makers has proven significant for achieving increased efficiency and better results in the application of the categories and criteria, and more direct uptake of results of the assessment process into conservation policies, though it has also presented challenges. Achieving biodiversity conservation targets will require reaching out beyond the environmental community to policy makers in other sectors, land use and development planners, macroeconomic planners, rural communities, and the private sector. This engagement can raise awareness about the drivers and stressors behind ecosystem changes, helping to quantify the value of healthy ecosystems for human well-being and sustainable resource use, and thus inform proactive rather than reactive conservation measures.

SYMPOSIUM ID 108. DEMONSTRATING AN EFFECTIVE MARINE BIODIVERSITY OBSERVATION NETWORK IN THE SANTA BARBARA CHANNEL: THE ROLE OF REMOTE SENSING

Robert Miller

University of California Santa Barbara

Time series data on marine biodiversity is collected at great expense, with the expectation that it will improve our capacity for science-based decision-making aimed at protecting natural ecosystems and sustaining the services that they provide. Unfortunately, most monitoring efforts in marine are done at small scales, and are not linked, rendering them inadequate to address regional and global shifts in biodiversity and ecosystem services that result from climate change, pollution, fishing, and other regional- to global-scale impacts. Existing but under-utilized technologies have the potential to dramatically expand our ability to assess species change at all scales. Remote sensing is one of these tools and is increasingly used to evaluate variables related to biodiversity in marine ecosystems. I present examples of the use of remote sensing to assess major autotrophic habitat elements important to marine ecosystems, phytoplankton and kelp forests, and

future directions to expand the use of remote sensing in the observation of marine biodiversity.

PROTECTING MARINE ECOSYSTEMS: PRESCRIPTIVE REGULATION VS MARKET INCENTIVES

Steve Miller

University of California, Santa Barbara

Robert DEACON, University of California, Santa Barbara

Tradable permit markets, an institution based on creating property rights for access to resources, are gradually replacing prescriptive regulations as a tool for managing U.S. commercial fisheries. The same market-based approach can in principle be applied non-commercial marine conservation goals, such as limiting the unintended catch (bycatch) of protected species. However, applications to this realm are rare and evidence on performance is lacking. We examine fishers' responses to the introduction of tradable bycatch rights in the U.S. West Coast groundfish fishery, finding evidence of adjustment along several margins and producing estimates of the marginal cost of conservation. We demonstrate that fishers responded to bycatch rights by changing fishing location, gear used, time of day fished, and duration of fishing activity in order to avoid protected species. The nuanced nature of these responses indicates that the least-cost way of achieving a conservation goal can involve fine-tuned behavioral adaptations, an outcome that would be difficult or impossible to achieve with prescriptive regulation.

SYMPOSIUM ID: 94 WHEN CONSERVATION GOES VIRAL: THE DIFFUSION OF INNOVATIVE BIODIVERSITY CONSERVATION POLICIES AND PRACTICES

Morena Mills

University of Queensland

Michael MASCIA, Conservation International

Initiatives aimed at conserving biodiversity are widespread and growing, but loss of biodiversity is yet to be mitigated. The factors that shape rates and patterns of adoption of conservation initiatives remain unclear, presenting a puzzle for scientists and a barrier for evidence-based policymaking. Diffusion of innovation theory - the study of how, why, and at what rate innovations spread through individuals, groups, organizations or countries - provides a novel lens through which to examine rates and patterns associated with the adoption of new conservation policies, programs, and practices. In this study, we highlight the potential for diffusion theory to explain spatial and temporal dynamics of different conservation initiatives including their rate of adoption, the degree to which they are adopted within the target population and adoption pattern. First, we introduce basic principles and insights from the innovation diffusion literature. We then

explore the potential for innovation diffusion theory to explain spatial and temporal patterns of patterns of conservation practices, drawing upon case studies in Tanzania and the Pacific. Case studies in Tanzania demonstrate the importance of program design in influencing the success of participatory conservation interventions. Our Pacific cases study demonstrates the importance of context in defining success of an individual initiative. Enabling policies, change agents, the compatibility of an innovation with decision makers' beliefs and values, and the perceived relative advantage of an innovation play a critical role in explaining the diffusion of our case studies. Our study offers insights into strategy of conservation interventions, e.g. the potential for action as a result of strategic versus ad hoc action, and tactical insight into the design of interventions that catalyse conservation at scale.

OPPORTUNITIES AND CONSTRAINTS FOR THE RESTORATION OF THE ATLANTIC FOREST

Morena Mills

University of Queensland

Ana Paula GIORGI, Earthwatch Brazil ; Azevedo THAÍS,

Earthwatch Brazil ; Vanessa M. ADAMS, University of

Queensland ; Andrew T. KNIGHT, Imperial College London ;

Hugh P. POSSINGHAM, University of Queensland[INSTITUTE]

Imperial College London

Forests worldwide have been severely degraded or destroyed by human activity, consequently the persistence of biodiversity and ecosystem services depends not only on habitat protection, but also on large scale implementation of restoration. Participants in forest restoration initiatives experience both costs and benefits associated with restoration activities. While approaches to make restoration more attractive have been suggested, there is little guidance of what approaches work in different socio-ecological systems. Multiple theories explain why people engage in different pro-environmental practices and inform opportunities and constraints in implementing conservation or restoration initiatives. However, these are rarely used to guide implementation. In this study, we investigate the motivations and barriers to participation in restoration initiatives and use the diffusion of innovation theory to predict the percentage of the population that is likely to adopt different programs and the rate of adoption. To do this we conducted 180 household interviews with small-scale farmers living in the catchments surrounding the National Park of the Serra do Itajai, within the Brazilian Atlantic Forest. The Brazilian Atlantic Forest is considered a major global biodiversity hotspot and is one of the most endangered ecosystems in the world, with less than 16% of its original extent. Our population could be separated into two groups based on the motivations and barriers for restoration. We recommend restoration programs tailored specifically to the needs and desires of each group, maximizing

likelihood of restoration uptake and therefore restoration program success.

76: QUICK AND DIRTY EVALUATION OF SOCIAL IMPACTS IN LOW-CAPACITY, DATA-POOR SITUATIONS

E.j. Milner-Gulland

Imperial College London

Katie SAINSBURY, Imperial College London ; Neil BURGESS, Imperial College London

Critical evaluation of the impact of conservation actions is essential to meet the challenges posed by the biodiversity crisis, but in many situations there is not the capacity or budget for proper attribution of impacts to conservation interventions. Often baseline data are unavailable, and programme goals are unclear. We used a new approach, the Ranked Outcomes (RO) method, to evaluate the planned and realised social outcomes of a set of small scale income-generating activities implemented in communities adjacent to the Uzungwa Scarp proposed Nature Reserve in the Tanzanian Eastern Arc Mountains.. RO converts qualitative information on planned and realised outcomes into a score for comparison between projects. We carried out an independent evaluation and also assessed project impacts from the perspective of target communities. We found a high level of heterogeneity of perception between and within stakeholder groups (implementers and target communities), both in terms of which outcomes were most important and how well they had been achieved. Ranked outcomes emerged as a flexible framework that defines the terms of the evaluation for all stakeholders from the outset, even in cases when evaluation and clear goal-setting are omitted from original project design and planning. It can be modified for use as a component of rigorous impact assessment, to incorporate perspectives of all stakeholders, and provides important insights in data-poor situations and where baselines are not available.

PARALLEL CONTRIBUTIONS TO EVOLUTIONARY DIVERSITY, TROPHIC DIVERSITY AND TROPHIC STRUCTURE IN A MAMMALIAN HERBIVORE ASSEMBLAGE

Maria Miranda

University of the Witwatersrand

Francesca PARRINI, University of the Witwatersrand

Biodiversity is a multifaceted concept that comprises taxonomic, structural and functional components. Individual taxa have been shown to unevenly contribute to the different components of biodiversity. An integrative conservation approach that concentrates on the taxa that most strongly contribute to multiple diversity components

could thus facilitate the retention of a sustainable level of biodiversity complexity, and of the derived ecosystem functions and services. We combined phylogenetic and network analyses to quantify species contributions to 2 essential biodiversity components, phylogenetic diversity and diversity of trophic interactions, in an African assemblage of mammalian herbivores. We found positive correlations between species contributions to phylogenetic and trophic diversity. Additionally, we identified a non-random trophic interaction structure between herbivores and their plant resources, which arranged both in a nested (specialists using a subset of the resources used by generalists) and modular pattern (sub-guilds of herbivore–resource relationships). We found a positive correlation between species contribution to such nested interaction structure and their contribution to phylogenetic diversity. The observed congruence between species contribution to phylogenetic diversity, trophic interaction diversity and interaction structure has important implications for conservation, and for maximizing the revenues from investments on conservation actions. Hence conservation approaches that aim at preserving phylogenetically distinct species may simultaneously maximise the retention of trophic interaction diversity and of the nested pattern of trophic interaction structure. Species contributions to modular interaction patterns were instead uncorrelated to their contributions to phylogenetic diversity, indicating the importance of some phylogenetic and trophic redundancy between species for retaining a modular structure in the system.

HUMAN VALUES AND THE BIOLOGICAL SIGNIFICANCE OF LARGE AFRICAN MAMMALS

Maria Miranda

University of the Witwatersrand

Fredrik Dalerum, University of Oviedo

We are currently facing the risks of driving the environment towards hostile states for our species. Public attitudes towards environmental values are important for promoting a societal change to more sustainable structures, since such public opinion largely drive environmental politics. The monetary price of a given good reflects the amount that we are willing to pay to acquire it, and constitutes a potentially useful indicator of human values. Wildlife in Southern Africa is frequently traded at game auctions for transfers between privately owned game reserves. These trade prices generate a unique source of information of the economic value of wildlife species. If combined with biologically relevant characteristics of each species, these game prices thus offer a rare opportunity to evaluate how humans values of particular organisms relate to their biological significance. We evaluated the relationship between trade prices over a 22-year period and the phylogenetic and functional significance of southern African

herbivores and carnivores. We found no correlation between price and either phylogenetic or functional significance of species. Furthermore, there were no trends over time in these relationships over the past 20 years. Since the economic value of southern African wildlife does not seem to reflect their biological significance, neither in evolutionary nor ecological terms, we stress that further work is needed to evaluate what humans value in biological organisms, and how potentially necessary shifts in such values can be initiated.

AGRICULTURE HOMOGENIZES DIVERSITY

Murilo Miranda

German Centre for Integrative Biodiversity Research (iDiv)
Thomas MERCKX, Biodiversity Research Centre, Earth and Life Institute ; Henrique PEREIRA, German Centre for Integrative Biodiversity Research (iDiv)

Global Biodiversity continues to decline at high rates. Currently, the main driver for this is land-use change as many native habitats like woodland, savanna and shrubland are being converted to agricultural land. Many studies show the effect of agricultural intensification at the local scale, whilst its effect is unknown at larger scales. For this reason, we analyzed the beta-diversity of macro-moths in agricultural, forest and shrubland landscapes within the Peneda-Gerês National Park, Portugal. The macro-moths were light-trapped at 84 fixed sampling sites during 2011 and 2012, each of which was sampled six times repeatedly (3 times/year). We collected 22,825 individuals distributed in 377 species. We estimated beta-diversity using Jaccard indices and we developed a simulation-based null model to verify if alpha-diversity may influence beta-diversity. Although beta-diversity in the shrubland landscape (0.51) was higher than in the forest (0.47) and agricultural (0.39) landscape, the null model detected that the low alpha-diversity in shrubland influenced beta-diversity. After correcting for this, beta-diversity of the forest landscape was significantly higher than the beta-diversity of the agricultural landscape, indicating a homogenizing effect of agricultural practices even for extensive agriculture.

STRATEGIC AND COLLABORATIVE CONSERVATION OF CHEETAHS AND AFRICAN WILD DOGS ACROSS THEIR AFRICAN RANGE

Nick Mitchell

Zoological Society of London & Wildlife Conservation Society
Rosemary GROOM, Zoological Society of London & Wildlife Conservation Society ; Audrey IPAVEC, Zoological Society of London & Wildlife Conservation Society ; Sarah DURANT, Zoological Society of London

Cheetah and African wild dogs are listed by the IUCN Red List as Vulnerable and Endangered respectively, but it is the

vast space requirements of both species that has warranted a particular tailored conservation approach. Their very wide ranging behaviour means that many populations exist across national boundaries and require collaborative conservation efforts. In addition, most protected areas are not sufficient to maintain viable populations. They will often roam across communal and private land to find space and will therefore come into regular contact and conflict with farmers and pastoralists. In order to address these unique challenges the Range Wide Conservation Program for Cheetah and African Wild Dogs (RWCP) was initiated in 2007 as a joint project of the Wildlife Conservation Society and the Zoological Society of London. The approach has been to work at the broadest scale possible, the range wide scale, and to define common strategies that allow a coherent approach to conservation across national boundaries. Collaboration between governments and with a broad range of stakeholders has been a hallmark of the program. The first two phases brought the establishment of three regional conservation strategies, and the coverage of 98% of known cheetah range with 17 national action plans. However, one of the major challenges not yet addressed remains that of preventing further loss and fragmentation of suitable habitat. With increasing pressures for land from the human population, the need for land use planning becomes ever more urgent. The third phase of the RWCP begins now with the aim of creating three major cheetah landscapes; each landscape being marked by participatory land use planning making provision for the livelihood needs of both human and cheetah populations. To facilitate this it will feature the training and mentoring of national coordinators who will also be able continue the implementation of the national conservation action plans.

USING BIG DATA TO QUANTIFY THE "CULTURAL VALUE" OF SPECIES FOR CONSERVATION

John C. Mittermeier

University of Oxford
Paul JEPSON, University of Oxford ; Richard GRENYER, University of Oxford

Cultural values form one of the core benefits that biodiversity provides to humanity and are an important force in motivating action and engaging interest in conservation. In species conservation, cultural values may influence whether an organism becomes endangered and impact the amount of conservation investment it receives. As a result, they are often as significant as biological and ecological factors in determining the outcome of conservation projects. While the significance of these values has been widely recognized in the conservation literature and enshrined in environmental legislation and international treaties, clear definitions of what cultural values entail in a conservation context and how they differ across taxonomic, social, and geographic scales remain

elusive. Outside of conservation, new technical and analytical tools are developing in the emerging field of “culturomics” that facilitate the synthesis of data stored in massive text archives such as Google Books, Wikipedia, and digitized newspaper corpora. Culturomic and natural language processing methods enable large-scale quantitative analyses of cultural patterns that were until recently infeasible, and offer techniques that may provide novel insight to the long-standing challenge of measuring cultural value in conservation. My presentation describes a new method to quantify the cultural value of species using culturomics and big data analytics and discusses how this can be applied to species conservation projects.

INTEGRATION AND APPLICATION OF POTENTIAL MUSEUM COLLECTIONS OF NATURAL HISTORY DISSEMINATED ON THE WEB FOR BIODIVERSITY DATA ACCUMULATION AND PUBLIC CONSERVATION AWARENESS

Yusuke Miyazaki

Kanagawa Prefectural Museum of Natural History
Atsunobu MURASE, Tokyo University of Marine Science and Technology ; Hiroshi SENOU, Kanagawa Prefectural Museum of Natural History

Citizens have uploaded numbers of biodiversity photographs with time and locality information onto websites, including social networking services, blogs, and homepages. We regarded such photographs disseminated on the Web as potential museum collections of natural history and have attempted to accumulate them as actual museum collections of the Kanagawa Prefectural Museum of Natural History (KPM), Japan. Based on these activities, which are centered on the public natural history museum, we are building a new conceptual model for biodiversity data integration and public conservation awareness by systematizing (1) collection/accumulation, (2) research/study, and (3) outreach/education. First, the fish photographs registered in the WEB sakana-zukan, as an example of a platform, archived more than 40,000 items for potential museum collections of natural history and accumulated them into the Fish Image Database of KPM by obtaining the consent forms of the purveyors (i.e., citizens). Second, the accumulated collections were used for studies on fish taxonomy, biogeography, ecology, and conservation biology by scientific experts. Finally, the identification and study results were made available to citizens, including the purveyors, through volunteer programs, exhibitions and media applications, including a serialization in an off-shore recreational fishing magazine. In this presentation, we will provide an overview of the conceptual model with some related issues based mainly on our published papers in order to consider and contribute to development of Citizen Science for biodiversity conservation.

SCIENCE LEADS GOVERNANCE FOR THE CONTROL OF INVASIVE LIONFISH IN BELIZE

Meira Mizrahi

Blue Ventures

Jennifer CHAPMAN, Blue Ventures ; Charlie GOUGH, Blue Ventures

With a voracious appetite for juvenile fish and invertebrates, invasive lionfish (*Pterois volitans*) constitute one of the greatest threats to the Caribbean’s coral reefs as well as the fisheries they support. This paper presents findings from four years of research by Blue Ventures (BV) on lionfish populations in Bacalar Chico Marine Reserve (BCMR), and demonstrates how this research guides management. Analyses confirm that lionfish are firmly established in BCMR and reproduce year-round. Spatial analyses show high variability of lionfish population density with mean abundance and biomass increasing with reef depth. This information is used to prioritise control efforts within BCMR and, considering Belize’s small-scale fishers are only able to harvest lionfish in unprotected areas up to 18 m deep, feeds into Belize’s developing multi-sectorial national strategy for lionfish control. Temporal analyses of opportunistically sighted and culled lionfish show changes in both population size and structure, with an indication of slowed growth rates in the last year. Gut contents analysis supports evidence for a highly diverse diet and in addition observed the first lobster (*Scyllarides aequinoctialis*) to be found in a lionfish stomach in Belize, a finding suggestive of potentially devastating implications for Belize’s dominant commercial fishery, the Caribbean spiny lobster (*Panulirus argus*). Given the outstanding ecological and social value of BCMR and its resources, there is a critical need to develop systems for the effective management of this potentially devastating threat. Although eradication of lionfish in its invaded range is no longer considered possible, population suppression to site-specific densities can allow native fish populations to recover. Using these data and approach, Belize is able to determine lionfish population densities and thresholds for coral reefs countrywide, which in turn supports the development of a holistic lionfish control strategy.

GRAZING EFFECT ON PRODUCTIVITY GRADIENT FOR A C4 PERENNIAL GRASS STIPAGROSTIS CILIATA (DESF.) DE WINTER

Lobna Mnif Fakhfakh

Faculty of Sciences of Sfax

Mohamed CHAIEB, Faculty of Sciences of Sfax

Most ecological studies in North Africa reveal a process of continuous degradation of ecosystems as a result of overgrazing. This degradation appears across the depletion of perennial grass. Indeed, the majority of Mediterranean arid ecosystems are characterized by a low density of perennial

grasses. *Stipagrostis ciliata* (Desf.) De Winter has wide ecological amplitude in North Africa and grows under a diversity of environmental conditions. Its distribution covers the desert regions of South and North Africa. In Tunisia, field studies show a low density and low recruitment of this species. The current study aimed to investigate the effects of grazing in a productivity and conservation of *Stipagrostis ciliata*. The experiment comprised three treatments (overgrazing, moderate grazing, and ungrazing), each at two levels: maximum rainfall (200 mm); normal rainfall (100 mm). The results show that overgrazing causes exhaustion tufts with a biomass mean 25 ± 11.3 g dry matter. The absence of grazing results in a significant tufts development (biomass produced varied from 67.45 to 345 g dry matter). Grazing showed variable results on final biomass. Regarding biomass productivity, we found significant effect of treatment ($F = 37.004$; $P < 0.001$) with higher productivity for non-grazed treatment at level (200 mm) (mean = 137.34 ± 12.3 g dry matter). When grazing increases, *Stipagrostis ciliata* productivity typically declines. Changes in biomass production have been also related to rainfall. Dry matter production of *Stipagrostis ciliata* showed significant differences in aboveground dry matter accumulation between the two rainfall regimes ($F = 9.746$; $P = 0.002$). So moderate grazing helps to enhance the aerial phytomass produced and preserve the tuft for a long time. In conclusion the conservation of perennial grasses steppe in arid bioclimate requires moderate grazing. Further, optimum grazing practices to conserve biodiversity of ecosystems may involve moderate stocking rate.

DARK DIVERSITY ILLUMINATES THE DIM SIDE OF RESTORATION PRIORITISATION

Jesper Erenskjold Moeslund

Aarhus University

Ane Kirstine BRUNBJERG, University of Birmingham ; Kevin CLAUSEN, Aarhus University ; Lars DALBY, Aarhus University ; Camilla FLØJGAARD, Aarhus University ; Anders JUEL, Aarhus University

Stopping biodiversity loss by 2020 is currently one of the major global concerns and calls for useful and effective tools for practical biodiversity management and planning at spatial scales relevant for these issues. Recently, scientists came up with a new concept; dark diversity, which could prove to be a central idea for the development of the aforementioned tools. Dark diversity encompasses the diversity articulated by all the species missing in an area, despite the fact that they could potentially thrive there considering current ecological conditions. In other words, dark diversity is the diversity of species represented in the regional species pool for a particular habitat which are not present at a local site within that particular habitat type. Here we present the first national application of the dark diversity concept for

restoration potential identification at a scale relevant to planning and management and covering a wide number of terrestrial habitats. More specifically we use a massive national plant dataset with very high accuracy and a combination of community composition statistics and calculations of maximum dispersal distance based on plant traits to address the following study questions: (1) is it possible to define realistic regional species pools using statistically based knowledge of plant community relationships and maximum dispersal distance modelling? (2) Can a dark diversity approach be used for pointing out local sites with high restoration potential?

BIOMASS INCREASES GO UNDER COVER: WOODY VEGETATION DYNAMICS IN SOUTH AFRICAN RANGELANDS

Penelope Jane Mograbi

Centre for African Ecology, School of Animal, Plant and Environmental Sciences, University of the Witwatersrand
Barend F N ERASMUS, Global, Change and Sustainability Research Institute, University of the Witwatersrand ; E T F WITKOWSKI, Restoration and Conservation Biology Research Group, School of Animal, Plant and Environmental Sciences, University of the Witwatersrand ; Gregory P ASNER, Department of Global Ecology, Carnegie Institution for Science ; Konrad J WESSELS, Remote Sensing Research Unit, Council for Scientific and Industrial Research - Meraka Institute ; Renaud MATHIEU, Ecosystems Earth Observation, Council for Scientific and Industrial Research - Natural Resources and Environment ; David KNAPP, Department of Global Ecology, Carnegie Institution for Science ; Roberta MARTIN, Department of Global Ecology, Carnegie Institution for Science ; Russell MAIN, Ecosystems Earth Observation, Council for Scientific and Industrial Research - Natural Resources and Environment

Unsustainable fuelwood harvesting is a major driver of woodland degradation in southern African semi-arid ecosystems. The rural poor often depend on natural resources; with a growing human population and non-linear resource base dynamics, coupled human-environment vulnerabilities are set to increase. Bushbuckridge, a densely populated former South African homeland, is characterised by high reliance on fuelwood, despite extensive access to electricity. Changes in woody biomass and vertical vegetation structure serve as an expression of wood extraction in a natural resource use environment. Using repeat light detection and ranging (LiDAR) data between 2008 and 2012 from the Carnegie Airborne Observatory (CAO), we estimated woody biomass in three communal rangelands under different levels of wood extraction pressure and compared the results to changes in three-dimensional canopy cover. Woody biomass in 2008 ranged from 9 Mg ha⁻¹ on gabbro geology sites to 27 Mg

ha-1 on granitic geology sites. Biomass increased at all sites, contrary to previous fuelwood models of the area. Change analysis of the vertical stratification of the vegetation canopy revealed the location of biomass increases as almost solely attributable to the 1-3m and 3-5m height classes within the vertical vegetation structure. These changes are exacerbated by anthropogenic factors. The rangeland under the highest wood extraction pressure had the largest biomass increases, likely a strong regrowth response to excessive harvesting. Within rangelands, areas closest to roads and settlements experienced substantial biomass increases in 'hotspots' as a result of shrub level gains; the greater the wood extraction pressure on the rangeland, the greater the spatial coalescence of biomass 'hotspots'. This research shows bush thickening across the communal rangelands, likely an interactive combination of newly established woody encroachers and strong coppice regrowth in harvested species.

CONSERVATION STATUS OF THE ENDANGERED NUBIAN DRAGON TREE DRACAENA OMBET IN GEBEL ELBA NATIONAL PARK, EGYPT

Usama Mohammed
National Parks of Egypt

The Nubian dragon tree *Dracaena ombet*, which is categorized as Endangered on the IUCN Red List, is found on the highest slopes of Gebel Elba National Park in Egypt, with scattered populations in Sudan, Djibouti, Ethiopia and Somalia. The Gebel Elba population is threatened by drought. Surveys were conducted in the Park to assess the condition and document the distribution of the species to prepare a baseline for conservation efforts. Eight sites were surveyed during 2007–2009: trees were tagged and their locations were recorded using a global positioning system, and tree density, diameter at breast height and population status were estimated. Of 353 trees recorded only 46% (161 individuals) were alive and only 27% (96 individuals) were in a healthy condition. Only 1% (2 individuals) were young trees, indicating a low regeneration level. Field-based observations suggest that 80% of the *D. ombet* population in Gebel Elba may soon be extinct. A conservation action plan is needed for this flagship species in Egypt and throughout its range.

PHOTOVOICE AS A KEY METHODOLOGICAL APPROACH IN CONSERVATION PLANNING

Chase Mohrman
Westminster College[INSTITUTE]The School for Field Studies
Samantha MURPHY, University of Washington[INSTITUTE] The School for Field Studies ; Jessica POTEET, Dickinson College[INSTITUTE]The School for Field Studies ; Andrew

VARUZZO, College of the Holy Cross[INSTITUTE]The School for Field Studies ; Edward HIND, The School for Field Studies

Established conservation sociology methodologies may no longer be the best means available for collecting socioecological data. Despite the seemingly successful history, for instance, of interview-based approaches in environmental research, more novel methods are beginning to prove more effective at eliciting tacit and hard-to-discover data. A case study from a small island community in the Turks and Caicos Islands is presented here to illustrate how the use of the photovoice technique can garner information beneficial to conservation planning efforts. Community-driven conservation, often reliant on substantial input of local ecological knowledge (LEK) and pro-environment human capital, has been suggested by policy-makers for South Caicos as its local terrestrial and marine ecosystems are coming under increasing stress. However, a previous two year interview-based study found that local residents did not possess the levels of LEK or pro-environment human capital likely required for successful community-driven conservation. In spite of this, community-environment interactions that researchers had made outside of their interview-based study led them to suspect that the study had underreported residents' LEK and conservation beliefs. The research was subsequently re-conducted, this time using a photovoice approach which firstly asked research participants to photograph what they believed to be important to their community, before then asking them to take part in follow-up interviews where they described their motives for taking each picture. This time, high levels of LEK and pro-environment human capital were discovered, with 28.7% of respondent photographs demonstrating community affinity for the natural environment. These results suggest that the photovoice technique can enhance traditional conservation sociology methodology and aid conservation planning efforts by providing researchers with a more comprehensive understanding of community capacities.

WASTE OR RESOURCE? INDIGENOUS USES AND CONSERVATION REIMBURSEMENTS OF COW DUNG BY MEMBERS OF THE MAUNGANI COMMUNITY, THOHYANDOU, LIMPOPO PROVINCE, SOUTH AFRICA

Mokgaetji Georginah Mokganya
University of Venda

Cow dung is the undigested residue of plant matter which has passed through the cow's gut. The main objective of this study was to investigate the uses of cow dung by the different members of Maungani Community. Furthermore, the study looked at the ways in which the uses of cow dung can help in the case of conservation aspects. The study consisted of the

qualitative explorative phase which included the households' visits and conduction of semi-structured interviews with individuals of the selected households. Households were selected based on interval or systematic sampling whereby only a certain number of houses per street were randomly selected to ensure that the survey covered the entire village. A variety of the uses of the cow dung were recorded during the interviews with the members of the community. The most predominant cow dung use was that it can be used as a fertilizer for vegetables like spinach and cabbage; these vegetables were found planted in the backyards of the households visited. Other uses outlined by respondents were to harvest honey, to pave and decorate the yards, to sprinkle over the fertilized vegetables to prevent herbivory and also for making fire. Few responses of all the interviews mentioned the use of cow dung in the generation of biogas which plays a pivotal role in many people's lives from many parts of the globe. The fact that cow dung can also be used as fuel was seen to reduce the collection of trees from the ecosystem and thus assisting in the promotion of conservation of many plant species. The current study recommended that people of the Maungani Community should be introduced to the technology used to harvest biogas from cow dung.

A FUNCTIONAL ASSESSMENT OF SCAVENGING IN MEDITERRANEAN AND AFRICAN SAVANNAH HABITATS

Marcos Moleón

University Miguel Hernández

Cayetano GUTIÉRREZ-CÁNOVAS, Cardiff University ; José Antonio SÁNCHEZ-ZAPATA, University Miguel Hernández

Scavenging is a widespread ecosystem process which provides important benefits to humans. Unfortunately, vultures and other major scavengers are largely threatened worldwide. Assessments aimed at identifying key functional traits in scavenging communities may be fundamental to understand the consequences of scavenger declines. In this study we relate scavenger functional traits and scavenging efficiency (carrion consumption rate) in two diverse ecosystems: the Mediterranean mountains (Spain) and the African savannah (South Africa). We characterised 13 biological traits at the species level, and defined four groups of scavenger species depending on their functional role. Then we examined the relationship between species richness, functional dispersion, functional redundancy and the richness of each functional group with carrion consumption. We also determined which set of traits best explained carrion consumption rate. Species richness, functional dispersion and functional redundancy showed non-significant correlations with consumption rate. However, the richness of certain functional groups correlated significantly with the rate of carrion consumption: terrestrial mesopredators showed a significant negative correlation with

consumption rate in both systems, while obligate scavengers presented a significant positive correlation with carrion consumption rate in the Mediterranean area. Biological traits contributed differently to explain the carrion consumption rates in both scavenger assemblages. In the African savannah, traits typically exhibited by large predators such as lions and spotted hyenas were the most frequent variables used to predict carrion consumption rate. However, in the Mediterranean system, diet (obligate scavenger) was the most important trait. Overall, our study highlights the pivotal and irreplaceable role that vultures and apex predators play in the scavenging process, and claims for their strict protection.

FLIGHT INITIATION DISTANCE AND GENETIC VARIATION

Anders Møller

Université Paris-Sud

Yiting JIANG, Université Paris-Sud

Predation is a common cause of death in numerous organisms, and a host of anti-predator defenses have evolved. Such defenses often have a genetic background as shown by significant heritability and micro-evolutionary responses towards weaker defenses in the absence of predators. If there is a genetic basis for anti-predator behavior, we should expect a loss of genetic variance to be associated with a loss of efficient anti-predator behavior. Flight initiation distance (FID) is the distance at which an individual animal takes flight when approached by a human and hence it reflects the life history compromise between risk of predation and the benefits of foraging. Here we analyzed FID in 80 species of birds in relation to band sharing coefficient for minisatellites, and observed and expected heterozygosity, number of alleles and inbreeding coefficients for microsatellites. We found consistently shorter FID for a given body size in the presence of high band sharing coefficients, low heterozygosity, few alleles and high inbreeding coefficients. These findings imply that many threatened species with low genetic variability will show reduced anti-predator behavior, and that subsequent predator-induced reductions in abundance may contribute to unfavorable population trends.

BUILDING CAPACITY OF THE NEXT GENERATION OF LIBERIAN CONSERVATION PROFESSIONALS

Mary Molokwu

Fauna & Flora International

Chloe HODGKINSON, Fauna & Flora International ; Matthew VARNEY, Fauna & Flora International ; John WOODS, University of Liberia ; Theo FREEMAN, Forestry Development Authority

; *Darlington TUAGBEN, Forestry Development Authority ;
Kathryn SHUTT, Fauna & Flora International*

Liberia covers one of the largest remaining intact blocks of the threatened Upper Guinea Rainforest, harbouring globally endangered species, including one of the last significant populations of the pygmy hippopotamus (*Choeropsis liberiensis*). However, years of civil unrest, disrupting the training of natural resource personnel and destroying infrastructure for research and education, has severely restricted conservation capacity. Fauna & Flora International in collaboration with Liberian and international partners have been working since 2012 to address the lack of technical capacity for effective conservation using a three-pronged approach: 1) establishing a training centre in Liberia's only national park, Sapo for practical training through residential field courses; 2) insertion of conservation modules into the curriculums of educational institutions; 3) development of a researcher mentorship scheme to support collaborative research between Liberian and international researchers. The project applies a training-of-trainer strategy all through implementation to promote sustainability and self-sufficiency. Here we present results, lessons learnt and progress so far on the creation and teaching of two biodiversity conservation courses at the University of Liberia, establishment of a novel internship training scheme and development and hosting of field courses at the Sapo Conservation Centre, established in 2013. A research programme was also initiated to empower national researchers to conduct independent research. This attracted a regional collaboration that produced the first detailed ornithological research, documenting 183 bird species at the Sapo National Park and identifying increasing anthropogenic threats within and around the park. A long-term biomonitoring programme implemented by locals identified 27 mammals. We report on results from our long-term monitoring and evaluation programme to assess project impact on conservation efforts in Liberia.

THE IMPORTANCE OF SAPO CONSERVATION CENTRE TO THE PEOPLE AND BIODIVERSITY OF THE SAPO NATIONAL PARK, LIBERIA

Mary Molokwu

Fauna & Flora International

Matthew VARNEY, Fauna & Flora International ; John KANNAH, Fauna & Flora International ; Kayjay GMATOH, Forestry Development Authority ; Morris JAH, Forestry Development Authority ; Thomas DOGBEH, Jalays Town Community, Sapo National Park ; Joshua LACTRO, Forestry Development Authority ; Kathryn SHUTT, Fauna & Flora International UK

Recent conservation initiatives attempt to marry the protectionist and community-based conservation models to enable more effective conservation of key species through

increased community support for biodiversity conservation. Against this backdrop, in 2013, Fauna & Flora International, in collaboration with Liberian and international partners, established the Sapo Conservation Centre (SCC) as a hub for research and community conservation of biodiversity in Liberia's only national park, Sapo (SNP). SNP holds one of the three most intact blocks of the Upper Guinea Rainforest and harbours several threatened globally important species including the West African chimpanzee. SCC addresses the lack of capacity for effective community-integrated and supported conservation in Liberia through: 1) formation of a steering committee (comprising local, national and international stakeholders), as a forum for stakeholders to address conflicts and other issues relevant to the protection of biodiversity and human interests - a vital link between park management and local communities; 2) establishment of a training course where forestry students and professionals are locally trained and can experience ecological field research and applied conservation; 3) coordination of a long-term biomonitoring project that monitors the status of SNP's biodiversity; and 4) establishment of a research programme incorporating biological and human dimensions. The project approach led to several interesting discoveries, particularly the lack of awareness of locals about the park boundary and legal use of the buffer zone; emerging human-wildlife conflicts (HWC) that may result from community encroachment into the buffer zone; and increasing hunting pressures. Future research and conservation action is now focused on exploring HWC issues and developing a collaborative buffer zone management plan. Here we share details of the project, our challenges and hopes for the future in this important landscape.

SOLVING CONFLICTS AMONG CONSERVATION, ECONOMIC AND SOCIAL OBJECTIVES IN BOREAL PRODUCTION FOREST LANDSCAPES

Mikko Mönkkönen

University of Jyväskylä

Eric LE TORTOREC, University of Jyväskylä ; Adriano MAZZIOTTA, University of Jyväskylä ; Kaisa MIETTINEN, University of Jyväskylä ; Dmitry PODKOPAEV, University of Jyväskylä ; Tähti POHJANMIIES, University of Jyväskylä ; Maria TRIVINO, University of Jyväskylä

Reconciling biodiversity conservation with increasing demands of natural resources and human well-being from ecosystems requires that ecological, economic and social values of the landscape are taken into account in decision-making. Joint production of economic and social values together with maintaining biodiversity is a challenging planning problem because conflicts that exist among the objectives make it impossible to maximize all of them simultaneously. Here, we first develop multi-objective optimization methods to measure conflicts among different objectives. We then propose a new

approach to resolving these multidimensional conflicts through compromise management plans. We exemplify the potential utility of the approach for simultaneous production of timber revenues, several ecosystem services and maintenance of biodiversity (species habitat availability) in large boreal forest landscape. In this production forest landscape, we applied seven alternative management options on 30,000 forest stands across 50 years planning horizon. We show that the conflicts among objectives are typically complex and asymmetric. Even if pairwise conflicts between objectives are severe, a management solution can be found with rather small losses in either of the objectives. For example, conflict between biodiversity and ecosystem services can efficiently be solved. However, incorporating timber revenue objectives narrows the margin for minimizing the conflict. Therefore, the current strong emphasis in boreal forests on timber production incurs into considerable social and ecological costs. We propose a planning approach where conflicts between social and economic values are being solved at a predetermined minimum level for biodiversity. This approach would ensure that societal optima among alternative ecosystem services can be found within the safe boundary levels of life supporting systems.

MODELLING THE PRE-WHALING DISTRIBUTION AND ABUNDANCE OF THE ENDANGERED NORTH ATLANTIC RIGHT WHALE FROM HISTORICAL WHALING RECORDS OF A CONGENERIC SPECIES

Sophie Monsarrat

Centre d'Ecologie Fonctionnelle et Evolutive, CNRS
 Maria G. PENNINO, *Universidade Federal do Rio Grande do Norte, Departamento de Botânica, zoologia e ecologia*; Tim D. SMITH, *World Whaling History*; Randall R. REEVES, *Okapi Wildlife Associates*; Christine N. MEYNARD, *Virginia Institute of Marine Science, College of William & Mary*; David M. KAPLAN, *Virginia Institute of Marine Science, College of William & Mary*; Ana RODRIGUES, *Centre d'Ecologie Fonctionnelle et Evolutive, CNRS*

The North Atlantic right whale (NARW, *Eubalaena glacialis*) is one of the world's most threatened whale species. Previously widespread, it came close to extinction after centuries of overexploitation, and was already commercially extinct by the mid-1700s. It currently persists as a small and slowly recovering population of ca. 500 individuals. Setting appropriate conservation targets for this species requires an understanding of its historical distribution and abundance, as a baseline for understanding its decline and measuring progress towards recovery. However, this is made difficult by the scarcity of records over its very long whaling history. In contrast, its congeneric North Pacific right whale (NPRW, *E. japonica*) was exploited more recently, in a short and well-

documented period in the mid-19th century. Here, we combine detailed whaling records for the NPRW with oceanographic data to generate a spatially-explicit statistical prediction of the environmental suitability and carrying capacity of the North Atlantic for right whales. The predicted extent of occurrence matches well historical records for the NARW, supporting the assumption that the two species have similar environmental preferences. Our results suggest that the historical summer range of the NARW extended from the eastern coast of North America to northern Norway, much wider than the current summer grounds off North America. Our estimate of a pre-whaling population of ten to twenty thousand individuals strongly suggests that the current population is extremely depleted, but also show the realms of possibility for future recovery. Our predictions of areas of high habitat suitability and historical abundance suggest priorities for monitoring the current population. More generally, this study illustrates the challenges and opportunities in using historical data to understand the original distribution of highly depleted species and to inform their future conservation.

33-HOW CONSERVATION SCIENCE INNOVATIONS SPREAD AND CHANGE PRACTITIONER BEHAVIOR IN LARGE INSTITUTIONS

Jensen Montambault

The Nature Conservancy
 Sheila REDDY, *The Nature Conservancy*; Yuta MASUDA, *The Nature Conservancy*; Jonathan FISHER, *The Nature Conservancy*; Kyle BURFORD, *The Nature Conservancy*

Conservation science innovations are intended to transform conservation practice and decision-making. Social networks have the potential to greatly accelerate the spread of these innovations far beyond what could be possible with traditional change management tactics including institutional policies and training. However, there is little research to help managers understand how science innovations spread and ultimately change the behavior of conservation practitioners. Research has been limited because of the challenges associated with employing experimental designs in large, geographically diffuse organizations. Further, intended outcomes, such as learning and behavior change, present particular measurement challenges. We address these challenges by examining the diffusion and uptake of new science innovations and policies in a large, global, non-governmental conservation organization, The Nature Conservancy. The innovations include methods for iteratively prioritizing, assembling and applying evidence to identify crucial conservation needs and actions, as well as integrating human wellbeing considerations into conservation strategies. We focus on conservation practitioners in a large operating geography and employ a randomized-controlled design to estimate the effects of training interventions on

conservation practitioner behavior and their egocentric networks. We also investigate network structures and characteristics to understand whether such characteristics can predict the spread of new innovations and policies. We present preliminary results on conservation practices and on network structures and characteristics from data gathered through administrative systems and self-reported communication networks. We expect that training combined with networks effects will lead to more efficient and effective spread of innovation, which is especially important when policy mandates are not feasible, innovations involve complex learning and training resources are limited.

NEGATIVE IMPACT OF A MARINE PROTECTED AREA UPON AN EMBLEMATIC MEDITERRANEAN RAPTOR POPULATION.

Flavio Monti

CEFE-CNRS

Olivier DURIEZ, CEFE-CNRS ; Jean-Marie DOMINICI, Réserve Naturelle Scandola, Parc Naturel Régional de Corse ; Andrea SFORZI, Maremma Natural History Museum ; Alois ROBERT, CEFE-CNRS ; David GRÉMILLET, CEFE-CNRS

Disturbance of charismatic wildlife by eco-tourism has become a major concern in the last decades. In the Mediterranean, sea-based tourism and related recreational activities increased rapidly, especially within marine protected areas (MPAs) hosting emblematic biodiversity. Here we investigated the impact of the Scandola MPA (Corsica, Western Mediterranean) on the population of a conservation flagship, the Osprey *Pandion haliaetus*. Over the 37-years study period, breeding parameters dropped for pairs nesting within the MPA compared to those breeding elsewhere in Corsica, while tourist fluxes increased rapidly. Recent breeding failures within the reserve are not caused by food scarcity, as 98 underwater transects and GPS-tracking of nine breeding adults conducted in 2012-2013 showed that fish consumed by ospreys are more numerous inside the MPA. Further, we performed direct observation in 2013 and 2014, which revealed that the overall number of boat passages and of boat approaches within <250 m from osprey nests were significantly higher within the MPA than in the control area. Finally, observations at osprey nests conducted across 2012-2014 demonstrated that boat traffic modified osprey time-budgets significantly, by lowering the number of prey items brought back to the nest by males, and increasing time spent alarming and flying off the nest in females. Overall, our integrative assessment combining raptor demography, movement ecology, behavioural ecology, with fish and boat surveys clearly demonstrates the impact of the Scandola MPA on the Corsican osprey population. This case study stresses the worldwide importance of rigorously implementing sustainable ecotourism.

THE CONTRIBUTION OF TOURISTS TO THE RESILIENCE OF SOUTH AFRICA'S NATIONAL PARKS

Christine Moore

University of Oxford

Graeme CUMMING, Percy FitzPatrick Institute of African Ornithology, University of Cape Town

South Africa's National Parks are an important part of the national conservation strategy and the role of tourists in ensuring the viability of parks should not be overlooked. Tourism is one of the central financial drivers of South Africa's National Parks (SANParks). Thus, understanding how tourists are using parks and their motivations for visiting will assist in building a sustainable and resilient tourism management approach. The aim of this study was to understand how tourist movements within SANParks, as well as the broader protected area network within Southern Africa, could contribute to resilience. Tourist surveys were distributed at all SANParks during 2013-2014, asking tourists about their movements within SANParks and protected areas within Southern Africa, as well as their motivations for visiting parks. Using a network analysis approach we found that each of South Africa's National Parks has a unique tourist base, with some appearing more resilient than others. For example, Kruger National Park was found to have a diverse tourist base, including many repeat visitors, frequent SANParks users and Private Protected Area users. Tourist profiles at other parks varied, with some parks relying more on one type of user such as repeat users or first time users. Additionally, the motivations of tourists also varied between parks, however, many expressed the intrinsic and cultural benefits of parks as being very important. The tourist movements and motivations studied here indicate that tourist base diversity is important in promoting the resilience of South Africa's National Parks.

EXPLORING THE BIOGEOGRAPHY OF HERBIVORE - PLANT COMMUNITY INTERACTIONS AND ECOSYSTEM FUNCTIONING

Leigh Moorhead

The University of Tennessee: Knoxville [INSTITUTE] Center for Macroecology, Evolution, and Climate; University of Copenhagen

Nathan SANDERS, Center for Macroecology, Evolution, and Climate; University of Copenhagen [INSTITUTE] The University of Tennessee: Knoxville ; Aimée CLASSEN, Center for Macroecology, Evolution, and Climate; University of Copenhagen [INSTITUTE] The University of Tennessee: Knoxville

Biotic interactions can shape landscape-scale ecosystem processes, thus understanding the connections between the biogeography of biotic interactions and ecosystem function will enhance our ability to inform management decisions.

The presence of herbivores, via their interaction with plant communities, can alter fire regimes. However, it is less clear if the impact of small mammals, which are common in many managed ecosystems, on fire regimes is similar to that of mega-herbivores like elephants. Using an experimental approach, we found that the presence of small rodents reduced the amount of area burned during a fire by 61%, indicating rodents can alter how a fire disturbance moves through an ecosystem. However, plant response to herbivory is not globally constant; it would follow that herbivore effects on fire regimes depend upon a combination of local mitigating factors. By building a global-scale database to explore how mammal-plant interactions vary across biomes, climatic regimes, and land-use histories I will discuss: (1) are there global patterns in small mammal-plant community interactions; (2) are there global patterns of large herbivore effects on fire regimes; (3) will combining the results from my first two questions provide insight on how small mammals may influence ecosystem response to changing fire regimes. Preliminary data indicate that the effects of large herbivores on fire regime are highly dependent upon grazer type, precipitation, and past land use history across ecosystem-types. These results suggests that the current research approach that seeks to predict how species, and ultimately ecosystems, will respond to climate change without considering interactions is flawed and may lead to poor management decisions. Thus integrating interactions into predictions will better inform local, regional, and global conservation strategies (e.g. ecosystem maintenance) and management choices (e.g. timing of prescribed fires).

THE RED LIST OF ECOSYSTEM IN BRAZIL -SUBNATIONAL PILOT EXPERIENCES TOWARDS A BROAD IMPLEMENTATION STRATEGY

Miguel A. Moraes

UICN/IUCN - Brasil

Carolina D.I. MARQUES, UICN/IUCN - Brasil ; Luiz F.k. MERICO, UICN/IUCN - Brasil ; Maria A. OLIVEIRA-MIRANDA, Provita ; J.p. RODRIGUEZ, Provita[INSTITUTE]IVIC

The IUCN Red List of Ecosystems (IUCN-RLE) is a quantitative tool for assessing the conservation status of natural ecological systems and their risk of collapse. It considers both biotic and abiotic aspects, and it is thought off as a standard methodology with global achievements. During the Rio + 20 Conference, IUCN presented the methodology, initiating a broad debate on its potential application at the country level, and as a means to support definition of priority areas for conservation. With the World Commission on Ecosystem Management (CEM-IUCN) and Provita-Venezuela, IUCN Brazil mobilized a working group to build capacities and to develop a national implementation strategy. Subnational pilot experiences were designed to help build a strong case of successful RLE stories and raise awareness of their usefulness as a tool to support existing

public policies. Satellite images were used to quantify and evaluate the effects of current reduction in the geographical distribution of the ecosystems assessed. Existing land use data and modeling tools were applied to estimate future reductions. Data on heat spots served as proxy for fire events and environmental degradation. Information available in the literature complemented the assessments. Results show that it is feasible to produce a Red List of Ecosystems in Brazil using existing data and tools. Furthermore, they show that such a list would be very helpful for strengthening existing policies on biodiversity conservation, leveraging on-going efforts. The articulation of the IUCN-RLE with other methodologies already institutionalized in the country, such as the Red List of Species and Priority Areas for Conservation, can contribute to the consolidation of more effective political instruments. Brazil presents opportunities for the development of new approaches for the RLE implementation and is strategically positioned to lead a South American articulation focused on trans-boundary ecosystems conservation.

THE RESILIENCE OF MANGROVE FOREST TO MAJOR DISTURBANCES: A CASE STUDY IN SUMATRA, INDONESIA

Lucia Morales Barquero

Bangor University & Universität Göttingen,
Ruben VENEGAS LI, University of Queensland

Sumatra lies in an area of high seismic activity. The infamous earthquake that caused the Tsunami in December 2004, and another one in March 2005 - 9.1 and 8.7 on Richter scale respectively - caused the land to rise up to 1m in certain areas, which in turn caused the gradual death of coral reefs and mangrove forests. In this study, we analyze the change in extent and condition of mangroves in the Pulau Banyak Archipelago, located off the southwest coast of Aceh. We carried out a multi-temporal analysis of Landsat satellite images, obtained pre-tsunami (2003), pos-tsunami (2007) and current state (2014). The image classification was guided and validated with the use of 128 ground truth points collected during 2009; field observations included the state of recovery, classified as: high, medium or low depending on the height and density of saplings. The results show that in 2003, approximately 2592 ha of mangroves were present. Four years after the earthquakes, approximately 60% of this mangrove had died as a result of the changes that arose from the uplifting of the land. Only in approximately 30% of the area that was destroyed, some type of recovery was observed. The death of these mangroves represents the loss of ecosystems services. For example, local fishermen commented to have noticed a reduction in the number of fishes and molluscs; moreover, considering a mean above ground carbon pool for Indonesian mangroves of 159 MgCHa⁻¹, approximately 200 000 MgC could have been liberated into the atmosphere. The next step of

this study includes a further analysis on the recovery process in order to obtain further insights on the resilience of this ecosystem.

EVALUATION OF THE NETWORK OF PRIORITY FEEDING AREAS FOR SCAVENGERS IN SPAIN: FROM BIODIVERSITY CONSERVATION TO ECOSYSTEM SERVICES

Zebensui Morales Reyes

Universidad Miguel Hernández

Juan M. PÉREZ-GARCÍA, Universidad Miguel Hernández ; Marcos MOLEÓN, Universidad Miguel Hernández ; Francisco BOTELLA, Universidad Miguel Hernández ; Martina CARRETE, Universidad Pablo de Olavide ; Carolina LAZCANO, Universidad Miguel Hernández ; Rubén MORENO-OPO, University Complutense of Madrid ; Antoni MARGALIDA, University of Bern [INSTITUTE] University of Lleida ; José A. DONÁZAR, Estación Biológica de Doñana (CSIC) ; José A. SÁNCHEZ-ZAPATA, Universidad Miguel Hernández

Political decisions and legal regulations may have important implications for the functioning of ecosystems and the services they provide. Due to the outbreak of the bovine spongiform encephalopathy (BSE) in Europe, a sanitary regulation (EC 1774/2002) forced farmers to remove livestock carcasses from the field and transport them to authorized plants for their transformation or incineration. This led to a strong food shortage for vultures and other scavengers of conservation concern, with negative effects on their populations and the ecosystem services they provide. Moreover, carcass transportation meant a new source of greenhouse gases (GHG) emission. As a result of these environmental costs, new legislation was approved (EC 142/2011) to allow farmers to abandon extensive livestock carcasses in certain areas (priority feeding areas for scavengers, ZPAEN), both in the field (where they die) and at feeding stations. This legislation was incorporated in Spain through the Royal Decree 1632/2011, which urged every region (autonomous community) to design their own ZPAEN. Our aim was to evaluate the potential effects of this new regulation on a) the conservation of endangered scavengers and b) the GHG savings. By means of a GAP analysis, we evaluated the effectiveness of the network of priority feeding areas for the conservation of vultures and other endangered facultative scavengers. Then, we quantified the GHG emissions associated with the transport of extensive livestock carcasses that would be saved after the implementation of the ZPAEN. Our results show that these priority feeding areas for scavengers enhances both scavenger conservation and the associated ecosystem services when compared with the effects of previous restrictive regulations. However, the regional regulations must assimilate that obligate scavengers are highly mobile organisms that require large scale

planning, so their improvement should focus on incorporating larger areas to the ZPAEN.

LARGE BIODIVERSITY CONSERVATION GAINS ARISE BY BEING STRATEGIC ABOUT BROAD-SCALE AGRICULTURAL DEVELOPMENT IN NORTHERN AUSTRALIA

Alejandra MORÁN-Ordóñez

University of Melbourne

Amy WHITEHEAD, University of Melbourne ; Gary LUCK, Charles Sturt University ; Garry COOK, CSIRO ; Ramona MAGGINI, University of Queensland ; Brendan A. WINTLE, University of Melbourne

The tropical savannas of northern Australia are one of the few remaining large natural areas on earth, supporting many endemic species. Their biodiversity values are currently under threat from Australian Government policies aimed at encouraging agricultural development in the region. We explored the tradeoffs between biodiversity conservation, agriculture production and carbon farming in northern Australia. We examined land-use change scenarios to identify areas of potential land-use conflict, where high agricultural development potential intersected high biodiversity values. We also identified areas of high biodiversity value and high carbon farming potential, presenting an opportunity for complementary land management. We used spatial prioritization to find the optimal solution from two different perspectives: (1) a conservation organization seeking to maximize biodiversity value and minimize cost; (2) a public policy-maker seeking to balance land-uses in the best interests of the public. We assessed how the solutions for these two perspectives differed in terms of which areas were prioritized for protection and agricultural development. We found substantial overlap between agricultural potential and biodiversity value: development of agricultural lands based solely on agricultural potential will have large negative effects on biodiversity values. If all suitable soils were converted to agriculture, three species would go extinct and 44 would lose more than 50% of their current distributions. Conversely, joint consideration of agriculture and biodiversity values allows 22,000+ km² of agricultural development with little biodiversity loss. Carbon farming represents a good alternative to agriculture in the 8,000+ km² of the tropical savannas identified as high-priority areas for biodiversity conservation. Our study shows the importance of planning strategically for multiple, and potentially conflicting land uses when making large land-use policy decisions.

27 PRIORITY QUESTIONS FOR BIODIVERSITY CONSERVATION IN MEDITERRANEAN-TYPE REGIONS

Francisco Moreira

Institute of Agronomy, University of Lisbon, InBIO Associate Laboratory

Nicky ALLSOPP, South African Environmental Observation Network (SAEON) ; Karen ESLER, Stellenbosch University ; Philip RUNDEL, University of California ; Peggy FIEDLER, University of California ; Ben MILLER, Botanic Gardens and Parks authority ; Grant WARDELL-JOHNSON, Curtin University ; Jasper SLINGSBY, University of Cape Town ; Margarita ARIANOUTSOU, University of Athens ; Danilo RUSSO, Università degli Studi di Napoli Federico II ; Lluís BROTONS, Forest Technology Centre of Catalonia ; Pablo MARQUET, Pontificia Universidad Católica de Chile ; Pedro BEJA, CIBIO-Centro de Investigação em Biodiversidade e Recursos Genéticos/ InBIO Associate Laboratory

This will be the concluding presentation of a symposium on the identification of priority questions for biodiversity conservation in Mediterranean-type regions. Resulting from a joint initiative of the Society for Conservation Biology (SCB) – Europe Section and the International Society of Mediterranean Ecologists (ISOMED) it aimed to identify questions that, if answered, would have a high probability of increasing the success of actions targeted at the conservation of biological diversity in the five Mediterranean regions of the world. In this presentation we will summarise the current state of implementation of the initiative and present the first results. Patterns in types of questions and thematic priorities will be compared across Mediterranean-type regions and stakeholder types, in order to identify topics of overall and regional importance. After the presentation, the floor will be open to exchange ideas and receive further comments from the participants.

FINDING MIDDLE GROUND: FROGS, PINES AND SUSTAINABLE FORESTRY IN CHILE

Virginia Moreno-Puig

Massey University

Dianne H. BRUNTON, Massey University

Telmatobufo bullocki is one of the most rare and endangered amphibian species in Chile's temperate forests. It is the top 5 EDGE amphibian, and one of the world's 100 priority species for conservation (ZSL, 2011). This ancient stream-breeding frog is micro-endemic to the coastal Nahuelbuta mountain range, a hot-spot for conservation that has suffered the recent replacement of nearly 70% of its natural forest by extensive commercial plantations of exotic pines and eucalyptus. Despite its potential detrimental effects, the impact of this land-use change on this critically endangered species has not been studied before. Some of the questions to be answered are: Are frogs using exotic plantations? Have plantations caused recent declines? Are plantations limiting amphibian dispersal? Can plantations and T. bullocki coexist in the long term?

Here I will present the results from a 4-year doctoral research project looking at several aspects of the species ecology and behaviour, aiming at finding ways to improve the current conservation status and securing the long-term survival of this Gondwanan relict. Some of the main results include improved and new knowledge about the species distribution, habitat use, movements, population genetics and life-history. Frogs were found migrating from breeding streams into adjacent forest, including mature pine plantations, up to 500 m upland. This suggests terrestrial habitat use is an important part of the life cycle, and that current legal protection of riparian zones (i.e. 5 to 20 m) might not be enough. Therefore, unless bigger riparian buffer zones, and permanent connectivity corridors are established, the future of this species might be in jeopardy. This highlights the urgent need for a more sustainable management of plantation forestry in Chile, a move that would not only benefit T. bullocki but also many other native species from these endemic-rich temperate forests.

HOPPING FROM THE FRYING PAN INTO THE FIRE: THE FUTURE OF TELMATOBUFO BULLOCKI UNDER CLIMATE CHANGE

Virginia Moreno-Puig

Massey University

Dianne H. BRUNTON, Massey University

Telmatobufo bullocki is a rare and critically endangered stream-breeding amphibian, endemic to Chile's temperate forests. Recent studies have shown they have complex habitat requirements, and have identified habitat loss, degradation, and fragmentation due to exotic forestry plantations as major threats. The species is known to occur in only a few localities within the Nahuelbuta mountain range; a hot-spot for conservation that has suffered a rapid, recent, and substantial loss of native forest. Using recent presence records and maximum entropy (Maxent) modeling, a species distribution model was created for T. bullocki in the Nahuelbuta range. The model reflects the relationship between the species presence and several relevant variables including topographic, climatic, and land cover. The best-performing model included elevation, precipitation, temperature, and percentage of native forest in the landscape as important variables predicting T. bullocki presence. To estimate the impact of recent native forest loss on the species distribution, the model was projected backwards into hypothetical past conditions of native forest cover. In addition, the potential impact of climate change was assessed through projecting the model into a future climate scenario under an intermediate representative concentration pathway (RCP4.5). The results suggest that not only T. bullocki distribution has been severely affected during the past century due to land-use change, but a further 70% reduction can be expected in the near future due to climate change alone. This highlights the urgent need to take immediate

and commensurable management measures in order to protect remaining habitat and populations, and minimize the predicted negative effects associated to climate change.

ECOSYSTEM SERVICE SUPPLY IN EUROPE: WHERE ARE WE NOW AND WHAT SHOULD WE EXPECT FROM THE FUTURE?

Maud Mouchet

Muséum National d'Histoire Naturelle

Rémy LASSEUR, UMR 5553 LECA ; Sandra LAVOREL, UMR 5553 LECA

The complex relationships among multiple ES supply and between the variety of demands for ES challenge landscape planning and environmental policies. Specifically, it is critical to foresee the impact of changes in one ES provision on other services or to set up an efficient management of multi-functionality. In the context of the EU FP7 VOLANTE project on the environmental and socio-economic consequences of transitions in land use, we developed a three-step methodological framework to analyse the interactions of multiple ES: (i) detecting ecosystem services associations, (ii) identifying bundles of ecosystem services and their geographic distribution, and (iii) the drivers of these bundles and trade-offs. Using this framework, we assessed current ES associations across Europe. We then investigated the evolution of ES associations under contrasting scenarios of land use transitions derived from SRES scenarios. We show that European ecosystems currently provide a variety of services, with often high multi-functionality (i.e. supply of multiple ES at a given location). Several services are closely and positively associated like biocontrol services, forest-related services and, to a lesser extent, carbon sequestration. Conversely, food-feed-fibre production is, not surprisingly, negatively associated to pollination, carbon sequestration and forested-related services. Future ES associations, on the other hand, vary across scenarios but also depend on the assumptions made about the evolution of bundles (i.e. the composition and number of bundles may or may not be constrained by our knowledge on current bundles). Here, we present one of the first spatially explicit assessments of ecosystem services supply across Europe and land use change scenarios. We will further discuss how the conceptualization of the evolution of ES bundles can modify projected trade-offs and synergies and interfere with future decisions of land use management in Europe.

MIGRATORY CONNECTIVITY OF THE ORTOLAN BUNTING

Caroline Moussy

Muséum National d'Histoire Naturelle

Eric PASQUET, Muséum National d'Histoire Naturelle ; Jean-Philippe SIBLET, Muséum National d'Histoire Naturelle ; Frédéric JIGUET, Muséum National d'Histoire Naturelle

The Ortolan Bunting (*Emberiza hortulana*) is a sub-Saharan migratory passerine breeding mostly across central and north of Europe. While it is a widely distributed and abundant species, important population declines have been recorded for several breeding populations, for instance in the Scandinavian and Baltic countries. The reasons for these declines are complex, although habitat loss through land-use change, intensive agricultural practices, climate change and hunting pressure are certainly involved. Further pressures could be applied at other times in the yearly cycle, during migration or at over-wintering sites. Unfortunately, the lack of information on migratory flyways, stop-overs or wintering areas precludes effective protection throughout the year. In such a context, the Museum of Natural History in Paris is leading an international program that aims to establish the migratory connectivity of this species and to estimate the origin and size of migratory population captured in south west France during annual traditional hunt. Geolocators are fitted to breeding males to establish migratory flyways and overwintering areas. Feathers collected on breeding birds and migrants are analysed for stable isotopes and genetics. A deuterium isoscape is built at the European scale using breeding bird samples and used to assign migrants to their probable breeding origin according to their deuterium value. Lastly, the genetic diversity and genetic structure of breeding populations were described after the development of specific microsatellite markers. Migrants can then be assigned to their putative breeding population according to their genotype. Here we give an account of the first results obtained from these genetic analyses on the migratory connectivity of the Ortolan Bunting.

CLIMATE CHANGE AND THUNBERGIA ATACORENSIS (ACANTHACEAE), A RARE AND ENDEMIC SPECIES OF THE ATACORA'S CHAIN: IMPLICATIONS FOR BETTER CONSERVATION STRATEGY

Jacob Koundouonon Moutouama

Laboratoire d'Ecologie, de Botanique et de Biologie végétale (LEB)

Belarmain FANDOCHAN, Ecole Nationale Supérieure des Sciences et Techniques Agronomiques, Université d'Agriculture de Kétou[INSTITUTE]Laboratoire d'Ecologie Appliquée, Université d'Abomey Calavi ; Samadori Honoré BIAOU, Laboratoire d'Ecologie, de Botanique et de Biologie végétale (LEB)

Conservation of endangered species occupies an important place in conservation biology because in theory they are most at risk of extinction. However our knowledge of the behavior of their ecological niche under climate change is limited. With a small number of occurrence records (15), we used maximum

entropy combined with Geographic Information System (GIS) to model the ecological niche of *Thunbergia atacorensis* and how climate change could affect the future geographical range (2050) of its suitable habitats. Presence records were collected and combined with current and future climate data from the considered study area. For future climate projections, the Miroc-H model was used under the new Representation Concentration Pathways' scenarios. Currently the most suitable habitats for *T. atacorensis* represent 8.68% of the national area. They were predominantly located in the Soudan endemism centre (mostly in the phytogeographical district (PD) of the Atacora chain) and a small part of the Soudan-Guinea transition zone (PD of Bassila). Currently only 4.69% of the protected areas' network is found to be highly suitable to the preservation of *T. atacorensis*. In other words 12.77% of suitable area of species are located in protected area network. This percentage will increase by 2050. The protected area network is relatively favorable to *T. atacorensis* conservation but conservation action of *T. atacorensis* should put an emphasis on riparian forest's protection, especially along the Atacora's chain which is the endemic zone of this endangered species. Key words: endangered species, Maxent, ecological niche, modeling, climate change, West Africa.

SELECTION OF DYNAMIC MODELS FOR BIRD POPULATIONS IN FARMLANDS

Lauriane Mouysset

CNRS

Marie MIGLIANICO, *Muséum National d'Histoire Naturelle* ; David MAKOWSKI, *Inra* ; Frédéric JIGUET, *Muséum National d'Histoire Naturelle* ; Luc DOYEN, *CNRS*

Agricultural changes have caused a severe decline in common bird community in Europe. Mitigating this loss requires to both understand and predict how agriculture affect biodiversity. The objective of this paper is to test different dynamic models coupling bird abundances and farming land-uses in the description and the prediction of birds to agricultural changes. The agro-ecological calibration relies on 2002-2009 data for 34 bird species and 14 agricultural systems in 620 small agricultural regions of metropolitan France. The models are compared through an indicator of goodness-of-fit and indicators of predictive quality. The results first stress the relevance of systemic, functional and mechanistic relationships between agriculture and bird populations both in descriptive and predictive contexts. However, it turns out that the best dynamic models to describe the past trends are not necessarily the most relevant to predict future trends. In particular, the role played by farming habitat is reinforced in the predictive context. Our study also suggests a new classification of farmland bird species according to the functional form of the intra specific competition and habitat quality.

CORAL REEF FISHES IN THE PHILIPPINES: FISHERIES AND CONSERVATION

Richard Muallil

Marine Science Institute - University of the Philippines
Porfirio ALINO, Marine Science Institute - University of the Philippines

The Philippines is within the Coral Triangle region, which is the global hotspot for coral reef biodiversity. Overfishing and various other anthropogenic disturbances are seriously threatening the coral reef fish communities in the country. In this study, we conducted fish visual census on coral reefs in over 40 municipalities all over the Philippines to assess the condition of coral reef fish communities, focusing on commercially important species. In each municipality, 8-10 10m by 50m belt transects, half of which were established inside marine protected areas (MPAs) and the other half in adjacent fished areas (FAs), were surveyed. Results showed that fish biomass in MPAs was generally higher by about 30% than in FAs. Fish biomass in MPAs was much higher for large individuals (i.e. ≥ 25 cm total length), the high trophic level species and those which are included in the IUCN red list of threatened species. There are also more species found in MPAs than in FAs. Unfortunately, only very few of the assessed reefs, including those inside MPAs, were in pristine condition suggesting that the current MPAs may not be strong enough to protect coral reef fishes from the negative effects of overfishing. We also conducted interview surveys with at least a hundred small-scale fishers in each municipality to gauge fishing pressure on coral reef fishes and to determine fishers' perception toward MPAs as coral reef fish conservation tool. Further, we discussed why some MPAs performed better than others using available ecological and socio-economic attributes of the sites. Our findings provide valuable science-based insights that will inform policy makers in prioritizing management actions for effective conservation of the valuable but highly threatened coral reef fishes.

CLIMATE CHANGE VULNERABILITY ASSESSMENT TOOL FOR CORAL REEF FISHERIES (CCVA-COREFISH)

Richard Muallil

Marine Science Institute - University of the Philippines
Samuel MAMAUAG, Marine Environment and Resources Foundation ; *Porfirio ALINO, Marine Science Institute - University of the Philippines*

Coral reef fisheries provide the livelihood of millions of population in the Philippines. However, overfishing and other anthropogenic disturbances, which are further aggravated by impacts of climate change, are seriously threatening the sustainability of coral reef fisheries in the country. In this study, we developed a tool called Climate Change Vulnerability Assessment Tool for Coral Reef Fisheries (CCVA-

CoReFish), which assesses the vulnerability of coral reef fisheries to impacts of climate change. CCVA-CoReFish follows the Intergovernmental Panel for Climate Change's (IPCC) framework of vulnerability assessment (VA), where Vulnerability is a function of Sensitivity, Exposure and Adaptive Capacity. It is also patterned from another VA tool we developed earlier called the Tool for Understanding Resilience of Fisheries (VA-TURF), which is designed mostly for localized (i.e. among villages within a municipality) VA. CCVA-CoReFish, on the other hand, is designed to cover much larger spatial scales in order to allow comparison of vulnerability levels among sites that are spatially far from one another (i.e. among municipalities). Like VA-TURF, CCVA-CoReFish also uses three sub-components, namely, (i) fisheries, (ii) coral reef ecosystems, and (iii) socioeconomic, both for Sensitivity and Adaptive Capacity components. For Exposure component, CCVA-Core Fish uses more parameters in addition to wave exposure such as sea level rise and sea surface temperature, which are more relevant for municipality-level VA. In this study, we demonstrated CCVA-CoReFish using data collected from more than 30 municipalities all over the Philippines. Insights are provided to inform policy makers for prioritization of management actions that can effectively and efficiently address the threats of climate change on coral reef fisheries and the millions of highly fishery-dependent population in the country.

FISH FOREVER: HOW MANY, FOR HOW LONG? MEASURING CONSERVATION AND SOCIAL RESULTS ACROSS FIVE COUNTRIES IN A GLOBAL SMALL-SCALE FISHERIES INITIATIVE

Janelle Mueller

Rare

Helen FOX, Rare ; Gavin MCDONALD, University of California, Santa Barbara ; Alejandro ARRIVILLAGA, Rare ; Michaela CLEMENCE, University of California, Santa Barbara ; D DARMAWAN, Rare ; Rod FUJITA, Environmental Defense Fund ; Kevin GREEN, Rare ; Raymond JAKUB, Rare ; Kendra KARR, Environmental Defense Fund ; Jake KRITZER, Environmental Defense Fund ; Sarah LESTER, University of California, Santa Barbara ; Roquelito MANCAO, Rare ; Enrico MARONE, Rare ; Pablo ROJAS, Rare ; Bernal VILELA, Rare

Improving the management of struggling small-scale fisheries has become a major focus of numerous governments and international conservation organizations. The approaches vary by region and by the implementing partners involved, yet some form of co-management has been successful in many contexts. Building on this, the "Fish Forever" program was launched in February 2014 by Rare, Environmental Defense Fund, and the Sustainable Fisheries Group of UC Santa Barbara to work with governments and communities in Indonesia, the Philippines, Belize, Brazil and Mozambique through the

implementation of territorial use rights in fisheries (TURFs) combined with marine reserves (aka TURF-Reserves). We hypothesize that TURF-Reserves can align incentives and increase the stewardship in small-scale fisheries through two mechanisms: 1) the managed-access of a TURF reduces the ability of non-local fishers to exploit the resource and increases the proportion of total catch available to local households while creating a way to implement catch or effort controls with potentially high levels of compliance; 2) the reserve enables fish stocks to recover within its borders, presumably leading to spillover of these stocks into the nearby TURF. The application of this model in 5 countries with different ecological, cultural, economic, and governance contexts provides an opportunity to evaluate these hypotheses, and the extent to which the model is generalizable. Fish Forever is designed to achieve a variety of social and ecological goals, making comprehensive monitoring and evaluation essential, since these outcomes are the basis of the "benefits exchange" that drives the Fish Forever model. To evaluate progress toward goals and adaptively manage, we anticipate collecting data on the same metrics across sites. Here we present the monitoring framework, how it has been adapted to account for country-level variability while retaining comparative ability, and preliminary results.

LEVELS AND TYPES OF HUMAN WILDLIFE CONFLICTS IN KENYA FROM 2008 - 2012

Lucy Wamuyu Muithui

Laikipia University

Nahashon MWONGERA, Kenya Institute of Public Policy Research and Analysis (KIPPRA)

Human wildlife conflict (HWC) is a severe and growing problem in today's world. The rate of human wildlife conflict in protected and unprotected areas in Kenya over the last decades has been a matter of concern by the both government and stakeholders involved in conservation efforts. The costs incurred by the communities living close to these areas in terms of human deaths, injuries, threats and loss of property is extensive. Conservation of wildlife has also been affected as people retaliate by killing animals responsible for the conflict and poaching for their economic gain leading to near extinction of some species. This study assessed the levels and types of (HWC) in Kenya. HWC data from Kenya Wildlife Service (KWS) was used to analyze the type and trends of HWC. About 50 people and 100 wild animals die yearly as a result of HWC. To reduce these conflicts, there is need to have good resolution strategies that aim at changing people attitudes. This can be done through education and by ensuring that affected communities benefit from proper wildlife management. Harmonization of both wildlife management and human development goals can help resolve conflicts since it involves bringing the two groups together to come up with sustainable solutions for wildlife and people.

PROTECTING THE FORESTS WHILE ALLOWING REMOVAL OF DAMAGED TREES MAY ECOLOGICALLY DEGRADE THE HYRCANIAN BEECH FORESTS OF IRAN

Jörg Müller

Nationalpark Bavarian Forest

Khosro SAGHEB-TALEBI, Research Institute of Forests & Rangelands ; Hassan BARIMANI, Agricultural and Natural Resources Research Centre of Mazandaran ; Martin GOSSNER, TU Munich ; Simon THORN, TU Munich ; Sebastian SEIBOLD, TU Munich

The 1.8 million ha of Hyrcanian forest south of the Caspian Sea represent a remarkably intact ecosystem with numerous old-growth features and unique species assemblages. To protect these forests, Iranian authorities passed a law which protects healthy trees but permits the removal of injured, dying and dead trees. To quantify the ecological effects of such a strategy, we sampled saproxylic beetles and true bugs in 24 plots distributed across the entire altitudinal gradient of Oriental beech forests. Of all environmental variables tested, dead wood volume best explained overall species richness, richness of endemics and of 'Urwald relicts', as well as community composition. Due to the striking evidence that dead wood is the major driver of saproxylic diversity in these forests, we urge Iranian authorities to reconsider their law and to restrict logging to healthy trees. Otherwise, a similar ecological degradation as experienced in European beech forests can be expected.

163: ECOSYSTEM BASED ADAPTATION (EBA) FOR MOUNTAIN ECOSYSTEMS: LESSONS AND EXPERIENCES FROM NEPAL, UGANDA AND PERU.

Musonda Mumba

United Nations Environment Programme

Resilient ecosystems have been seen as an important foundation to human well-being and also necessary for better adaptive capacity for the communities that depend on them. Resilience has been described as the ability of a social or ecological system to maintain basic structural and functional characteristics over time regardless of external stressors. It's on this premise that the concept of Ecosystem based adaptation (EbA) is particularly relevant. Evidence has shown that mountain ecosystems are particularly vulnerable to climate change and as such the ecosystem services that they provide for communities and species within and without the proximity of these areas are also threatened. This paper discusses the Ecosystem based adaptation (EbA) approach that has been applied to mountain ecosystems of Nepal, Peru and Uganda. Vulnerability Impact Assessments (VIAs) were undertaken in all three countries to understand community

vulnerability, mapping the important ecosystems services provided and options offered for reducing this vulnerability for resilient ecosystems. The outcomes from the VIAs informed the EbA interventions options in all three countries. The EbA implementation in all three countries also demonstrates a move from EbA conceptualization to realization on the ground and at the policy level. Finally this paper will also examine the policy implications of this approach nationally and ability for the work to be up-scaled to other mountain ecosystems and other ecosystems as well. Key words: Ecosystems services, Climate change adaptation, mountains, Ecosystem based Adaptation, Uganda, Peru, Nepal

INFLUENCE OF VINEYARD EXPANSION ON CALIFORNIA'S WOODLAND BIRD COMMUNITIES

Andres Munoz Saez

University of California, Berkeley

Emily HEATON, University of California, Berkeley ; Adina Merenlender, University of California, Berkeley

The agricultural matrix has long been a part of Mediterranean-climate ecosystems and is the primary factor for why these ecosystems are among the most threatened on Earth. Vineyard expansion is one of the main drivers of land use change for these regions today. California oak woodlands are one of the richest mediterranean-climate ecosystems, providing habitat for more than 300 terrestrial vertebrates. The goal of this study is to determine how vineyard landscapes influence bird abundance and richness in California's north coast woodlands. Bird survey plots were done at 137 oak woodland locations for two years across a gradient of surrounding vineyard development. The surveyed areas were characterized at local and landscape scales through vegetation plot data and aerial photographs to quantify land cover. Generalized linear models were used to analyze the relationship among bird assemblages, local vegetation, and surrounding vineyard land cover. Measures of local woodland structure contributed more to explaining the abundance of cavity nesters, agricultural adapters, and granivorous birds than surrounding land cover information across the vineyard development gradient. These results emphasize the importance of maintaining remnant patches of woodland in Mediterranean-climate wine grape growing regions where biodiversity conservation is a high priority.

PRIORITIZING FRESHWATER HABITATS FOR CONSERVATION IN INDIA

Madhushree Munsri

Ashoka Trust for Research in Ecology and the Environment

N. A. ARAVIND, Ashoka Trust for Research in Ecology and the Environment

Freshwater systems harbour a wide range of biodiversity, provide a range of ecosystem services and are important for sustaining human wellbeing. Freshwater systems, being the hotspots for human activities, have been overexploited, polluted and habitats are degraded. Until recently, water bodies in India did not have any special policy enactments for their conservation. Their management was largely dependent on the legal status of the larger ecosystem in which they are located. Lack of policies and anthropogenic pressures not only led to loss of biodiversity, but have also greatly altered the quality and quantity of safe water available for human use. Thus, freshwater habitats require immediate conservation efforts. However, with increasing human population demanding for more space, it is not possible to convert large areas into conserved areas in India. Thus for conserving these habitats, it is practical to identify sites that are of high conservation value. In India, all previous attempts of prioritization for conservation were restricted to terrestrial systems and have looked only at the biodiversity factors, without considering the livelihood benefits. The present work was carried out to develop a protocol by combining biodiversity factors along with informations on threats, resource use practices and biophysical factors to identify high conservation value sites. This is the first ever attempt in India to look at the freshwater prioritization in a comprehensive manner. The model helped in identifying and mapping sub-basins that require immediate attention. Identification of these sub-basins not only helps in improving conservation efforts, but the result can also be used in developing management plans at local sub-basin level to develop sustainable strategies that support both biodiversity conservation as well as livelihood opportunities.

CLARIFYING CONNECTIVITY PATTERNS IN THE MEDITERRANEAN SEA BY A MULTI-DISCIPLINARY APPROACH: THE ROLE OF EARLY LIFE HISTORY STAGES OF RED MULLET (MULLUS BARBATUS)

Manuel Muntoni

University of Cagliari

Delphine ROCKLIN, University of Murcia ; Cheoma FRONGIA, University of Cagliari ; Irene MUNOZ, University of Murcia ; Carlos VERGARA CHEN, University of Murcia ; Jessica GARCIA, University of Murcia ; Maximiliano GIACALONE, CNR-IAMC ; Olga RENONES, IEO ; Amalia CUADROS CASADO, IEO ; Nuria RAVENTOS, Barcelona Otolith Reading Services, CEAB-CSIC ; Jonathan BEUVIER, Mercator Ocean ; Jose Antonio GARCIA

CHARTON, University of Murcia ; Giovanni D'ANNA, CNR-IAMC ; Matteo MURENU, University of Cagliari

Integrating connectivity patterns into marine ecosystem management is a fundamental step, specially for stock subjected to the combined impacts of human activities (overfishing, habitat degradation, etc.) and climate changes. Thus, management of marine resources must incorporate the spatial scales over which the populations are connected. Notwithstanding, studying these dynamics remains a crucial and hard task and the predictions of the temporal and spatial patterns of these mechanisms are still particularly challenging. This research aimed to puzzle over the red mullet *Mullus barbatus* population connectivity in the Western Mediterranean Sea, by implementing a multidisciplinary approach. Otolith sclerochronology, larval dispersal modelling and genetic techniques were gathered in this study. More particularly, this research project focused on early life history stages of red mullet and their role in the characterization of connectivity dynamics. The results show that *M. barbatus* larval dispersal distances can reach a range of 200 km. The differences in early life traits (i.e. PLD, spawning and settlement dates) observed between various areas of the Western Mediterranean Sea suggest a certain level of larval patchiness, likely due to the occurrence of different spawning pulses during the reproductive period. The dispersal of individuals across distant areas, even not significant in demographic terms, is accountable for the maintenance of the genetic flow among different demes. Fluctuations in the level of exchange among different areas, due to the variability of the source-sink dynamics, could have major implications in the population connectivity patterns. These findings highlight the reliability of combining several approaches and represent a benchmark for the definition of a proper resource management, with considerable engagements in effectively assuring the beneficial effects of the existent and future conservation strategies.

91: AN EVIDENCE ASSESSMENT TOOL FOR ECOSYSTEM SERVICES AND CONSERVATION STUDIES

Due to the striking evidence that dead wood is the major driver of saproxylic diversity in these forests, we urge Iranian authorities to reconsider their law and to restrict logging to healthy trees. Otherwise, a similar ecological degradation as experienced in European beech forests can be expected.

ECOLOGICAL EFFECTS ON PRIMATE SOCIAL NETWORK STRUCTURE AND IMPLICATIONS FOR INFANT SURVIVAL

Derek Murphy

University of Aberdeen

David LUSSEAU, University of Aberdeen ; Sp HENZI, University of Lethbridge ; Louise BARRETT, University of Lethbridge

For social animals, the social environment is arguably as influential as the ecological environment in determining individual fitness. An individual's social environment determines its ability to acquire and pass on information, its susceptibility to disease, and even its longevity and reproductive success. The social environment, however, also responds to fluctuations in local ecological conditions. We used social network analysis to determine the effects of the ecological environment on the network structure of a free-ranging troop of chacma baboons. We found that individuals display seasonal, cyclical patterns of sociality, but these patterns were perturbed by ecological drivers, such as variation in rainfall levels within seasons, and a disease epidemic. We then investigated the impact of the social environment experienced by a mother baboon on her infant's chances of survival to independence. Allogrooming, an important social behaviour among old world primates, was particularly important in predicting infant survival. While mothers of young infants typically receive more grooming and attention from other females, we found that the amount of grooming mothers directed towards others was a more important predictor of infant survival. Females increased their rate of grooming others after becoming mothers, and those mothers who groomed others very little had very low probability of their infants surviving to one year. Grooming interactions were also affected by rainfall levels. In dryer seasons, females groomed a more diverse group of partners, but engaged in grooming less often than in wetter seasons. Our results suggest that females actively alter their patterns of sociality following the birth of an infant, and do not simply engage passively in social interactions. However, their ability to choose the optimal response for their infant's survival may be restricted by environmental pressures.

CAN REDD+ DELIVER BIODIVERSITY BENEFITS? SPATIAL PATTERNS OF CARBON, BIODIVERSITY AND REDD+ PROJECTS IN INDONESIA

Josil Philomena Murray

Bangor University

Richard GRENYER, School of Geography and the Environment, University of Oxford ; Sven WUNDER, Center for International Forestry Research ; Niels RAES, Naturalis Biodiversity Center, Darwinweg ; Julia JONES, Bangor University

There are concerns that Reduced Emissions from Deforestation and Forest Degradation (REDD+) may fail to deliver potential biodiversity co-benefits if it is focused on high carbon areas. We explore the spatial overlaps between carbon stocks, biodiversity, projected deforestation threats, and the location of REDD+ projects in Indonesia, a tropical country at the forefront of REDD+ development. For biodiversity, we assembled data on the distribution of terrestrial vertebrates (ranges of amphibians, mammals, birds, reptiles) and plants (species distribution models for eight families). We then investigated congruence between different measures of biodiversity richness and carbon stocks at the national and sub-national scales. Finally, we mapped active REDD+ projects and investigated their carbon density, potential biodiversity richness, and modelled deforestation pressures, relative to protected areas and non-protected forests. The results show little internal overlap between hotspots (richest 10% of cells) of different measures of potential species richness. There is also no consistent spatial congruence between carbon stocks and the biodiversity measures: a weak negative correlation at the national scale masks highly variable and non-linear relationships island by island. Current REDD+ projects are preferentially located in areas with higher species richness but lower carbon densities than protected areas and non-protected forests. Although a quarter of the total area of these REDD+ projects face relatively high deforestation pressure, the majority of the REDD+ area do not. In Indonesia at least, first-generation REDD+ projects are located favorably to deliver biodiversity benefits (possibly reflecting the high involvement of conservation NGOs). However, if REDD+ is to deliver additional gains for climate and biodiversity, it will need to focus more on forests with the highest threat to deforestation which will have cost implication for future REDD+ implementation.

INDIVIDUAL VARIATION IN TEMPORAL AVOIDANCE OF TRAFFIC IMPACTS SURVIVAL FOR AN URBAN CARNIVORE

Maureen Murray

University of Alberta

Colleen Cassady ST. CLAIR, University of Alberta

Many species living in developed areas adjust their activity and habitat selection to avoid humans. Such avoidance might reduce the risk of vehicle collisions, which tend to occur most frequently in spring and fall and at dusk and dawn. The ways by which animals might avoid vehicle collisions are poorly understood, but could be investigated in species that thrive in areas with high road densities such as cities. We explored potential mechanisms for avoiding vehicles by examining relationships between vehicle mortality and movement in coyotes (*Canis latrans*), an urban-adapted carnivore that inhabits many North American cities. We measured seasonal patterns of mortality for 80 road-killed coyotes and compared these patterns to the movements of 19 coyotes fitted with GPS collars. Specifically, we used steps between 3-hour GPS locations to compare the activity patterns and road crossings made by coyotes that were or were not killed in vehicle collisions. Reports of road-killed coyotes were highest in spring and fall, and during this time collared coyotes that were killed on roads ($n=7$) were more active at rush hour than were surviving collared coyotes ($n=12$). Vehicle collisions were most associated with crossing roads when traffic volume was higher; road-killed coyotes crossed most often at dusk, and earlier in winter when days were shorter, while surviving coyotes crossed roads mainly at night in all seasons. Temporal avoidance of human activity appears to vary across individuals and to be important for the co-existence of humans and wildlife, especially in highly fragmented areas where avoiding roads may be less feasible. Management strategies that foster separation of humans and wildlife in time, for instance using hazing techniques or by deploying on-demand deterrents at dusk in spring and fall, may help to mitigate vehicle-caused mortality for many species.

MANAGING SCALE DEPENDENCE OF DISTRIBUTION MAPS IN ECOSYSTEM RISK ASSESSMENT

Nicholas Murray

University of New South Wales

David KEITH, University of New South Wales

In 2014, the IUCN launched the Red List of Ecosystems, which is founded on a set of five criteria for assessing the conservation status of ecosystems. Two of the criteria rely on accurate measurements of the extent and distribution of ecosystems; criterion A requires estimates of ecosystem area over time to assess declines in ecosystem extent, and criterion B utilises two standardised measures of spatial distribution, the area of occupancy (AOO) and the extent of occurrence (EOO). With increasing use of a wide range of remotely sensed data for ecosystem mapping, the spatial data used for developing ecosystem maps often differs in grain size (resolution). Grain size can significantly influence area estimates and distribution patterns, and the potential consequences of ignoring grain

size include erroneous classifications of the risk of ecosystem collapse, incorrect identification of areas of high conservation priority and potentially invalid comparisons of ecosystem status across time and space. Through a series of simulations using a global dataset of more than 1000 ecosystem distributions, we investigate the influence of grain size on assessment outcomes under the Red List of Ecosystems criteria. Our results indicate that the Red List of Ecosystems criteria are robust to grain size for the majority of ecosystems assessed. However, our analysis suggests that the Red List of Ecosystems spatial criteria could be improved by using scale-area relationships to explicitly incorporate grain size into criteria thresholds, reducing information loss and utilizing the full benefits of high-resolution sensor data currently available. In addition, we provide practical guidance on the application of the Red List of Ecosystems to a variety of ecosystem types.

RUN-OF-RIVER HYDRODAMS CHANGE HABITAT QUALITY BY INCREASING TEMPERATURE VARIABILITY AND STRANDING RISK FOR COASTAL TAILED FROG TADPOLES.

Rylee Murray

Simon Fraser University

Michael ARBEIDER, Simon Fraser University ; Wendy J PALEN, Simon Fraser University

Around the world small Run-of-River (RoR) hydrodams are largely touted as a low-impact alternative to large storage dams as they maintain relatively natural flow regimes and have regulated minimum flows designed to conserve an acceptable amount of wetted habitat. However, acute fluctuations in flow, due to changes in electricity generation, introduce extreme variation in water level, while chronic low flow below the dam may increase temperature. The link between acute flow disruption and adverse effects such as stranding – when animals cannot keep pace with rapid reduction in water level – has been established for some vertebrates, such as salmonids, but the response of benthic vertebrates is unclear. We used an in situ mesocosm to test the response of the Coastal Tailed Frog tadpole to changes in stream water level and found that tadpoles were 30 times more likely to be stranded during reductions in water level faster than 5cm/hr. Additionally, we monitored stream water levels and temperature throughout the south coast of British Columbia, Canada along cross-sections of a variety of channel morphologies above and below RoR dams to quantify the proportional increase in 'shallow habitat' (<20cm) that may expose tadpoles to increased stranding risk and warmer temperatures. We found that stream sections below the dam had proportionally more shallows than would be expected if discharge rates were the same as above the dam, and that disruptions in flow exceeded the naturally observed variation, causing rapid changes in water level. Additionally, streams were on average >1°C warmer below

the dam. Our results indicate that RoR dams are changing the quality of habitat by increasing temperature and the risk of stranding for tadpoles. Future work will focus on the effects of increasing temperature on performance and growth of Coastal Tailed Frog tadpoles.

ALPINE GRASSLAND PALAEOECOLOGY OF THE VIRUNGA VOLCANOES: A NEW PHYTOLITH RECORD FROM MT. MUHAVURA, EASTERN AFRICA

May Murungi

University of the Witwatersrand

Gayle MCGLYNN, Trinity College, University of Dublin ; Julius LEJUU, Mbarara University of Science and Technology

The Virunga volcanoes are located in the Albertine Rift, one of the most important conservation areas in Africa but until recently, very little has been published regarding how their vegetation has responded to the environment over the past several millennia. A recent pollen study has been conducted with the aim of reconstructing the vegetation history and associated environmental changes at high altitude. Phytolith analysis (plant microfossils) offers complimentary data and the opportunity to refine our knowledge of such palaeoenvironments where grasses dominate. This paper presents results of an analysis of phytoliths from sedimentary records from a crater lake at the summit of Mt. Muhavura (4127 m asl) and selected alpine flora that provide insights into the grassland history of an alpine setting estimated to the last two millennia. C3 Poaceae characteristic of cold climate/ high altitude and Panicoideae grasses (mainly C4) that are characteristic of warm and wet climate seem to co-exist throughout this period. Whereas phytoliths prove to be an important tool in reconstructing past grasslands, we discuss the issues involved in interpreting phytolith records from such high altitudes and the tentative results present a foundation for future interpretations of the palaeoenvironmental data.

ECOLOGICAL AND GENETIC TRAITS OF THREATENED CARIBOU: CONSERVATION PLANNING FROM THE INDIVIDUAL TO THE METAPOPULATION

Marco Musiani

University of Calgary

Crysoula GUBILI, University of Calgary ; Byron WECKWORTH, University of Calgary ; Mark HEBBLEWHITE, University of Montana ; Stefano MARIANI, University of Salford

The Canadian government proposed the use of ecologically and evolutionarily discrete Designatable Units (DUs) as primary management units for threatened caribou under the Species at Risk Act. Overall, caribou units are organized hierarchically, with ecotypes (sometimes called "populations") including multiple DUs, and DUs including multiple "local populations", or herds. Recovery strategies were recently released for two ecotypes:

"Boreal" and "Southern Mountain". However, these strategies adopt contrasting definitions for finer-scale units within each DU. To reconcile the discrepancies, we used for the first time an individual-based approach to detect distinguishable caribou units and at the same time to determine the drivers of population differentiation and isolation. First, we employed autosomal microsatellites to estimate gene flow among individuals in herds representing 2 ecotypes and 3 DUs. Then, Causal Modelling was used to examine the factors contributing to isolation of caribou units. Migratory or sedentary behaviour of individuals was documented with satellite-GPS technology and also tested as contributing factor. We found that geographic distances, habitat (un)suitability between units and low population size had a direct effect on gene flow, with far lesser influence by anthropogenic habitat fragmentation or by presence of predators. Our results therefore indicate the need to evaluate and maintain quality of habitat between caribou conservation units to avoid population isolation –i.e. not just amount of habitat within herd ranges. Moreover, genetic variation was influenced by whether individuals were migratory or sedentary, which calls for a more nuanced approach to conservation planning. Overall, we argue that using herds as conservation units within a DU is often too fine a scale for recovery planning. Instead, the emphasis on maintaining meta-population dynamics within DUs is essential for the long-term recovery of caribou in Canada.

A FRAMEWORK FOR MEASURING CONFLICT IN CONSERVATION

Karen Mustin

Universidade Federal do Amapá

Morena MILLS, University of Queensland ; Fernanda MICHALSKI, Universidade Federal do Amapá ; Juliette YOUNG, NERC Centre for Ecology and Hydrology ; Steve M. REDPATH, University of Aberdeen

Conflicts are ubiquitous and occur when different groups pursue incompatible goals, and where one side is imposing their views or has more power to act. In the context of conservation, conflicting goals typically include farming, hunting, recreation, forestry or other industry. There is growing recognition among conservationists that conflicts must be managed in order to assure positive outcomes for biodiversity and human livelihoods alike. Conservation conflicts have two main elements: one related to human-animal interactions and one related to human-human conflict. In general the focus has been on the impacts of wildlife on humans, such as crop-raiding by large herbivores or losses of livestock to predators. This approach belies the more complex conflicts between the various people involved, which might include differences in values, damaged relationships or feelings of injustice. So, even in situations where the impact of wildlife on people has been reduced, the conflicts may still be present. Here we argue that

conservationists need to understand the social conflicts which underlie such human-wildlife impacts. In order to identify where conflict management interventions are most needed we need to be able to measure conflict in a way that allows comparisons to be made. Here we draw upon literature from applied development, peace-building and social psychology to propose a framework structure which details the different components of conservation conflicts including both the issues which are a source of conflict, and the behaviours which those involved display. We also propose methodologies to measure the various components of conservation conflicts, so that we can begin to map out the conflicts which hinder our conservation efforts.

LONG-TERM DEMOGRAPHY AND RECENT IDENTIFICATION OF DISEASE: USEFUL INFORMATION FOR CONSERVATION

Erin Muths

U.S. Geological Survey

Bradley LAMBERT, Colorado Natural Heritage Program ; Scott SCHNEIDER, Colorado Natural Heritage Program ; Robert SCHORR, Colorado Natural Heritage Program

Information about population dynamics prior to perturbation (i.e., baseline data) is lacking for many species. Perturbations, caused by climate change, disease or other stressors can lead to population declines and conservation concerns. A dearth of baseline information challenges our ability to anticipate and respond to agents of population decline. Without a picture of what a system looks and behaves like in a steady or healthy state, it is difficult to identify the effects of perceived stressors and thus implement actions to ameliorate those effects. There are only a handful of boreal toad (*Anaxyrus boreas*) populations remaining in the southern Rocky Mountains (SRM), USA and very few are disease-free. Boreal toads in the SRM putatively represent a distinct population segment and are being considered for Federal listing as endangered. Despite the apparent region-wide occurrence of the amphibian chytrid fungus (*Bd*), our focal populations have revealed no evidence of this pathogen. Long-term data and disease-free status elevate these populations to a vital resource for understanding the dynamics in a system without disease and thus informing conservation efforts to secure this toad in the SRM. We assessed demographics at three sites to bolster our understanding of a disease-free system and to determine if earlier work was peculiar to the single site or representative of toad populations in this region in general. Despite care in clean protocols, one of our sites tested positive for *Bd* in 2014. While this new information did not change the aims of our analysis, the presence of *Bd* shifts the context for our demographic data, adds immediacy to our conclusions and allows for a discussion of differences in vulnerability among sites.

AGRO-DIVERSITY IN A COMMERCIAL SUGARCANE CULTIVATION LAND MATRIX IN A SUBSISTENCE ECONOMY

Edward Nector Mwavu

Makerere University, Kampala

Understanding the impacts of commercial agriculture on biodiversity in a landscape is critical for biodiversity sustainability and meeting natural resources dependent households' needs in the face of increasing human population and climate change. In this study, the level of agro-diversity and its contribution to rural household livelihood strategies within a commercial sugarcane cultivation landscape was assessed with a view to enhance our understanding of the impacts of commercial agriculture on agro-diversity conservation and household livelihood strategies. A total of 68 crop species from 27 families and 46 genera were recorded from 120 home-garden patches within a commercial sugarcane cultivation land matrix. Plant species richness within the home-gardens was low ranging from 6 to 19 species. The sampled home-gardens featured high species diversity with Alpha diversity based on a Shannon-Weiner diversity Index (H') ranging from 0.6 to 2.3 and 104 out of 120 sampled home-gardens having a Shannon's Index greater than 1. Agro-diversity differed significantly ($F_{11,108}=2.165, p<0.05$; Global RANOSIM = 0.153, $p<0.001$) across study villages. The crops, which are most important and commonly maintained in the home-gardens, are the ones utilised for food and income generation. Commercial sugarcane growing is the major factor resulting in reduced land available for food crop. This is a threat to food crop availability and conservation consequently affecting household food security. Trees that provide fuel wood and food are those that are commonly maintained in the home-gardens. In conclusion, home-gardens continue to maintain crop diversity making their management very important for food security, biodiversity conservation and diversification of rural household livelihoods in the face of climate change and declining land availability and fragmentation. Key words: Biodiversity, climate change, commercial agriculture, home-gardens, rural livelihoods.

HOW TO OVERCOME A BUSY ROAD: THE WOLF CANIS LUPUS MOVEMENT ACROSS MOTORWAYS IN POLAND

Robert Mysłajek

University of Warsaw, Faculty of Biology

Sabina NOWAK, Association for Nature 'Wolf'

The transport infrastructure is considered one of the most harmful for wildlife. Roads may act as a barrier to animal movement and reduce habitat connectivity hampering

dispersal and limiting access to vital sources. The development of motorways in Poland accelerated after accession to the European Union becoming a potential treat for terrestrial animals, including wolves recovering in western Poland. Currently the largest wolf subpopulation in Polish lowland inhabits the Lower Silesian Forest (ca. 2,000 km²) located near the Polish-German state border. The area is intersected by two major roads – partly upgraded A18 motorway and the newly built section of A4 motorway. During our study conducted in 2010-2013 we applied non-invasive DNA monitoring in order to recognize a potential barrier effect of the transport infrastructure for wolf dispersal, as well as intensive field tracking to assess habitats utilization by wolves in relation to main roads and railways within forest. We also evaluated the use of 16 wildlife crossing structures by wolves and their primary prey on the 51 km-long section of A-4 motorway using sand-beds and video cameras. We recorded exchange of wolves between the Lower Silesian Forest and other forest tracts located both in Germany and Poland. Wolves utilized proximity of motorways during their hunting activity, but avoided setting dens and rearing pups closer than 1.9 km from major roads. Both wolves and their prey used wildlife crossing structures, however those with high human activity were avoided. Wolves used all sorts of wildlife crossing structures, but with preference for overpasses. We recorded differences in behaviour of individuals crossing overpasses and underpasses, with number of fear responses observed in wolves using underpasses. We conclude that adequate wildlife crossing structures are able to sustain an exchange of individuals between subpopulations and utilization of wolf territories intersected by motorways.

STUDIES ON SOME ASPECTS OF REPRODUCTIVE BIOLOGY OF CUTTLFISH SEPIA OFFICINALIS IN THE SOUTHERN MOROCCAN ATLANTIC (BOUJDOUR, CAP BLANC)

Fatima Mzaki

Hassan 2 university, faculty of sciences Ain Chok Casablanca *Ouadiaa TAZI, Hassan 2 university, faculty of sciences Ain Chok Casablanca ; Khalid MANCHIH, National Institute of Fisheries Research (INRH)*

Study of reproductive biology of any fish species is important to get information for successfully management its stocks. The cuttlefish *sepia officinalis* is the second fished cephalopod species along the Moroccan coasts and most valuable commercial cephalopods. However, their reproductive biology, essential for fishery management, is poorly known. So, some aspects of reproductive biology of cuttlefish, *Sepia officinalis* in the southern Moroccan Atlantic (Boujdour, Cap Blanc) are studied: Sex-ratio, length at first sexual maturity, gonadosomatic index (GSI) and spawning periodicity. The samples used for this study are sorted monthly from

commercial catches of coastal trawlers operating in this area from March 2014 to October 2014. Multi-modal size-frequency distributions were apparent in both sexes. Sexually mature cuttlefish were found throughout the year, with generally more mature cuttlefish in spring-summer and fewer in autumn-winter. The maturity in both sexes peaked in spring and a spawning period in April is revealed by the study of the gonadosomatic index (GSI). The Size at maturity is different between both sex, with female maturing over a greater size range (125-140 mm (mantle length ML)) than male (70-85 mm ML). Fecundity was estimated by counting the number of maturing and mature ova of *Sepia officinalis*, in the southern Moroccan Atlantic Sea, estimated from (1000 at 100) eggs per female. Mean egg diameters of matures oocytes is recorded to 50 mm. The results could be useful in drawing up more suitable management measures for *sepia officinalis* stocks

CAPACITY BUILDING KEY TO IMPLEMENTING SPECIES CONSERVATION PLANS MALAWI'S PROTECTED AREAS: LIWONDE NATIONAL PARK CASE STUDY

Tiwonge Mzumara

University of KwaZulu Natal

Effectively managed protected areas (PA's) are a proven method for safeguarding biodiversity. Research and monitoring are among the key components of PA effective management. In most developing countries, financial and human resources available limit monitoring and research of biodiversity in PA's. Liwonde National Park (LNP) in southern Malawi is one of the 'popular' PA's in the country. In 2014 a conservation plan for the near threatened small parrot, the Lilian's Lovebird *Agapornis lilianae*, was submitted to the management of LNP. LNP is the only PA in Malawi where a breeding resident population of the species occurs. This study was conducted to evaluate the human and financial capacity of LNP to implement the conservation plan. Furthermore, alternative ways in which the conservation plan could be implemented were presented. Findings confirmed that in its current state, LNP is unable to implement the conservation plan. Financial capacity is low with only large mammals having a specific designated annual budget for research and monitoring. Human capacity is also low with only 2% of the staff qualified with the necessary skills to implement proposed activities. The largest need for research capacity building is amongst the park rangers/scouts who coincidentally are the largest human resource for the park. We suggest that institutional partnerships for capacity building of these rangers are the key in achieving biodiversity research and monitoring for conservation. University post- and under-graduate students are also an untapped resource to be explored.

FARMERS KEY ROLE IN CONSERVATION OF ENDEMIC AGROBIODIVERSITY IN GEORGIA

Kakha Nadiradze

Association for Farmers Rights Defense, AFRD
Nana PHIROSMANASHVILI, Association for Farmers Rights Defense, AFRD ; Mariami GOGINASHVILI, Tbilisi State University, Economic and Business Faculty, Student of Business Administration

Georgia is a richest country in terms of Biodiversity and due to global warming and climate change ongoing processes Biodiversity is declining sharply. We are losing species at a rate that is by some accounts up to 1000 times the natural rate of extinction. As a consequence, the ability of ecosystems to provide valuable services to us and our economy is weakened with each and every disappearance. The conservation of our endangered animals, plants and ecosystems is one of the greatest environmental challenges facing Georgia today. The key reason for our historically high extinction rates is habitat degradation and loss, initially from over-grazing and clearing for agriculture, and more recently from the clearing of native vegetation for urban development. Innovative approaches are needed to tackle the challenge of balancing development needs (to provide the community with new housing, jobs and amenities), while also conserving biodiversity for the future. BioBanking is a market-based scheme that provides a streamlined biodiversity assessment process for development, a rigorous and credible offsetting scheme as well as an opportunity for rural landowners to generate income by managing land for conservation. Biodiversity Conservation and Bio Banks in Georgia are our areas of our activities with close cooperation with IUCN, Global Genome Initiative (GGI) and Global Genome Biodiversity Network (GGBN), ESBB, Planta Europe, REDD, UNCCD. Local Farmers can manage their biobanking activities in order to improve or maintain the overall biodiversity values by using in vitro, in-vivo, in-situ, ex-situ, in-farm and on-farm activities.

94-COMPARING AND CONTRASTING BENEFITS DERIVED FROM TOURISM AND HUNTING ON COMMUNAL CONSERVANCIES IN NAMIBIA

Robin Naidoo

WWF-US
L. Chris WEAVER, WWF in Namibia ; Richard DIGGLE, WWF in Namibia ; Greenwell MATONGO, WWF in Namibia ; Greg STUART-HILL, WWF in Namibia ; Chris THOULESS, WWF in Namibia

Tourism and hunting both generate significant revenues for communities and private operators in Africa, but few studies have quantitatively examined the tradeoffs and synergies that may result from these two activities. Here,

we evaluate benefit streams from tourism and hunting on 74 communal conservancies in Namibia from 1998 to 2013, where community wildlife conservation has been promoted as an alternative form of land-use to traditional subsistence agriculture. In aggregate, total benefits from hunting and tourism over all conservancies have grown at roughly the same rate. Disaggregation of data reveals that benefits from hunting are largely income that goes to conservancy management committees and meat to the community at large, while most tourism benefits are salaried jobs at lodges. On average conservancies start generating benefits from hunting twice as fast after their formation as from tourism (3 versus 6 years post-establishment). A simulated ban on trophy hunting significantly reduced the number of conservancies that were able to cover their operating costs, whereas eliminating income from tourism did not have as severe an effect. Given that the benefits generated from hunting and tourism typically begin at different times (earlier versus later) and flow to different parts of local communities, these two activities complement one another and together provide the greatest incentives for conservation. Notably, the removal of benefits from either hunting or tourism would likely reduce the competitiveness of wildlife as a viable form of land-use, and have serious negative implications for the viability of Namibia's Community-Based Natural Resources Management program.

CAUCASUS PLANT INITIATIVE: A REGIONAL PLANT CONSERVATION STRATEGY AND PLANT CONSERVATION IN GEORGIA

George Nakhutsrishvili

Ilia State University
Ketevan Batsatsashvili, Ilia State University ; Shalva SIKHARULIDZE, Ilia State University

From 2006 to 2010, the project Coordination and Development of Plant Red List Assessments for the Caucasus Biodiversity Hotspot was implemented by the IUCN Species Survival Commission in collaboration with Missouri Botanical Garden, USA, the WWF Caucasus Programme Office, and botanists from six countries of the Caucasus (Armenia, Azerbaijan, Georgia, Iran, Russia, and Turkey). The project aimed to provide a series of Red List training and validation workshops specifically tailored to the Caucasus region so that local botanists could use internationally accepted methods for plant conservation assessment and monitoring (the IUCN Red List Categories and Criteria) and the Species Information Service as tools for data management and analysis. The work has resulted in a comprehensive overview of the distribution and conservation status of the endemic plant species of the Caucasus region based on current knowledge. A map of the Caucasus region produced by WWF Caucasus was initially used for the project; however, it was suggested that the border of the Caucasus region be extended southwards into the territory of Iran based

on local plant cover characteristics. The map with the extended borders was then used as base map to distinguish endemic plants of the Caucasus. This resulted in a comprehensive list of the region's endemic taxa containing as many as 2,810 species, subspecies, and varieties, a significant increase over the 1,600 species estimated in the original project proposal and mentioned in the Ecoregional Conservation Plan for the Caucasus. The Caucasus Plant Red List Authority was established under the auspices of the IUCN Species Survival Commission developed the present Caucasus Plant Initiative: a regional Plant Conservation Strategy, targets of which correspond to the targets of the Global Strategy for Plant Conservation. We consider the objectives of the Strategy in connection with plant conservation in Georgia, one of the countries of the Caucasus.

CROP-RAIDING BARBARY MACAQUES, *MACACA SYLVANUS* (PRIMATES: CERCOPITHECIDAE) AND CONSERVATION IMPLICATIONS AT THE HIGH OURIKA VALLEY, WESTERN HIGH ATLAS, MOROCCO

Salwa Namous

Cadi Ayyad University, Faculty of Science-Semlalia
Mohammed ZNARI, Cadi Ayyad University, Faculty of Science-Semlalia ; Mohamed AOURIR, Ibn Zohr University, Faculty of Science ; Jan SIESS, Lycée Agricole de Montmorot ; Soraya MOKHTARI, Direction Régionale des Eaux et Forêts, Haut Atlas, Parc National Toubkal

In areas with agriculture and wild primate species, the coexistence of these and their human neighbors often turns to conflict, as many primate species eat cultivated plants. This study is aimed to get an overview of the problem of crop-feeding Barbary macaques (*Macaca sylvanus*) in the western High Atlas Mountains, Morocco from the farmer's perspective in order to evaluate the severity of the damage experienced by the farmers. More than 100 interviews were conducted with local farmers in 13 villages along the Ourika valley during spring-autumn 2014 in order to gain information about their perception of the local crop-feeding macaques. The overall mean annual percent eaten or damaged by the macaques was about 30%, although the incurred loss of agriculture varied among villages and plant types. The macaques have a slight preference for walnuts, plums and apples, yet these differences are likely a result of the frequency and abundance in which the preferred crops are grown. Time of harvest is also a likely factor, especially when natural food sources are lacking for the macaques. Interviewed farmers view the amount of damage caused by macaques to be substantial, particularly for the most important items in the local economy. Most farmers believe that the situation had worsened with time, and try to reduce crop-raiding damage by guarding fields but macaques disproportionately raided farms in the early hours of

the day, presumably to avoid conflict with farmers. Setting up a local reforestation plan in order to plant palatable trees for the macaques, such as oak and possibly multiple kind of fruit trees, could possibly shift the macaques ranging patterns. With declining populations in almost all known ranges, Barbary macaques are not usually seen as pests. Thus mitigating the issue of crop damage in the Ourika valley is needed in order to keep the image of this species in a positive light, as viewing a species negatively will undoubtedly lead to less conservation support.

GENOME-WIDE SNP DATA REVEAL FINE-SCALE POPULATION STRUCTURE OF INDIAN TIGERS

Meghana Natesh

National Center for Biological Sciences
Goutham ATLA, National Center for Biological Sciences ; S P GOYAL, Wildlife Institute of India ; Yadavendra JHALA, Wildlife Institute of India ; Anuradha REDDY, Centre for Cellular and Molecular Biology ; Arun ZACHARIAH, Kerala Veterinary and Animal Science University ; Udayan BORTHAKUR, Aaranyak ; Uma RAMAKRISHNAN, National Center for Biological Sciences

Conservation genetics has seen a shift towards the use of genomic approaches to make inferences about population structure and local adaptation. Single Nucleotide Polymorphism (SNP) data provide independent bits of information from potentially thousands of loci, allowing greater access to the genome. Additionally, lower error rates and ease of transferability across laboratories makes them highly advantageous in comparison to microsatellites. In the present study, we employ SNP markers to study population structure of the Bengal tiger. Tigers have undergone a dramatic range contraction in the recent past and currently occupy barely 7% of their historical range. Loss of habitat connectivity is known to cause greater genetic differentiation. Understanding population structure is an important component of delineating evolutionary significant units. A previous study using 8 microsatellite loci identified three genetic clusters from the sampled populations across India. One of these clusters encompasses the whole of peninsular India, a broad geographical region with wide separation between the populations therein. We used SNP markers to test if they could further resolve population structure. For SNP discovery, we used the double digest RADseq approach. We obtained 57 samples, either blood or tissue, representing the geographical range of tigers in India. The Siberian tiger genome was used as the reference to call SNPs. By allowing for varying amounts of missing data and retaining different samples, we obtained data sets with different number of SNP markers. We tested for population structure with over 2000 SNPs and recovered additional genetic clusters corresponding to Central and Southern population groups within Peninsular India. We conclude that SNPs are a powerful set of markers to infer fine-

scale population structure. We plan to develop a panel of SNPs suitable for individual identification from non-invasive samples to help improve long-term monitoring projects.

NATIVE POPULATION OF ANTHERAEA ASSAMENSIS HELFER (MUGA SILKWORM) OF NORTH EASTERN INDIA AND STRATEGY FOR CONSERVATION

Ramesh Nath

DHING COLLEGE

Dipali DEVI, SERI-BIOTECH LAB, LIFE SCIENCES DIVISION, INSTITUTE OF ADVANCED STUDY IN SCIENCE AND TECHNOLOGY

The sericigenous Saturniid *Antheraea assamensis* Helfer, 1837, (muga silkworm) having the lowest chromosome number $n=15$ is known as the ancestral form of the genus *Antheraea*. This insect is exclusively confined to the Brahmaputra valley of Assam, India and some parts of neighboring states of North Eastern region of India due to its unique ecological niche. Although it is a monotypic species, it has four distinct larval color morphs, namely green, blue, orange and yellow and these are non diapausing multivoltine in nature. A diapausing wild morph is also found in the forests of this region. The wild types are very important for breeding and evolution of new muga silk worm strains with desired characters. The wild stock of muga silk worm, available in nature comprises both diapause and non-diapause forms. Due to various reasons, the populations of wild counterparts have declined and it had led to inbreeding depression in *A. assamensis*. Lack of systematic study of this natural population instigated to study the distinguished morphological characters in egg, larva, cocoon and moth stages. During the study variation was observed among the color morphs in respect of voltinism, geotropism, chorion structures, larval tubercle, setae number, cocoon characters, wing pattern, male genitalia and antennae between the color morphs and the wild morph. Based on this study the three color morphs viz. green, blue and orange could be clubbed together and the wild morph remains separately. It is expected that this study will help in designing the breeding programme for improved hybrid vigor as the population is suffering from inbreeding depression as well as to maintain the stable and sustainable population, thereby saving the precious germplasm of *A. assamensis* from extinction. The suitable strategy should be made to conserve their natural habitat with co-ordinated activities on germplasm collection, documentation, evaluation and utilization.

IDENTIFYING KEY HABITATS TO CONSERVE THE THREATENED BROWN BEAR IN THE HIMALAYA

Muhammad Ali Nawaz

Quaid-i-Azam University

Jodie Martin, Department of Ecology and Natural Resource Management, Norwegian University of Life Sciences ; Jon Swenson, Department of Ecology and Natural Resource Management, Norwegian University of Life Sciences

The threatened Himalayan brown bear has a fragmented range in the Himalayas. However, its habitat has never been documented, which hinders conservation efforts. The Deosai Plateau in northern Pakistan has long been recognized as the core area for this subspecies. To provide knowledge to help conserve the remnant populations in the Himalayan region, and especially in protected areas, we investigated habitat selection of brown bears and the influence of human presence in Deosai National Park, Pakistan. We used an Ecological Niche Factor Analysis to assess brown bear habitat selection, using scats sampled along transect routes throughout the park as location data. Our analyses indicated that brown bears avoided higher elevations and steeper slopes and selected more productive parts of the park (marshy, grassy, and stony vegetation types). The marshy vegetation was the most preferred habitat, probably because it had the highest forage production and density of golden marmots. Brown bears tolerated human infrastructures, like roads and camps, but strongly avoided grazing areas with high livestock density. The habitat suitability map generally followed the biomass productivity patterns of the park. It indicated the central part as suitable, and classified half of the park, mainly peripheral areas, as unsuitable for brown bears. The vegetation and habitat suitability maps provide an objective criterion for evaluating present and future developments in the park. Until recently, communities seem to have used the park's resources without significantly affecting the brown bear population. However, in recent years a large influx of nomadic communities with their livestock has become a challenge, which needs urgent attention to continue the present brown bear population recovery and to secure its habitat. We recommend monitoring the livestock and conducting a detailed inventory of the rangeland to understand grazing dynamics in the park and to maintain sustainable stocking rates.

PROTECTION FROM GRAZING INDUCES SHIFT IN THE PLANT COMMUNITY IN THE WESTERN HIMALAYAS

Rajat Nayak

Foundation for Ecological Research, Advocacy and Learning Mayuresh Gangal, Researchers for Wildlife Conservation

Livestock grazing is one of the most prevalent and oldest forms of human interventions experienced by terrestrial ecosystems. Several ecosystems are believed to have reshaped by grazing by large ungulates. However, over the last few decades, there is an increasing concern about the detrimental effects of overgrazing by livestock on biodiversity

and ecosystem processes and grazing has been restricted in several landscapes worldwide. In most cases, such restrictions are based on perceptions and their effectiveness is limited by a lack of knowledge on grazing-vegetation relationships. We investigated the effects of recent restrictions and changes in livestock grazing practices on herbaceous vegetation characteristics in the Western Himalaya, which has a long history of livestock grazing. We found that livestock grazing had a greater influence on vegetation at the level of plant functional groups. Both richness and abundance of annual species were higher in grazed sites compared to non-grazed sites. This suggests a shift in vegetation composition from a system with both annual and perennial plants to a system dominated by perennials under protection from grazing. The western Himalayas, with a long history of pastoralism and human use, have very low density of wild herbivores. Under these circumstances, grazing by livestock might play an important role in maintaining the existing diversity and abundance of palatable annual plants in the landscape. We observed a higher percentage of bare ground in grazed sites resulting from overcrowding and subsequent over grazing of available pastures outside protected areas. We conclude that the future management efforts should be directed towards establishing maximum permissible levels of grazing in each of the pastures based on regular monitoring and experimental studies. This can help in developing better strategies to manage both wildlife and livestock and to conserve the existing biodiversity in this landscape.

RESPONSES OF AFRICAN ELEPHANTS IN THE KRUGER NATIONAL PARK TOWARDS A BEE THREAT: ITS IMPLICATIONS FOR MITIGATING THE HUMAN-ELEPHANT CONFLICT.

Mduduzi Ndlovu

University of the Witwatersrand

Emma DEVEREUX, Organisation for Tropical Studies ; Emma CHIEFFE, Organisation for Tropical Studies ; Kendra ASKLOF, Organisation for Tropical Studies ; Alicia RUSSO, Organisation for Tropical Studies

Human settlement expansions into elephant ranges, coupled with increasing elephant *Loxodonta Africana* populations within confined areas has led to heightened levels of human-elephant conflict in southern African communities living near protected areas. Several methods to mitigate this conflict have been suggested including the use of African bees *Apis mellifera scutellata* as an elephant deterrent. We investigated whether bee auditory and olfactory cues (surrogates for live bees) can be used to effectively deter elephants. We evaluated the responses of elephants in the southern section of Kruger National Park to five different treatments (1) control noise, (2) buzzing bee noise, (3) control noise with honey scent, (4) honey

scent, and (5) bee noise with honey scent. Elephants did not respond or displayed less heightened responses to the first four treatments. All elephants exposed to the bee noise with honey scent responded with a defensive behaviour and 15 out of 21 individuals also fled. We concluded that buzzing bees or honey scent as isolated treatments (as may be the case with dormant beehives) were not effective elephant deterrents, but rather an active beehive emitting a combination of auditory and olfactory cues was a viable deterrent. However, mismatches in the timing of elephant raids and activity of bees may limit the use of bees in mitigating the prevailing human-elephant conflict.

“ADVANCING THE LIMITS OF CORAL REEF SENSING IN A TIME OF GLOBAL CHANGE: THE CATLIN SEAVIEW SURVEY”

Benjamin Neal

University of Queensland

Coral reefs worldwide are suffering dramatic declines, with an estimated 40% of coral reef habitat degraded within the last 50 years due to a suite of factors, including pollution, overfishing, destructive fishing and climate change. This degradation will affect the ~500 million people globally who utilize coral reefs for food, tourism income and coastal protection, along with the potential future losses to the still partially unknown biodiversity of these ecosystems. The Catlin Seaview Survey is a multiyear program creating a baseline record of coral community composition over 150 worldwide coral reef locations, using multi-camera, high-resolution, panoramic underwater imaging. These images are processed by a novel, computer-vision driven, automated benthic image analysis system capable of producing summary statistics of population and community composition. This system, called CoralNet, reduces underwater ecological image processing time by at least two orders of magnitude, making this a potentially valuable tool for many field managers. I will present both the underwater imaging and benthic community analysis processing systems in detail, along with coral reef case studies and data from expeditions to the Caribbean, The Great Barrier Reef, and the Coral Triangle. The standardized data produced will enable comparison for the first time of impacts and changes to coral reef ecosystem across large-scale world regions and across differing regimes of anthropogenic and natural disturbances, assisting local conservation managers and scientists to place local changes into a global context.

BIRDS, BATS AND BETA-DIVERSITY: BIODIVERSITY PATTERNS IN A FOREST PRODUCTION LANDSCAPE.

Wendy Neilan

Australian National University

David LINDENMAYER, Australian National University; Philip BARTON, Australian National University; Clive MCALPINE, University of Queensland

Habitat loss and fragmentation are major drivers of biodiversity loss in modified landscapes. Yet recent work suggests the erosion of beta-diversity, i.e. the loss of compositional variation, across a landscape could be an underestimated driver of biodiversity loss. Our research surveyed bird and bat assemblages in a natural fragmentation experiment of remnant eucalypt forest patches within a 50 000 ha pine plantation in temperate Australia. We investigated whether increased heterogeneity in landscape structure results in an increase in beta-diversity of birds and bats, after controlling for habitat amount. Species responses were analysed at patch and mosaic (i.e. among patch) scales. The diversity of both bird and bat faunas differed between mosaic types and habitat types within the mosaics. Our data suggests that elevated levels of beta-diversity among patches within heterogeneous mosaics may outweigh the loss of biodiversity at local scales.

HOW SCIENTIFIC RESEARCHES CAN CHANGE CONSERVATION PRIORITIES? -THE DECADE-LONG RESEARCH OF EURASIAN BLIND MOLE-RATS (RODENTIA: SPALACINAE) IN THE CARPATHIAN BASIN

Attila Németh

MME BirdLife Hungary, Hungarian Ornithological and Nature Conservation Society

Gabriella KRIVEK, University of Szeged; Tímea SENDULA, Eötvös Loránd University; Zsolt HEGYELI, 'Milvus Group' Bird and Nature Protection Association; Szilárd SUGÁR, 'Milvus Group' Bird and Nature Protection Association; János FARKAS, Eötvös Loránd University; Nikola STOJNIC, Institute for Nature Conservation of Serbia; Gábor CSORBA, Hungarian Natural History Museum

A research program that started 10 years ago in Central Europe, focusing on Eurasian blind mole-rats, not only provided novel information on the phylogeny, taxonomy, distribution and ecology of this scarcely investigated and enigmatic group of rodents but also influenced the conservation biological approach of decision makers. It was also evidenced, that blind mole-rats of this region are not locally endangered, peripheral populations of a wide-ranging species, but very localized endemics some of them with extremely low population sizes, facing extinction. Thanks to the wide communication of these results, - a species action plan laying down the strategy required to protect the blind mole-rat populations of Hungary was officially accepted; - a Mole-rat Protection Consulting Committee was established by the relevant ministry in Hungary; - a good working relationship had been established between the Hungarian Committee and the Novi

Sad Department, Institute for Nature Conservation of Serbia; - the intergovernmental Hungarian–Romanian Joint Committee on the Environment set the investigations of all blind mole-rat species occurring in the two countries as one of its main priorities; - Red List categories for all species of Carpathian Basin blind mole-rats were assessed; - a new protected area was established in Hungary; - the Hungarian protected species' list had been updated and elevated species of the Lesser blind mole-rat complex to the highest conservation rank; - the first-ever relocation program of a subterranean mammal started. These studies not only emphasized the importance of scientific investigations for conservation purposes, but also highlighted a phenomenon in which less known and cryptic species can be pushed to the brink of extinction as a result of the lack of information, unclear taxonomic status and unrecognised tasks in conservation. In their specific habitat, blind mole-rats can serve as umbrella species to protect the wildlife of Central European steppes.

THE NETWORK OF KNOWLEDGE APPROACH - MANAGING THE COMPLEXITIES OF KNOWLEDGE INTEGRATION ACROSS SCALES AND KNOWLEDGE DOMAINS

Carsten Neßhöver

Helmholtz Centre for Environmental Research - UFZ
Marie Vandewalle, Helmholtz Centre for Environmental Research - UFZ; Ilse GEIJZENDORFFER, IMBE; Christoph GÖRG, Helmholtz Centre for Environmental Research - UFZ; Rob JONGMAN, Alterra; Barbara LIVOREIL, FRB; Stefan SCHINDLER, UNIVIE; Luis SANTAMARIA, CSIC; Josef SETTELE, Helmholtz Centre for Environmental Research - UFZ; Isabel SOUSA PINTO, CIIMAR; Katalin TOROK, Hungarian Academy of Science; Jiska VAN DIJK, NINA; Heidi WITTMER, Helmholtz Centre for Environmental Research - UFZ; Juliette YOUNG, CEH

A better functioning interface between knowledge and decision-making especially in environmental issues has long been called for by policy as well as science. Recent advancements at the global scale, such as the recent launch of the Intergovernmental Platform on Biodiversity and Ecosystem Services (IPBES) and the integration of several Science Policy Interfaces (SPIs) into the global platform Future Earth, may open a window of opportunity for the development of proactive SPIs at national and regional levels. In Europe, a number of functions of this interface have been highlighted as needed to be further improved: the provision of consolidated knowledge to policy, the identification of research needs, the integration of networking and capacity building, and a sustained link between European and international activities. All these aspects need to be addressed in this interface in order to be relevant, credible and inclusive. In this paper, we explore these functions and their implications for improving

the science-policy-interfaces at the European level. We introduce a concrete proposal for a “Network of Knowledge on Biodiversity and Ecosystem Services – BiodiversityKnowledge” which acknowledges the high diversity of knowledge holders and governance levels in Europe and offers a framework for improved interaction by building a joint Community of Interest. BiodiversityKnowledge offers a model to jointly address requests from decision-makers using established methods (e.g. systematic reviews, expert consultation formats, adaptive management approaches among others). The main focus of the model proposed is to reach a high level of transparency and to ensure the required balance of relevance, legitimacy and credibility.

ARE PROTECTED AREA NETWORKS REPRESENTING BIODIVERSITY AND ECOSYSTEM SERVICES? CASE STUDIES FROM CAMBODIA AND MADAGASCAR

Rachel A. Neugarten

Conservation International

Will R TURNER, Conservation International

Protected areas (PAs) are considered the cornerstones of conservation, touted for their positive impacts on biodiversity and benefits to people. Globally, the coverage of PAs has expanded in the past decade, however PAs are not always strategically located. We conducted spatial modeling of ecosystem services in order to analyze whether PAs are representing these important benefits of ecosystems to people. We focused on protected area networks in two countries with high biodiversity and a high level of human dependence on ecosystem services: Cambodia and Madagascar. We analyzed the PA networks’ spatial representation of biodiversity priority areas, forest cover, carbon stock, inland fisheries, freshwater services and non-timber forest products. We examined whether PA networks are spatially representing biodiversity and ecosystem services better than would be expected if they were located randomly throughout each country, and whether spatial representation has improved in the past ten years. PA networks have expanded from 2003 to 2014, from 4% to 11% of land area in Madagascar and from 20% to 29% in Cambodia. We found that PA networks are spatially representing forests, biodiversity priority areas, carbon stocks, and inland fisheries better than would be expected if they were randomly configured. In Cambodia, the PA network configuration is “better than random” in terms of representing freshwater ecosystem services, but this is not the case in Madagascar. In both countries, the PA networks are doing no better than random in terms of representing non-timber forest products. In both countries, PA expansion has led to greater representation of biodiversity and ecosystem services over the past decade, but major gains would be possible if PA networks were spatially configured to optimize these benefits. While major gains have been made, there is more work to be done to ensure that PA

networks are securing biodiversity and providing benefits to people.

THE ROLE OF TRIBAL COLLEGES IN PRESERVING TRADITIONAL ECOLOGICAL KNOWLEDGE AND BIOCULTURAL DIVERSITY

Teresa Newberry

Tohono O’odham Community College

Over the past decades, biocultural studies have shown that diversity in language and culture are strongly linked to biological diversity and have established that a loss of diversity in one domain negatively impacts diversity in the others. The rapid decline in both biological and cultural diversity has increased awareness about the urgency to preserve not only the diversity of life but the diversity of culture and language as well. Over 40% of all the world’s languages today are at risk of disappearing and this loss signifies a monumental loss of cultural heritage and traditional ecological knowledge. Indigenous languages encode the world views and traditional knowledge systems of indigenous peoples gained by extended histories of interactions with the natural world and therefore, carry intricate understandings of natural processes and landscapes. In addition, indigenous culture and language incorporate knowledge about human relationships and rules of engagement with nature which are crucial to promoting long-term sustainability of the land. Therefore, a thriving linguistic and cultural diversity sustains the vitality and resilience of our planet, while a loss of it threatens the sustainability of all life on earth. In spite of the growing awareness of the interrelationships between loss of traditional knowledge and loss of biodiversity, there has been a lack of broad, systematic initiatives to preserve traditional knowledge. The tribal college system in the U.S. which consists of thirty eight tribal colleges and serves 65,000 Native American undergraduate students plays a pivotal role in the biocultural preservation and resilience for indigenous communities. The unique science curriculum developed at tribal colleges that incorporates language and validates traditional ecological knowledge can provide curricular models which may be applied across institutions of higher learning and play an important role in preserving biocultural diversity.

INTEGRATING CULTURAL TECHNOLOGY IN CONSERVATION PLANNING

Martin Nganje

Individual Researcher

This research, on a conservation-based traditional ecological practice was undertaken in 2010/11 around the Ankassa, Bia and Kakum conservation areas in Ghana. Based on

responses from conservation area managers and local community leaders, the research assessed how abstention from harming the elephant as a cultural interdiction affected the planning and delivery of elephant conservation objectives specifically and biodiversity conservation efforts generally. The purpose was based on the principle of “selective attention,” (Worchel., et al, 2000), which postulates that people will take responsibility for issues that support their group values and attitudes; implying that, taking account of cultural values in the planning and management of biodiversity had the potential to commit communities to such plans and in their execution. Forty-five percent of the 300 research respondents indicated that the elephant abstention culture was evidently relevant for conservation, but it was not specifically captured in conventional conservation plans. Despite broad interest by conservation area managers and policy makers to integrate such cultural values in conservation plans, limited knowledge and skills in handling the traditional ecological technology of communities was noted to be the main handicap. The research captured favorable culture-based technology that could be integrated to conservation plans, noting that; neither culture as a conservation technology nor conventional conservation efforts could succeed alone (without the other) in long-term conservation efforts. As a way forward, the research made use of ‘task analysis’ to generate indicators for cultural technology also expected to help explain, familiarize and build the capacity of conservation stakeholders in handling cultural technology. The resulting outcome may also be used to capture intangible biodiversity conservation heritage for registration in the new UNESCO Intangible Heritage Register.

INDIGENOUS AND LOCAL COMMUNITIES’ WILLINGNESS-TO-PAY FOR FOREST ELEPHANT CONSERVATION IN THE DJA-ODZALA-MINKEBE LANDSCAPE - CONGO BASIN

Jonas Ngouhou Poufoun

INRA - Laboratory of Forest Economics

Jens ABILDTRUP, INRA - Laboratory of Forest Economics ; Denis SONWA, CIFOR - Center for International Forestry Research - Central Africa Regionl Office ; Philippe DELACOTE, INRA- Laboratory of Forest Economics

In 2011, the Central African forest elephant (*Loxodonta cyclotis*) population was less than 10% of its potential size, occupying less than 25% of its potential range due to poaching and ivory illegal trade for trinket and Asian medicine. Currently, *Loxodonta Cyclotis* is increasingly threatened with extinction, while it is crucial for the socio-cultural identity of local people and indigenous Baka. It contributes to their main ritual practices, cultural enriches as well as sustainable livelihood. By disseminating seeds of important and multiple-use tropical tree species like *baillonella toxisperma*, *Loxodonta Cyclotis* also

provide biodiversity conservation beyond carbon storage. The extinction of such iconic species would lead to irreplaceable costs. This paper aims to determine and characterize the social-cultural opportunity cost of forest elephant extinction in the Dja-Odzala-Minkebe’s cross-border (Tridom) landscape. Its tests the hypothesis that, (1) the extinction of forest elephant can lead to a significant loss in the household’s wellbeing. (2) The implication of the households for elephant’s conservation increases with the distance of their locations to the nearest protected area and decreases with the human-elephant conflicts presence and that (3) the household’s willingness-to-pay is significantly influenced by their autochthonous status and their various Forest Land Use, Land Access and other social factors such as education, Income, religion and the household size. Using data from a double-bounded contingent valuation survey with a random sample of 1100 households conducted between December 2013 and July 2014 in 102 villages of the Tridom landscape between Cameroon, Congo and Gabon, it estimates and characterizes the Willingness-To-Pay of local households using a binary Probit model. This study will provide decision makers with additional incentives and relevant information to better shaping the forests’ elephants conservation into the Tridom landscape.

FLORISTIC, STRUCTURAL AND FUNCTIONAL CHARACTERISTICS OF TREE DIVERSITY IN THE DENSE HUMID FOREST OF SOUTHERN - CAMEROON

Jules Romain Ngueguim

Institute of Agricultural Research for Develoment (IRAD)

Sophie GACHET, IMBE - UMR CNRS 6372 / IRD 237 Aix-Marseille University, campus St-Jérôme, Case 421, 13397 MARSEILLE Cedex 20 ; Dieudonné ONANA, Institute of Agricultural Research for Develoment (IRAD) ; Bernard RIÉRA, UMR 7179, CNRS ? MNHN, 4 av du Petit Château, 91800

The floristic diagnostic in three forest stations of Cameroon helps us to understand that, these ecosystems knew natural and anthropogenic disturbances in the pass. Mangombé (about 10 years), Bidou (60 years) and the site of Campo in the national park is more stable. According to Letouzey (1957; 1968), several centuries ago, human communities lived in the dense humid forest of Cameroon. The recorded disturbances constituted the engine of sylvigenesis and one of the major constraints to the conservation of the forest resources. These disturbances affected the density, basal area, structure and diversity of the studied sites. Some authors (Bedel et al., 1998, Chazdon et al., 2007 ; Lebrija-Trejos et al., 2010) indicate that a setting in rest of a forest having no important disturbance can make it possible to reconstitute in meaning or long term a forest very close to the initial settlement. Therefore, which differences can exist on the structural level, floristic and functional between the studied stations? The studied sites are diversified as indicated by their index of Shannon, the generic

coefficient of diversity and the specific richness. Mangombé (38 families and 91 species), Bidou (32 and 88) and Campo (29 and 75). Basal area is significantly low in Mangombe station (49 m²/ha) compared to Bidou (54 m²/ha) and Campo (87 m²/ha). Zoochory concerns more than 71% of the censured species. According to the sample, floristic composition of Mangombé is very different from those of Bidou and Campo. The restoration of forest cover can be done naturally taking into consideration the large spectrum of ecological distribution of species, the high density of small stems and the importance of animals for the dispersion of the diaspores.

THE CONSUMERS OF IVORY AND RHINO HORNS

Trang Nguyen

University of Cambridge

There is a high demand for wild animals and products made from them worldwide. Despite efforts undertaken by governments, non-government organisations and other parties to tackle unsustainable wildlife consumption, the consumption of wildlife products, including threatened species, in China and Vietnam have risen rapidly. Law enforcement action to apprehend poachers and illegal traders is the primary mechanism for stemming these crimes. However, enforcement action alone may not be sufficient to eliminate this threat in the long term. The nature of the market is changing rapidly, with economic growth stimulating a status driven consumption that goes beyond traditional uses. Consumption is now about complex social issues, such as lifestyle, recreational choices, social, corporate status and aspirations. This research provides the first in-depth and comprehensive review of a wide range of communication materials that reached hundreds of millions across major markets in Southeast Asia, particularly Vietnam and China in order to raise awareness about rhino horns consumption and its impact. It mapped the demand reduction activities that are currently planned for major market countries for rhino horn and ivory, identified values could be added to different approaches, distinct interventions could be made more mutually supportive and complementary, and avoid conflicting messages to the public. Some of the most successful techniques in changing consumer behaviour in other sectors have also been documented, including sustainable lifestyles, consumer choice and public health, can be adapted to demand reduction for elephant and rhino products.

PERSPECTIVES IN DEVELOPMENT OF THE MARINE PROTECTED AREA NETWORK IN VIETNAM: CHALLENGES AND LESSONS LEARNED

Quan Nguyen Van

Institute of Marine Environment and Resources, Vietnam Academy of Science and Technology

Cuong CHU THE, Institute of Marine Environment and Resources, Vietnam Academy of Science and Technology ; Thanh TRAN DUC, Institute of Marine Environment and Resources, Vietnam Academy of Science and Technology ; The NGUYEN DUC, Institute of Marine Environment and Resources, Vietnam Academy of Science and Technology ; The NGUYEN DUC, Institute of Marine Environment and Resources, Vietnam Academy of Science and Technology ; Thu NGUYEN THI, Institute of Marine Environment and Resources, Vietnam Academy of Science and Technology

A marine protected area (MPA) network is an organized collection of individual sites, designed to link individual areas and to comprehensively represent the region's spectrum of marine life characteristics. International commitments to MPA networks recognize that they fulfill ecological and social aims that a single MPA alone cannot. With the long term political commitment and will, a network of the marine protected areas consisted of 16 MPAs has been declared by the Vietnamese government under the decision No 742/QD/TTg dated 26th May, 2010. Among of them, 5 MPAs were efficiently managed, others kept on going the zoning plan procedures and all would be put on running in the year of 2015. There are several constraints and challenges in relation with the development network of the MPAs in Vietnam, including gaps in laws and integrated governance frameworks, conflicts among sectors and stakeholders, variation in the central/local government interests, and maintenance of the funding sources. This paper will propose some directions for sustainable development of the MPAs network in the vision of the green economy aspects and human wellbeing.

TAXONOMICALLY-DEFINED SAMPLING EXTENT IMPROVES THE PERFORMANCE OF SPECIES DISTRIBUTION MODELS

Aidin Niamir

Senckenberg Biodiversity and Climate Research Centre

Andrew K. SKIDMORE, University of Twente ; Albertus G.

TOXOPEUS, University of Twente ; Raimundo REAL, University of Malaga

Species distribution models are now an essential tool in conservation studies. The use of species atlas data and correlational modelling approaches has become a common practice in species distribution modelling. However, the effect of sampling extent on the performance of the models remains unclear. We proposed using species taxonomy to delineate sampling extent, and assess how this affects the performance of species distribution models. Using species atlas data, two taxonomically-defined species occurrence datasets (i.e. family and order datasets) were created for 356 terrestrial species of mainland Spain. Species presences were identical in both datasets, while an absence was only recorded for localities

where another species of the same family (in family dataset) or of the same order (in order dataset) was known to be present. We then assessed the effects of sampling extent on the predictive performance of five classical species distribution models, namely on model calibration and discrimination capacity, comparing the results to those obtained with the original atlas dataset. Using taxonomically-defined datasets significantly improved the calibration of the species distribution models. The discrimination capacity slightly decreased for several species when using the family dataset, this drop was significant when the models were trained with the order dataset. Enhancement of atlas data by excluding non-informative absences based on species taxonomy significantly improved the calibration of species distribution models and thus their capacity to predict environmental potential. We therefore recommend the inclusion of species taxonomical extent when atlas data are employed in distribution models.

AN OPTIMAL APPROACH TO MANAGING TWO-SPECIES COMPETITION: STOPPING THE GAMBUSIA FISH INVASION OF EDGBASTON MOUND SPRINGS

Sam Nicol

CSIRO

Nathalie PEYRARD, INRA Unité de Mathématiques et Informatique Appliquées de Toulouse (MIAT) ; Regis SABBADIN, INRA Unité de Mathématiques et Informatique Appliquées de Toulouse (MIAT) ; Iadine CHADES, CSIRO

Interactions between pest species and endangered species that share the same niches are particularly difficult challenges for conservation managers. In these situations, attempts to eradicate the pest species may often also negatively affect the native species. Similarly, attempts to aid the endangered species must also be designed so that they do not unwillingly promote the spread of the pest. Management approaches need to be carefully planned in space and time to ensure the desired outcomes are achieved for the two species. Using a case study of two interacting fish species from desert spring systems in central Queensland, Australia, we demonstrate how we can learn the factors that predict occupancy for both species, and then show how we can exploit differences in occupancy predictors to design an optimal plan for the eradication of the pest fish (mosquitofish, *Gambusia holbrooki*) and translocation of the endangered fish (the red-finned blue-eye, *Scaturiginichthys vermeilipinnis*). Our approach uses a modelling technique called Markov Decision Processes, which allows us to find the optimal management action for any state of a stochastic system that can be influenced by management intervention. We use a classification tree to simplify the complex results of our optimization into a general 'rule of thumb' that is easy for managers to understand and implement. An additional challenge is presented by climate change, which may change the future water balance in the

springs, affecting both colonization potential and extinction probability. We demonstrate how to design a control policy to optimally manage the two fish species under uncertain future rainfall scenarios. Our novel approach provides managers with a robust optimal plan to effectively control a major global aquatic pest species and simultaneously prevent extinction of a critically endangered fish.

A NOVEL BIODIVERSITY FOOTPRINT BASED ON EXTINCTION RISKS TO EVALUATE THE EFFECT OF INTERNATIONAL WOOD TRADE

Shota Nishijima

Yokohama National University

Takuya FURUKAWA, Forestry and Forest Products Research Institute ; Taku KADOYA, National Institute for Environmental Studies ; Fumiko ISHIHAMA, National Institute for Environmental Studies ; Thomas KASTNER, University of Klagenfurt ; Hiroyuki MATSUDA, Yokohama National University ; Nobuhiro KANEKO, Yokohama National University

Trading of various resources among countries can degrade biodiversity far from the place of consumption, but a previous biodiversity footprint (BF_{prev}) of international trade may be imprecise because of a qualitative, spatially-implicit evaluation. In this study, we propose a novel biodiversity footprint based on extinction risks (BF_{ex}) to evaluate the effect of international wood trade. Using more than 500 bird species that are categorized as threatened by wood harvesting in the IUCN Red List, we firstly quantified per species extinction probability from population sizes and habitat loss rates computed by overlapping species distribution maps and a forest loss map. We then calculated the expected number of bird species that would go extinct in the future, or BF_{ex}, and revealed the associations between producers and consumers using a bilateral wood trade data. We compared this BF_{ex} with BF_{prev} obtained from the same data, and found that whereas Indonesia was by far the most threatened from abroad in BF_{prev}, Brazil was an important exporter that was comparable, or superior in the short run, to Indonesia in BF_{ex}. Moreover, the impacts of major importers, such as China, Japan and USA, on overseas relative to those on their own countries are larger in BF_{ex}, suggesting a big responsibility of wood importers for bird extinctions abroad. A scenario analysis using BF_{ex} also showed, surprisingly, that total BF_{ex} would slightly increase if each country produced woods so as to satisfy its own demand. This is because extinction risks in two major importers, or China and Japan, and several tropical countries including Mexico and Philippines would increase greatly by self-supporting, and suggests that other scenarios are needed for preventing bird extinctions. Our developed BF_{ex} is useful to identify countries whose birds are so threatened as to be extirpated due to wood consumption and trade, and to search effective trade patterns for biodiversity conservation at a global level.

ABUNDANCE AND DIVERSITY RESPONSE OF BIRD COMMUNITIES TO LANDSCAPE MATRIX EDGES IN NYUNGWE NATIONAL PARK, RWANDA.

Protais Niyigaba

WCS Rwanda/Nyungwe Project

Beth KAPLIN, University of Rwanda & Antioch University ; Aisha NYIRAMANA, University of Rwanda

This study examined and compared the edge effects created by two landscape matrixes (tea and pine) around Nyungwe National Park – Rwanda, on bird communities in function of the distance from edges into the forest interior. In total, 324 point counts were established along transects perpendicularly to pine and tea buffer zones (3 adjacent to pine buffer zone, 3 adjacent to tea matrix) and 3 control-transects in the forest interior. Circular plots of 20m radius were visited six times and birds were detected audibly and/or visually. The distance of edge influence on bird diversity for pine and tea was found to be 600m but with the highest impact penetrating deeper in the forest adjacent to tea (at 400m) than in the forest adjacent to pine (at 200m). The overall predominance of frugivores and frugivore-insectivores are characteristics of tropical forest bird communities. Bark-gleaning insectivores were the most negatively affected by both edges and can therefore be used as ecological indicators to track the effects of edges and disturbance. The proximity of both pine and tea matrixes, positively affects the abundance of forest independent species, and showed no significant influence on forest-interior dependent species. Among habitat attributes, percentage canopy cover strongly increased near pine matrix, stem density strongly increased with the distance from tea matrix, while the average tree dbh strongly decreased when moving from both pine and tea matrixes into the forest-interior. The physiognomy of landscape matrixes contiguous to Nyungwe National Park was found to influence the edge effect penetration into the natural forest; therefore, any buffer-zone management practices that induce abrupt hard edge near the forest is likely to deepen the effects further than 600m into the forest. Further continuation of this study was recommended on other land-uses around Nyungwe, and on other bird groups of particular conservation interest.

MORPHOLOGY AND MANAGEMENT OF THE AGGRESSIVE ENCROACHER PLANT SERIPHIDIUM PLUMOSUM IN BANKENVELD GRASSLAND, SOUTH AFRICA

Sellina Ennie Nkosi

University of South Africa

Leslie Robert BROWN, University of South Africa ; Alan Sean BARRETT, University of South Africa

Seriphidium plumosum is an aggressive encroacher dwarf-shrub threatening grasslands in most of the provinces of South Africa. It is an indigenous pioneer plant that invades poorly managed natural veld and cultivated areas. In this study we investigated the morphology of *S. plumosum* and looked at different ways of controlling it at Telperion Nature Reserve, Mpumalanga, South Africa. Plants were classified into three height classes <0.5 m, 0.5–3 m, and >3 m. Above and below ground morphology of plants growing in flat and sloping areas were investigated. Biomass was estimated at 25 cm intervals above and below the soil surface. Ground cover and root spread was estimated for all samples. Treatment options that were investigated for controlling *S. plumosum* included chemical control, proportional removal and fire. For monitoring herbivore impact, treatments were applied in enclosure plots and replicated in areas accessible to herbivores. Morphology investigations revealed a comprehensive underground root system for *S. plumosum*. Our preliminary results indicate that an integrated approach should be adopted for controlling the plant. A combination of burning and herbicide application proved most effective. Findings from this study provide valuable information for the management of *S. plumosum* in different growth stages and growing in different terrain types. Recommendations for the control of *S. plumosum* can be used in similar environments to effectively control encroachment.

DO POLLARDED TREES SUPPORT A HIGHER SPECIES DIVERSITY OF LICHENS, BRYOPHYTES AND FUNGI THAN LARGE UNPOLLARDED TREES?

Björn Nordén

Norwegian Institute for Nature Research

Marianne EVJU, Norwegian Institute for Nature Research

Pollarding of trees for leaf fodder was historically an important practice in many temperate regions of Europe, but now previously pollarded trees mainly occur as remnants in forests. Old pollarded trees are often assumed to have exceptional value for biodiversity compared to other trees, but this was rarely tested. In this study, we compare the species diversity of lichenized fungi, wood- and bark-living fungi, and bryophytes among equal number of trees (n=350) that were either 1) Previously pollarded at least once, or 2) Never pollarded. All trees had a diameter at breast height > 40 cm, and pollarded trees were significantly coarser than unpollarded trees. We ask if the two categories differ in the number of trunk cavities (often used as a proxy for biodiversity), and in species richness and species composition. Sampling was balanced regarding geographical and climatic regions, and slope exposition. On 400 *Ulmus glabra* and 300 *Fraxinus excelsior* trees at 66 sites in southern and western Norway, we found 207 lichenized

fungi, 123 wood- and bark-living fungi, and 109 bryophytes (in total >13000 records). Using GLMM, we found that coarser trees had higher species richness than thinner trees, and that Fraxinus trees had higher species richness than Ulmus trees. Interestingly, there were no significant differences between pollarded and unpollarded trees regarding total species richness or species richness of nationally redlisted species of lichenized fungi or bryophytes. For wood- and bark-living fungi, total and redlisted species richness were both higher on pollarded trees, probably due to more dead wood habitat on the previously pollarded trunks. Pollarded trees had significantly more trunk cavities, but the number of trunk cavities was not correlated to, and thus not a good proxy of, cryptogam diversity. Based on our results, we conclude that the value of (re-)pollarding as a conservation effort can be questioned, at least for epiphytic cryptogams.

URBAN MIRES REMAIN HOTSPOTS OF EPIGAEIC ARTHROPOD DIVERSITY DESPITE THE DETRIMENTAL EFFECTS OF URBANIZATION

Norbertas Noreika

University of Helsinki

Timo PAJUNEN, Finnish Museum of Natural History ; D. Johan KOTZE, University of Helsinki

Urbanization causes a considerable loss of natural habitats worldwide. Furthermore, regional biodiversity within cities is shrinking due to the homogenization of remnant habitats through the loss of specialist species. However, this phenomenon can be reduced if urban biodiversity hotspots are identified and conserved. Mires have the potential of being such refuges, since many mire specialist species of, e.g. arthropods, are documented. Little is known about the effects of urbanization on mire specialists and subsequently whether urban mires are able to sustain mire specialist species and communities. Therefore, it is essential to evaluate processes shaping mire communities and affecting specialist species at both local and regional scales. We investigated twenty pine mires that differed in urbanization level (from highly urbanized to non-urbanized) in southern Finland by evaluating the responses of epigaeic arthropod (carabid beetles and spiders) species and communities. Pitfall trapping was used to collect the arthropods. Local (pH of peat, vegetation cover, wood volume) and regional (level of urbanization, amount of peatlands in the landscape, total mire area) variables were measured to determine how they affect the structure of arthropod communities and individual species. We showed that high levels of urbanization have a negative effect on mire arthropod biodiversity. However, urban mire community structure seems not to be very different from rural ones and they are still inhabited by mire specialists. Furthermore, tree-covered parts of urbanized mires can serve as refuges for rare forest specialist species and Sphagnum mosses play an

important role in predicting the responses of mire species and communities, thus their growth should be promoted. It appears that urban mires can be considered urban biodiversity hotspots and their protection should be emphasized while planning urban development.

LANDSCAPE RELATEDNESS: INSIGHTS INTO CONTEMPORARY SPATIAL STRUCTURE OF A TOP PREDATOR

Anita J Norman

Swedish University of Agricultural Sciences

Astrid Vik STRONEN, Aalborg University ; Jonas KINDBERG, Swedish University of Agricultural Sciences ; Aritz RUIZ-GONZÁLEZ, University of the Basque Country ; Geir-Arne FUGLSTAD, Norwegian University of Science and Technology ; Göran SPONG, Swedish University of Agricultural Sciences

Population sub-structuring is typically identified through genetic differentiation between spatial areas. However, a lack of genomic resolution, uninformative markers, skewed sampling, or a lack of sampling resolution can lead to inferences that are not representative of the actual underlying substructure. In this study, we use a set of 96 SNPs designed for the purpose of inferring relatedness in the Scandinavian brown bear (*Ursus arctos*). Consequently, the SNPs lack the characteristics to properly show population sub-structuring since they are fairly evenly distributed throughout the geographic range. To maximize the utility of the SNPs, we take a different approach to studying spatial structuring. Our approach uses pairwise relatedness with 412 individuals to predict overall relatedness across a landscape larger than 46,000 km². The results of this interpolation reveal novel insights into kin-structuring of brown bear. We show that some areas contain individuals that are significantly more related and others that are significantly less related than what is expected by chance. We also show how these areas vary with males and females. These findings have implications for conservation efforts as they contribute a contemporary, fine-scale spatial analysis of an important umbrella species.

#165: SYSTEMS AND DESIGN THINKING FOR CONSERVATION ACTION AND IMPACT

Cameron Norman

CENSE Research + Design

How do we take the best evidence and transform it into outcomes that create conservation impact? Quality science is not enough, nor is simply having motivation to create change. Science, practice and policy are all embedded within nested systems of conservation, requiring modes of thinking, action and evaluation that reflect systems not just individuals or organizations (Hiatt, Best & Norman, 2008). Connecting

intention with action to achieve impact falls within the purview of the field of design, which is focused on the process of creation for reproduction (Van Alstyne & Logan, 2007). Design thinking is the process of using creative principles to guide actions intended to produce and reproduce an outcome consistently. Conservation science seeks to generate new knowledge, practices and policies that produce change within these systems, thus systems and design thinking hold promise. The dominant models for translating science into impact focus on improving research quality as a driver of change. This has been shown to be incorrect: achieving impact involves understanding the social, structural, and procedural systems where knowledge is embedded and the human relationships that mediate throughout. Systems thinking introduces theoretical and practical tools to make sense of these relationships. Design thinking comprises set of skills, activities and ideas that allow for the development of strategic options to best navigate these relationships. In this presentation, participants will be introduced to these two fields and the manner in which they can be used to support conservation efforts. Examples will be provided drawing on the work of the Silwood Group, a multidisciplinary collaborative focused on linking systems thinking, evaluation and conservation. The implications for using systems and design thinking to support conservation science and practice will be discussed and supported with real-world case examples and from the literature.

194. ESTABLISHING SOCIAL-ECOLOGICAL BOUNDARIES: FOUNDATIONS FOR ASSESSMENT AND INNOVATION

Karma Norman

NOAA Northwest Fisheries Science Center
Kevin St Martin, Rutgers University ; Melissa POE, NOAA Northwest Fisheries Science Center ; Chris HARVEY, NOAA Northwest Fisheries Science Center ; Sara BRESLOW, NOAA Northwest Fisheries Science Center ; Greg WILLIAMS, NOAA Northwest Fisheries Science Center ; Phillip LEVIN, NOAA Northwest Fisheries Science Center

The inclusion of human wellbeing within ecosystem assessments emerges from the assertion that humans are indeed part of ecosystems. Even within traditions of single species approaches to environmental management, where human roles are reduced to those that are extractive in nature, we see this approach transformed by ecosystem-based management. Within these new frameworks, human wellbeing is often thought of as a benefit provided by well-managed ecosystems. Such work suggests that the value of ecosystems often exceeds our ability to account for them, and that humans are fundamentally linked to, if not directly dependent upon, ecosystems near and far. In this presentation we explore the ontological dilemma of humans as both part of these systems,

and as recipients of these systems' services. The recognition of systems that are both social and natural requires that we also recognize a need for new hybrid objects that are ontologically and spatially grounded, that can be measured and assessed, and may be integrated into and constituted by socio-technical practices and processes. These new objects problematically force us to draw boundaries, inclusive of humans and human communities, but are also open to new possibilities. Our work focuses on which metrics and measures we may use to assess the human dimensions of such systems, and which metrics and measures we may use to assess human wellbeing within the context of assessing ecosystems. To do so, our work provides guidelines that make clear when we are assessing the wellbeing of those humans who are ontologically part of the system and when we might be assessing the wellbeing of those humans who serve as recipients of services from the system. Establishing the boundaries of "the system" for state sponsored ecological assessments and management cannot be divorced from establishing what is internal and what is external to the system. Such boundaries are socially constructed but, nevertheless, do necessary work.

OBSERVER EFFECTS AND THE RISK-DISTURBANCE HYPOTHESIS IN SAMANGO MONKEYS

Katarzyna Nowak

Durham University
Kirsten WIMBERGER, University of Cape Town ; Russell HILL, Durham University ; Aliza LE ROUX, University of the Free State

A fundamental step in the management and conservation of wild species is advancing understanding of how an animal perceives its habitat. Variation in risk – either from natural predation or anthropogenic pressure – across space generates a "landscape of fear" that can be measured and assessed using an experimental patch approach such as giving-up densities (GUDs). For primates inhabiting a matrix of human habitation, exotic plantation and indigenous forest, it is possible to explore the "risk-disturbance hypothesis", which posits that human risk parallels natural predation risk in its effects on animals' habitat use and decision-making. Here we report on a combination of studies conducted on samango monkeys' (*Cercopithecus mitis* ssp.) risk-sensitive foraging at two sites in South Africa subject to varying anthropogenic pressures. Using GUDs experiments and ranging data, we documented pronounced effects of human observers and human habitation. However, the impact of humans did not simplistically follow predictions from the risk-disturbance hypothesis. At a site with limited human infrastructure, monkeys exploited typically high-risk food patches more intensively in the presence of researchers, who they likely perceived as shields against terrestrial predators. Meanwhile, at a predator-poor site where monkeys regularly come into contact with human infrastructure and gardens (adjacent to natural forest), monkeys regularly exploit exotic

garden resources in the food-scarce winter periods. Here, experiments indicated high sensitivity to risk at lower strata in garden trees, and monkeys' preference for indigenous forest, if given the choice of foraging at experimental patches in the forest versus the gardens. We also explore the effect of prior experience on monkeys' risk-taking behavior in the presence of humans.

LEGAL PROTECTION DRIVES THE RECOVERY OF WOLF POPULATIONS IN DISTANT REGIONS

Sabina Nowak

Association for Nature 'Wolf

Robert MYSLAJEK, University of Warsaw, Faculty of Biology

Wolves became strictly protected in Poland in 1998, after over 20 years of the wolf control program followed by over 20 years of trophy hunting. Several years after, they started to re-settle forests in Western Poland (WPL) far from the source population in the eastern part of country. Since 2002 the population increased from 7 to approximately 140 wolves living in 30 family groups in 2012, with the annual rate of increase reaching 38%. The area of permanent occurrence increased from 600 to 10,900 km². Among 35 recorded wolf groups 17% persisted for one year, while the rest survived at least two years. Most (70%) of 10 ephemeral groups were recorded before 2005, and they mostly disappeared after ≤ 2 years of presence. Since 2009 no single wolf group ceased to exist. The mean pack size was 4.6 individuals. It increased up to the eighth year of the group duration, from 2.3 to 7.3 individuals, and then fluctuated from 6 to 8 members. On average 93.8% of packs produced offspring annually. From birth 84% of pups survived until August and 56% until November. On average 1.6 pups per pack were recorded in late winter. Of 28 wolves found dead, 64% were killed by vehicles, 25% were poached, 11% died because of natural factors. Wolves in WPL preyed mostly on red deer *Cervus elaphus*, roe deer *Capreolus capreolus* and wild boar *Sus scrofa*, while damage to livestock was sporadic. The re-colonization starts from jump dispersal, but along the recovery the dispersal pattern shifts to stratified, being a mixture of the diffusion and jump dispersal. We conclude that legal protection, rather than hunting management, supports fast recovery of wolves in distant but suitable habitats when the source population provides dispersers of both genders following reduced anthropogenic mortality and maintained connectivity.

DO WOLVES CANIS LUPUS SETTLE IN AREAS PREDICTED BY HABITAT SUITABILITY MODELS?

Sabina Nowak

Association for Nature 'Wolf

Robert MYSLAJEK, University of Warsaw, Faculty of Biology

Habitat suitability models (HSM) are widely applied in conservation of endangered taxa, although their predictive power has been hotly debated. We attempted to compare predictions of HSM for wolves in Poland with the actual distribution of the species after over a decade of its spontaneous recolonisation of western Poland. Data were analysed in a grid of cells 10×10 km with predicted relative probability of wolf occurrence calculated for every cell. We compared habitat variables and relative probability of wolf occurrence in: (1) cells with the permanent wolf occurrence, where no reproduction was recorded; (2) cells with the permanent wolf occurrence, where reproduction was confirmed; (3) cells with the sporadic wolf occurrence; (4) cells randomly selected within study area, where wolves were absent. In 2001–2013 wolves were recorded in 182 cells in western Poland, among which 118 were permanently inhabited by these animals at least during one year. In remaining 64 cells wolves were observed sporadically. Cells with the permanent wolf occurrence were characterized by a higher probability of wolf occurrence predicted by HSM when compared with cells sporadically visited by wolves and cells randomly selected from outside of the wolf range. Reproduction of wolves was confirmed within 31 cells. These cells were characterized by the highest probability of occurrence predicted by HSM, a higher forest cover and lower area of arable fields and a lower density of public roads compared to cells with the permanent wolf occurrence but without reproduction. Over the time there were no differences in the quality of cells where the permanent wolf occurrence was recorded, but the sporadic wolf occurrence was registered in cells of lower quality.

ID195 THE GOOD, THE BAD, AND THE WELL-INTENTIONED: THE EVOLUTION OF COMPENSATION AND INSURANCE PROGRAMS AS WILDLIFE CONFLICT MITIGATION TOOLS

Philip Nyhus

Colby College

Human conflict with wildlife is an important driver of population decline among species that compete with humans for space, resources, or that threaten the safety of people and their property. Eliminating the frequency and severity of conflict is typically a preferred management goal but may not be achievable because of the characteristics of the wildlife species of interest, human behavior, or factors associated with governance and institutions. When prevention is not possible, strategies are needed to reduce the negative social and economic impacts of conflict. Compensation and insurance are two tools to accomplish post-conflict mitigation. I review changes in the growth and types of compensation and

insurance programs, describe factors that promote or constrain the effectiveness of these tools, and discuss the evolution and future of these strategies as tools in the conservation toolbox. Characteristics of interest include those related to verification and payment, such as eligibility criteria, payment amount, type, and timing; institutional considerations, such as the type and effectiveness of managing agencies and organizations, type and quality of rules and procedures, and trust and transparency; biological considerations, including species abundance, conservation status, and the degree, type, and frequency of conflict; equity and justice considerations, including gender and socio-economic status; perceptions of risk and reward; technology for reporting and verification; type, size, and responsibility for payment of premiums and subsidies; geographic variations; linkages to improved husbandry and conservation; and degree of coupling with other conservation tools and goals.

90 HERBICIDE TOLERANT CROPS IMPLICATED IN DECLINING MONARCH BUTTERFLY POPULATION

Karen Oberhauser

University of Minnesota

Kelly NAIL, University of Minnesota ; Carl STENOIEN, University of Minnesota ; Myron ZALUCKI, University of Queensland ; John PLEASANTS, Iowa State University

Each fall, the vast majority of the eastern North American population of the monarch butterfly migrates to overwintering sites in central Mexico. The area occupied by the overwintering population, a proxy for the whole population, has decreased since measurements began over two decades ago. While many factors could be contributing to this decline, increasing use of herbicide tolerant, genetically modified crops and the resultant loss of the monarch's primary host plant, mainly *Asclepias syriaca* (common milkweed), in crop fields in the Upper Midwestern U.S. has been strongly implicated. Before the advent of these crops, it is likely that the vast majority of monarchs that migrated to Mexico each fall originated in corn and soybean fields, but the milkweed in these fields has been almost completely eliminated as the adoption of herbicide tolerant crops has approached 100%. While monarchs could potentially compensate for this loss by laying more eggs in the remaining habitat, this is not happening. In fact, monarch egg density is declining, perhaps indicating that there are too few monarchs to find the remaining habitat in the same numbers as before, and supporting modeling work that suggests declining fecundity as host plants are removed from the agricultural matrix.

DEVELOPMENT VS CONSERVATION DILEMMA: CASE STUDY OF LAIKIPIA UNIVERSITY AND THE IGUAMITI STREAM IN KENYA

Benson Obwanga

Laikipia University

Veronica NGURE, Laikipia University ; Outa OMONDI, Egerton University ; Kennedy OCHIENG, Egerton University

Universities all over the world are key in providing solutions to global challenges. Communities around them benefit from disseminated research outputs. Such solutions are needed to cope with environmental degradation & climate related challenges. This study investigated the importance of Laikipia University in protection of vegetation at the source of Iguamiti stream in Laikipia County Kenya, a small but crucial system for downstream communities. Selected physico-chemical parameters showed a variation in trends between September 2013 & April 2014. Four sampling points along the stream were selected: Upstream within the University (I1, I2, I3) & Downstream I4 outside the University. Conductivity ranged from 53.25 μScm^{-1} at the I1 in November 2013 to 132.85 μScm^{-1} in April 2014 at the I2. Highest TP mean values recorded were at I2 and I4 ($0.22 \pm 0.46 \text{mg/L}$ and $0.22 \pm 0.47 \text{mg/L}$ respectively). For PO4-P the highest recorded values were at I2 & I4 ($0.21 \pm 0.45 \text{mg/L}$ & $0.22 \pm 0.47 \text{mg/L}$ respectively). High values of NO3-N ($0.76 \pm 0.58 \text{mg/L}$) were recorded at I2 compared to other sites. NO2-N concentration did not exceed 0.01 mg/L for all the sampling sites while for NH4-N did not exceed 0.04 mg/L for all the sampling sites. There was no significant difference in concentrations for Total P, NO2-N and PO4-P between the sites for the whole study period. These trends highlighted the significance of a series of wetlands along the stream which play a critical role in maintaining good water quality. Results highlight a significant role Laikipia University has played conserving this freshwater ecosystem. The study also raises the need for extra efforts by the institution to train the community on the relevance of protecting the wetlands against degradation. There is need for continued data collection to show the trends of the parameters over years to develop climate change mitigation strategies. Key words: Higher Education Institutions, Iguamiti Stream, physicochemical parameters, trends

CAN POWERLINE RIGHTS-OF-WAY CONTRIBUTE TO CONSERVATION OF GRASSLAND BUTTERFLIES?

Erik Öckinger

Swedish University of Agricultural Sciences

Åke BERG, Swedish University of Agricultural Sciences

With decreasing areas of natural and semi-natural habitats, the importance of anthropogenic habitats for biodiversity conservation is increasing. Infrastructure rights-of-way, such as road verges and power-line corridors cover large areas of

land. In Sweden their combined area exceeds that of semi-natural grasslands. Hence, they have a great potential for conservation of species associated e.g. with grasslands. As linear habitats they also have the potential to act as dispersal corridors and increase landscape connectivity. We compared species richness and community composition of butterflies in power-line corridors and semi-natural grasslands, and tested how this was influenced by local management and landscape configuration. Power-line corridors had higher species richness than semi-natural grasslands, but contained a partially different set of species. Butterfly communities in power-line corridors were not affected by the amount of grasslands in the landscape. Instead, power-line corridors appeared to act as source habitats and influenced butterfly communities in semi-natural grasslands and road verges in the vicinity. Studies of dispersal behaviour indicated that the power-line corridors function as habitat rather than as dispersal corridors only, and did not direct dispersal movements. We conclude that power-line corridors and other rights-of-way habitats are important butterfly habitats in forest-dominated landscapes, and can at least to some extent be managed to act as a substitute for rapidly declining semi-natural habitats.

ID 34 TOWARDS SUSTAINED, LONG-TERM AND GLOBAL OBSERVATIONS OF LAND COVER CHANGE FOR BIODIVERSITY CONSERVATION

Brian O'Connor

UNEP-WCMC

Han MENG, IUCN (International Union for Conservation of Nature); Neil BURGESS, UNEP-WCMC; Jon HUTTON, UNEP-WCMC

Global biodiversity is facing a crisis as evidenced by ongoing global declines in species populations and numbers as well as their habitats. In response, the Convention on Biological Diversity (CBD) set out the "Strategic Plan for Biodiversity 2011-2020" whose vision is to restore, value and conserve biodiversity for the benefit of all people by 2050. In order to implement this plan, 20 Aichi Biodiversity Targets were adopted and supported by a suite of 98 indicators as the basis for a reporting progress target by target. Land Cover Change (LCC) monitoring from satellite remote sensing has the potential to contribute data to a number of these indicators for assessing biodiversity status and trends. Firstly, we introduce the basic principles of land cover classification followed by why it's important for biodiversity conservation. Secondly, we review a suite of current LCC products summarising their strengths and weaknesses. Thirdly, we use illustrative examples to demonstrate the performance of these LCC products at a national-scale in Tanzania. This is followed by a discussion of why land cover classification has not worked to date to meet the needs of the global biodiversity and conservation policy community in tracking progress towards the Aichi

Targets. We also show what can work as highlighted by some recent product developments. We conclude that a multi-decadal global LCC product could improve some biodiversity indicators in support of the 2020 Aichi Targets in areas as diverse as tracking protected area management effectiveness, quantifying the loss of critical habitat to human activities, inferring species diversity and abundance and monitoring the impacts of human pressures such as urban development and agriculture. Finally, we make recommendations on how the remote sensing and conservation community can work collaboratively toward a global LCC product and what the key challenges are to achieving this goal.

#129 USE OF THE OPEN STANDARDS TO DEVELOP A NETWORK OF MARINE PROTECTED AREAS OFF THE WEST-COAST OF SWEDEN THAT MEETS EUROPEAN NATURA 2000 OBLIGATIONS

Jens Odinga

Van Hall Larenstein University

Lena TINGSTRÖM, Swedish Agency for Marine and Water Management; Maria KILNÄS, County Administration Board Västra Götaland; Ilke Tilders, Foundations of Success

Dealing with national policies and international treaty obligations (i.e., those related to Oskar, Helcom, Natura 2000, the Marine Strategy Framework Directive) in MPA management is challenging. Policies and obligations are at best complementary, and often overlap and are couched in ambiguous language. Authorities responsible for the management of individual Marine Protected Areas and the network they form are struggling to practically interpret and implement these policies in their management efforts. The Swedish Agency for Marine and Water Management in collaboration with various County Administration Boards and Foundations of Success teamed up and delivered a "proof of concept" that shows how the use of the Open Standards can help integrate these policies in a useful and practical standardized MPA Network design. The proof of concept shows how this standardized design can be applied to a suite of individual MPAs. It also shows how this design enables meaningful roll-up of data across MPAs to inform management decisions on the MPA network level and to track the performance towards policy objectives and treaty obligations. Ultimately, this system will enable systematic conservation and learning within and across this network of MPAs.

DEGRADATION IN A CRITICAL WATERSHED OF NORTHERN HAITI: THE RIVER HAUT DU CAP AND CAP-HAITIEN BAY

Samantha Oester

George Mason University

More than 5.5 million people occupy the Republic of Haiti's 27,750 km². A dense population, historically unstable government, intense agriculture, premature urbanization and utilization of charcoal as a chief fuel source led to extreme degradation and destruction of Haiti's watersheds. Little natural vegetation remains. This has caused hydrologic malfunctioning throughout the country. Several rivers and lakes have dried up completely or no longer have permanent flow. Aquifers have been contaminated due to these factors, as well as unmanaged underground pumping and quarries. Extreme vegetation removal and pollution also led to the deterioration of coastal and marine environments. Several coastal mangroves, considered critical ecosystems, are located on the northern coast, near Cap-Haitien, Haiti's second largest city. The River Haut du Cap that feeds the Cap-Haitien Bay has been subject to severe overexploitation and degradation. This was exacerbated after the 2010 earthquake by much of the country fleeing the Port-au-Prince area, heading north to the Cap-Haitien region. After the earthquake, this area contained the only medical facilities and the little resources the country maintained. Furthermore, most Haitians do not have access to potable water. Water-borne diseases have increased due to lack of natural filtration, infrastructure for water treatment, and healthcare resources, as well as intense population shifts to more condensed regions. This three-part project will assess the Cap-Haitien Bay watershed, identify point and non-point sources of pollution and evaluate the prevalence of waterborne infectious diseases in Cap-Haitien waterways. Working with the Fondation pour la Protection de la Biodiversite Marine—Haiti's only marine conservation NGO—results will be used to design and implement community conservation projects, outreach and education, as well as a plan to improve ecosystems of the Cap-Haitien region.

ECOSYSTEMS AND PEOPLE ADAPTING TO CLIMATE CHANGE IN NEPAL

Judy Oglethorpe

WWF US

Sunil REGMI, CARE Nepal ; Eric WIKRAMANAYAKE, WWF US ; Gokarna Jung THAPA, WWF Nepal ; Dev Raj GAUTAM, CARE Nepal ; Dipesh JOSHI, WWF Nepal ; Shant JNAWALI, WWF Nepal ; Pabitra JHA, CARE Nepal

As climate in the Himalayas, mid-hills and plains of Nepal becomes more variable, many impacts are occurring, and significant longer term climate change impacts are projected. The Hariyo Ban (Green Forest) Program promotes climate adaptation for people, ecosystems and species in the Gandaki river basin and Terai Arc Landscape. Work has included over 300 vulnerability assessments and adaptation plans at different scales from community forest level through

village development committee (lowest administrative unit), protected area, and landscape. Different methodologies were used, including Integrated Vulnerability and Capacity Analysis at local level, and Flowing Forward methodology at protected area/landscape level. This is backed with climate information, and modeling of possible vegetation shifts, climate refugia and species distribution changes. Resilience building and adaptation are being implemented both through stand-alone climate adaptation plans, and mainstreamed into sectoral and protected area/landscape plans. At community level these include ways to empower the most marginal and vulnerable people to participate, and ensure interventions are locally appropriate. Many lessons come from integrating ecosystem and community adaptation, which brings benefits and helps avoid maladaptation, but requires work at multiple ecosystem scales beyond site level. Water catchments are useful units for adaptation despite institutional challenges. Ecosystem impacts often take longer than community impacts; hence planning for different timescales is important at different levels. A multi-sectoral approach is essential for successful adaptation, including conservation, forestry, agriculture, water, energy, health, disaster risk reduction, and infrastructure. Lessons show that multiple approaches at multiple scales are necessary, with flexibility, innovation and learning, especially given the growing climate uncertainty and rapid social, economic and political change in Nepal.

ECONOMIC BENEFIT OF WILD ANIMALS; A POSSIBLE THREAT TO CONSERVATION IN OVIA SOUTHWEST, EDO STATE, NIGERIA

Bukola Oguntuase

Federal University of Technology Akure

Motunrayo OLOFINSAE, Federal University of Technology Akure

This study was carried out to assess the contribution of bush meat to Edo people's livelihood and the consequence of utilization on conservation. Five markets were selected in Ovia Southwest local government area of Edo State, twenty bush meat sellers were selected from each market. Direct observations were made to document the composition of wild animals under sale in the study area. A total of one hundred questionnaires were administered to the respondents. The questionnaires were all retrieved and analyzed using descriptive analysis. The results show that thirteen animal species are being traded in the area. The price for the animal species (whole animal) ranged from N200 to N9,520. Respondents reported that there is a decline in the animal population over time. Between 64% and 95% of the respondents acknowledged population decline in seven of the thirteen animal species available for sale compared to what it used to be some ten years ago. Sales of Wild animal species could be regarded as a profitable business in the rural community, supporting livelihood of the community, but could

have devastating effect on conservation as already observed in this study if harvesting of Wild animals is not regulated on controlled or sustainable basis.

BROWSING BY HARES ON FOREST VEGETATION IN RESPONSE TO SUPPLEMENTARY FOOD

Sara Öhmark

Mid Sweden University

Baiting and supplementary feeding causes change in distribution and foraging behaviour of wild herbivores and are extensively used methods for management and conservation purposes. However, these methods remain controversial as they bring about ecological effects that are sometimes detrimental. Further, responses by herbivores to added food are ambiguous and depend on characteristics of both the target population and the environment. We investigated how browsing pressure imposed by mountain hare (*Lepus timidus*) on mountain birch (*Betula pubescens* ssp. *czerepanovii*) vegetation near feeding stations varied with a) amount and b) type of offered food and with c) vegetation density and d) previous browsing distribution. An increased rate of browsing was observed near added food even where a relatively little preferred food type (oat straw) was added in small amounts (120 g). Vegetation density had a clear impact on the rate of browsing near feeding stations while the rate of previous browsing by hares had a marginal effect. A higher visiting frequency of hares near feeding stations relative to at control sites was evident three weeks after the removal of the added food, but no difference in browsing pressure on birch remained one year after the study. The results show that browsing pressure on vegetation that is induced by baiting and supplemental food can be controlled both by the design and location of feeding stations. Further, the high potential impact of artificially placed food on ecological systems was demonstrated. We recommend that added forage should be separated from sensitive vegetation and that baiting and supplemental feeding always should be planned with due consideration for associated ecological impact.

UNDERSTAND THE SKIN TO BETTER UNDERSTAND THE DISEASE: THE ROLE OF SKIN SLOUGHING IN THE SUSCEPTIBILITY OF AMPHIBIANS TO A FUNGAL FROG-KILLER

Michel E. B. Ohmer

The University of Queensland

Rebecca L. CRAMP, The University of Queensland ; Craig R.

WHITE, The University of Queensland ; Craig E. FRANKLIN, The University of Queensland

The fungal pathogen *Batrachochytrium dendrobatidis* (Bd), which causes the amphibian disease chytridiomycosis,

has resulted in the declines and extinctions of amphibians worldwide and is a major conservation concern. This generalist pathogen infects a wide range of amphibian hosts, and a combination of ecological, physiological and environmental variables likely influence differences in susceptibility within and between species. As a skin pathogen, variation in susceptibility to Bd may also be influenced by aspects of skin functioning, such as the rate of routine amphibian skin sloughing or shedding. It has been demonstrated that sloughing may be involved in immune defence by regulating the growth of skin-associated microbes, and thus could play an important role in the pathogenesis of chytridiomycosis. To determine the relationship between skin sloughing and disease progression, we exposed adult Australian green tree frogs (*Litoria caerulea*) to Bd, and monitored the change in sloughing rate and infection load over time using infrared cameras and quantitative PCR. We found that sloughing rate increased with Bd infection load in infected frogs, but the act of sloughing did not reduce Bd load on the ventral skin surface. In this susceptible species, sloughing does not appear to limit the progression of disease and may actually exacerbate the loss of physiological homeostasis seen in terminally ill frogs by further inhibiting water and electrolyte transport across the skin. By measuring sloughing rates directly for the first time, our results provide insight into how variation in sloughing may influence susceptibility, and we are currently examining sloughing rates across amphibian species to investigate this relationship within a phylogenetic context. Understanding the factors driving variation in intra- and interspecific susceptibility can improve our predictions of amphibian responses to Bd in wild populations, allowing for better species conservation planning.

62. A SOCIO-ECOLOGICAL APPROACH TO HUMAN VALUES

Shigehiro Oishi

University of Virginia

Human values are often defined as “desirable transsituational goals, varying in importance, that serve as guiding principles in the life of a person or other social entity” (Schwartz, 1994, p. 21). The dominant approach in the study of values explored the origins of individual differences in human values in terms of genetics versus family environments, and examined correlates of human values ranging from political ideology, religiosity, to environmental preservation and pro-social behaviors. The traditional approach views values as an internalized entity (“inside the person”) and a predictor of individual differences in social behaviors (e.g., “Who recycle?” “Who vote?”). The socio-ecological approach to human values emphasizes the mutual constitution of human values and social ecology, namely how physical, societal, and interpersonal environments give rise to certain human values, and how certain human values create

certain physical, societal, and interpersonal environments. The main insight from the socio-ecological approach to human values is that values are the product of dynamic adaptation to environments. The prevalence of pathogens, for instance, gave rise to the importance of security, tradition, and collectivism (as a collective defense against pathogens) in many parts of Africa and Southeast Asia, whereas the relative lack of pathogens gave rise to the importance of autonomy and individualism in many parts of Northern Europe and North America. Likewise, climate changes and natural disasters should give rise to change in human values (e.g., victims of major earthquakes value collectivism more than non-victims). The socio-ecological psychology of human values sheds new light on individual, group, institutional, and societal adaptations to environmental changes.

HUMAN ACTIVITIES AND THEIR RELATIVE THREATS TO BIODIVERSITY AT SELECTED FOREST RESERVES IN NIGERIA

Samson Oluwagbemiga Ojo

University of Ibadan

Oladapo. O Oduntan, Federal University of Agriculture

Thousands of years of cutting and burning, especially in Africa have so transformed vegetation and subsequently land that it bears little resemblance of its original state in which tree cover was probably denser than it is today. Concern has developed about the rapid rate of tropical deforestation, the temporary or permanent clearance of forest for agriculture and other purposes. Evaluation of pressure degrees and threats imputed by human activities on protected areas was determined in the study area. Four forest reserves out of seven in the division were randomly selected as representative samples, namely: Ilaro, Imeko, Oja Odan and Aworo forest reserves. Primary data were used for this study. Data were collected through the use of Rapid Assessment and Prioritization of Protected Areas Management (RAPPAM) designed questionnaire that was recommended for evaluation of threats and Pressure on protected areas (WWF, 2003). Descriptive statistics and ANOVA were the statistical tools used for data analysis in this study. The findings show that all the reserves are severely threatened by logging while only Oja-Odan F.R. is severely threatened by conversion of land use. In addition, Oja-Odan and Imeko are the only reserves that are severely threatened by hunting, although Aworo F.R. is also highly threatened. Oja-Odan F.R. and Imeko F.R. are severely threatened by harvesting of non-timber forest products while Aworo is also highly threatened by same activity. Furthermore, all the forest reserves are highly threatened by grazing except Ilaro F.R. while cross boundary influence severely threatened Oja-Odan F.R., although severity of threat in Ilaro F.R. and Aworo F.R. is high as well. No significant difference ($LSD = 9.04$; $p < 0.05$) between activities in each forest reserves; although analysis of variance shows a

significant difference between the pressure and threat across the forest reserves. Policy recommendations were made based on the outcome of this study.

IMPACTS OF METAPOPULATION DYNAMICS ON OVERFISHING RISK AND VULNERABILITY IN MULTISCALE FISHERIES

Daniel Okamoto

Simon Fraser University

Salomon ANNE, Simon Fraser University; Margot HESSING-LEWIS, Simon Fraser University

Fisheries management generally strives to balance trade-offs between complex economic, social and ecological systems. Yet estimates of overfishing risk under individual harvest guidelines are likely to be biased where the spatial and temporal scales of science and management are improperly aligned with that of either the biology and/or the socioeconomic dynamics of the fishery participants. These biases have the potential to be especially pronounced in the presence of individual sub-stocks (i.e. metapopulation structure). Moreover the consequences of those biases are likely asymmetric when multiple fleets operate at different spatial scales. Specifically fleets targeting the entire metapopulation may be less vulnerable to risky harvest guidelines or naive biological assumptions than those dependent upon a subset of local stocks. We explore the degree to which bias in overfishing risk and asymmetry in vulnerability among fleets result from the nature of harvest control rules, patterns of synchrony and connectivity among populations, and the scientific uncertainties in spatial and temporal population dynamics using a combination of metapopulation modeling and management strategy evaluation. We first use a basic simulation framework to illustrate how population connectivity, synchrony and harvest guidelines influence both local (single population level) and regional (metapopulation level) overfishing risk and extirpation probabilities. We then apply the models to a case study of Pacific Herring in British Columbia. Here, both transient industrial fishing fleets and local First Nations fleets target a complex suite of herring stocks whose spatial structure is poorly understood at smaller scales. Results are valuable in demonstrating which scenarios may benefit from improved knowledge of the temporal and spatial dynamics of the target species or the risk tolerance of individual fishery fleets.

WILDLIFE DETECTION DOGS; HELP OR HINDRANCE IN TROPICAL CONSERVATION CONTEXTS?

Hannah O'Kelly

Wildlife Conservation Society

Due to their extremely powerful sense of smell, trained wildlife detection dogs can greatly increase the efficacy of field surveys in a range of contexts. Dogs can search large areas and difficult terrain more easily than human search teams and they will detect targets (i.e. animals or animal sign) that human observers may miss, thereby potentially alleviating sources of bias. Detection dogs can be used to rapidly and reliably establish presence in certain scenarios and also to increase detection rates and therefore sample size. However, the training and handling of these dogs is a specialized skill and the logistical and financial costs associated with deploying canine survey teams in the tropics can be high compared to, for example, employing local field assistants. There is nonetheless growing interest in this method in areas outside its traditional sphere of use and it is particularly appealing where rare and elusive species are concerned, as is so often the case in the tropics. By presenting several short case studies we identify circumstances where detection dogs can yield tangible gains in challenging field contexts, but we also highlight potential situations where the use of dogs may not represent an optimal approach in terms of overall efficiency. Through these contrasting examples we formulate some general guidelines on when the use of detection dogs might be warranted and emphasize key considerations which should be taken into account by any conservation practitioners contemplating this approach.

AVIAN SPECIES DIVERSITY AND PHYSICO-CHEMICAL PARAMETERS OF WATER BODIES IN UNIVERSITY OF LAGOS, NIGERIA.

Fatsuma Olaleru

UNIVERSITY OF LAGOS, NIGERIA

Ann UDEH, UNIVERSITY OF LAGOS, NIGERIA ; Michelle FASONA, UNIVERSITY OF LAGOS, NIGERIA

The richness and diversity of avian species in wetlands can be influenced by physical and chemical parameters in their habitat. This study considers the interactions between abiotic factors and bird richness and diversity in the wetland and its water bodies around Faculty of Science, University of Lagos, Nigeria. Point count method was used for the bird census and physico-chemical parameters such as temperature, pH, conductivity, turbidity, salinity and depth of the water bodies studied using Horiba U50G. Morning and evening bird surveys were conducted for three months, April – June. Twenty four (24) species of water birds belonging to 12 families were recorded. These were Accipitridae, Alcedinidae, Antidae, Ardeidae, Charadriidae, Ciconiidae, Columbidae, Indicatoridae, Musophagidae, Phalacrocoracidae, Scolopacidae, and Threskiornithidae. Large waders such as *Ardea cineila* and *Ardea albawere* the most abundant species group (45.8%);

too tiny such as *Halcyon malimbica* and *Halcyon senegalensis* constituted 29.2% of the birds. The relationship between species richness and diversity was significant ($P = 0.0026$) with r value of -0.78 . There was a significant relationship between the water pH and species richness ($P < 0.05$, $r = 0.56$); while all other parameters were not significant ($P < 0.05$). Activities and the physico-chemical parameters of the wetlands in the University of Lagos should be monitored regularly for the conservation of wildlife species in general and avian species in particular that depend on it as their habitat.

FARMERS ADOPTION OF SOIL MANAGEMENT PRACTICES FOR IMPROVED CROP PRODUCTION IN THE FEDERAL CAPITAL TERRITORY, ABUJA, NIGERIA.

Rotimi Saka Olaleye

Federal University of Technology

F.e ONWUMERE, Agriculture and Rural Development

Secretariat, Federal Capital Territory Administration ; Bolaji, O.

ADENIJI, Federal University of Technology

Study examined farmers adoption of soil management practices for improved crop production. Data collected from 264 randomly selected farmers were analyzed using descriptive and inferential statistics at 5% significant level. Mean age was 43.5yrs and family size was 8, while 58.3% were literate, Mean annual farm income was N416, 059.28 and farm size was 7.44 ha, Major information source was extension agent (96.2%). Most adopted soil management practices were crop rotation (90.9%), use of inorganic fertilizer (89.8%), cover crops (83.3%) and mulching (81.1%). Regression analysis shows that age has negative but significant relationship with adoption. Annual farm income and family size were positively significant with adoption of soil management practices. Correlation analysis shows a positive relationship ($r = .258$) between attitude and adoption. Therefore, more awareness should be created on the most adopted soil management practices. Study examined farmers adoption of soil management practices for improved crop production. Data collected from 264 randomly selected farmers were analyzed using descriptive and inferential statistics at 5% significant level. Mean age was 43.5yrs and family size was 8, while 58.3% were literate, Mean annual farm income was N416, 059.28 and farm size was 7.44 ha, Major information source was extension agent (96.2%). Most adopted soil management practices were crop rotation (90.9%), use of inorganic fertilizer (89.8%), cover crops (83.3%) and mulching (81.1%). Regression analysis shows that age has negative but significant relationship with adoption. Annual farm income and family size were positively significant with adoption of soil management practices. Correlation analysis shows a positive relationship ($r = .258$) between attitude and adoption. Therefore, more awareness should be created on the most adopted soil management practices

ASSESSING THE RISK OF COLLAPSE OF NEOTROPICAL FOREST ECOSYSTEMS

María A Oliveira-Miranda

Provita

Jon Paul Rodriguez, Instituto Venezolano de Investigaciones Científicas ; Irene ZAGER, Provita ; Andrés ETTER, Universidad Javeriana ; Bernal HERRERA-FERNÁNDEZ, CATIE ; Carlos M. ZAMBRANA-TORRELIO, EcoHealth Alliance ; Pat COMER, NatureServe ; Carmen JOSSE, NatureServe ; Edmund G BARROW, International Union for Conservation of Nature ; David A KEITH, University of New South Wales

In 2014, the International Union for Conservation of Nature (IUCN) adopted a set of categories and criteria for assessing risks to ecosystems, thus establishing a new official global standard for biodiversity assessment and monitoring. Over the last six years, the IUCN Red List of Ecosystems Thematic Group developed the science underlying the criteria, tested them widely, and received feedback from the global community of conservation scientists and practitioners. This talk will be the first synthesis of the implementation of the Red List of Ecosystems protocol at the continental level, contrasting results at various spatial scales. We begin by summarizing the outcomes of "From Alaska to Patagonia: Red List of Continental Ecosystems of the Americas," our first major research effort, which ends in mid-2015. Outputs at the sub-national and national level (e.g. Colombia, Costa Rica, Venezuela), are compared to those at regional (e.g. tropical Andes) and continental levels. Our focus in this talk is on forest ecosystems of Meso and South America, as data on their change in extent and quality are less uncertain than other ecosystem types (e.g. grasslands). Data on potential and current extent were used to quantify "historical" rates of decline, while recent change was measured by projecting observations made between 2000 and 2010 into the future. At this broad geographical scale, ecosystem degradation was illustrated by examining moisture variation in montane ecosystems, as determined by remote sensing. We highlight that assessments carried out at different spatial scales lead to different policy recommendations, thus assessors must begin by clearly delimiting the assessment unit and justifying the preferred typology of ecosystem types. Future stages of our analysis will focus on questions such as: How can information on species losses and global climate change be integrated into the Red List of Ecosystems protocol? Which are their best indicators of risk of collapse?

DIVERSITY-STABILITY RELATIONSHIPS: FROM THEORY TO NATURAL COMMUNITIES

Théophile Olivier

National Museum of Natural History

Benoit FONTAINE, National Museum of Natural History ; Marianne ELIAS, National Museum of Natural History ; Colin FONTAINE, National Museum of Natural History

The diversity-stability relationship is one of the most debated topics in ecology, but mostly using theoretical or experimental approaches. Such approaches usually focus on the stability of randomly assembled communities experiencing common experimental conditions. However, the composition of natural communities is not random but depends on both local environmental conditions and perturbations. Here we analyzed the temporal stability over 8 years of 131 local butterfly communities spread all over France. We used path analysis to disentangle the direct and indirect effects of habitat degradation on community stability. Our results indicate that habitat degradation affects both the species richness and the phylogenetic diversity of butterfly communities which in turn affect community stability but via different mechanisms. While species richness increases stability directly, phylogenetic diversity increases community stability via a decrease in population synchrony. Interestingly, we also found that the temporal stability at the population level also increases in richer communities. A finding that contrasts with experimental and theoretical results carried out on plant communities. Thus two distinct mechanisms appear to drive the stability of natural butterfly communities: a portfolio effect where more species induces a stronger statistical averaging of the population dynamic and a response diversity effect where more distantly related species tend to respond more differently to environmental fluctuations. Finally, the higher stability of populations might also contribute to the higher stability at community level. These results highlight additional pathways by which habitat degradation threaten the conservation of butterfly communities.

BUSHMEAT COMPARED TO OTHER ECOSYSTEM SERVICES FROM A TROPICAL FOREST

Ola Olsson

Lund University

Agnes ANDERSSON-DJURFELDT, Lund University ; Magnus JIRSTRÖM, Lund University ; Laura GUIA DIAZ, Lund University ; Edu EFFIOM, Lund University

Bushmeat hunting threatens many mammal species, but it also leads to a disruption of the ecological functions that these mammals provide, such as seed dispersal. This leads to diminished regeneration of many tree species with large seeds and/or fleshy fruits. We present results from both ecological and socio-economic surveys from a tropical forested area in Cross River, Nigeria. Much of the hunting, of all species including primates, is for local consumption in the villages near the forest. Bushmeat provides an important part of the protein intake in these communities, but provides very little monetary

incomes. Compared to 10 years ago, hunting of apes, drills and pigs has declined, whereas that of rodents has increased. Meat is only one of the resources that the households obtain from the forests. They also collect large amounts of fruits and nuts, as well as leaves, for food, other non-timber forestry products, and some timber. Economically, fruits and nuts are the most important ecosystem service that the communities get from the forest, and the harvest might be sustainable. By contrast, the economically much less important bushmeat hunting not only threatens some of the hunted species, but in the long run also the forest's capacity to provide the non-meat foods.

SPATIAL ASPECTS OF LAND USE THROUGH TIME: A GIS BASED STUDY OF THE EARLY LEVANTINE SITES OF GATH (ISRAEL) AND GADARA (JORDAN) AND THEIR SURROUNDINGS

Linda Olsvig-Whittaker

German Protestant Institute of Archaeology in the Holy Land
Dieter VIEWEGER, German Protestant Institute of Archaeology in the Holy Land ; Katja SOENNECKEN, German Protestant Institute of Archaeology in the Holy Land ; Liora KOLSKA HORWITZ, National Natural History Collections, Hebrew University of Jerusalem ; Ehud WEISS, The Tel es-Safi/Gath Archaeological Project, The Institute of Archaeology, The Martin (Szusz) Department of Land of Israel Studies and Archaeology, Bar-Ilan University ; Suembikya FRUMIN, The Tel es-Safi/Gath Archaeological Project, The Institute of Archaeology, The Martin (Szusz) Department of Land of Israel Studies and Archaeology, Bar-Ilan University ; Oren ACKERMANN, The Tel es-Safi/Gath Archaeological Project, The Institute of Archaeology, The Martin (Szusz) Department of Land of Israel Studies and Archaeology, Bar-Ilan University ; Aren MAEIR, The Tel es-Safi/Gath Archaeological Project, The Institute of Archaeology, The Martin (Szusz) Department of Land of Israel Studies and Archaeology, Bar-Ilan University

Many factors influenced the manner in which past societies used the landscape, including their cultural traditions, which are reflected in their subsistence base, type of agricultural and pastoral practices, extent and character of commerce, trade and industry, nature of infrastructure developed (such as roads), site function and socio-political system. By studying diachronic patterns of past land use, we can begin to understand the changing dynamic between societies and their environment over time. We present here two cases studies from the Near East. Tell es-Safi (Canaanite and Philistine Gath) in Israel and the Tall Zira'a (ancient Gadara) in Jordan, are two major archaeological sites spanning the Early Bronze Age to modern times, representing about 4,000 years of human occupation. Data obtained from archaeological surface surveys recording all anthropogenic activity in the landscape around these tells by period, was compiled. Using GIS mapping of

modern habitats derived from orthophotos, we developed a modern standard against which to compare and contrast the archaeological surface survey data for the two regions, looking for patterns of correlation with biological and physical features over time. The results of this study enabled us to understand the degree to which land use is determined by the landscape geography and ecology on the one hand, and by the culture of the people using the land, on the other.

SPATIAL DISTRIBUTION OF ECOSYSTEM SERVICES AS PERCEIVED BY NATURE CONSERVATION PROFESSIONALS AND LAY PEOPLE - AN EXPERIMENTAL STUDY USING FACILITATED WORKSHOPS

Agnieszka Olszanska

Institute of Nature Conservation Polish Academy of Sciences
Agata PIETRZYK-KASZYNSKA, Institute of Nature Conservation Polish Academy of Sciences ; Marcin RECHCINSKI, Institute of Geography and Spatial Management, Jagiellonian University ; Barbara PEEK, Institute of Nature Conservation Polish Academy of Sciences ; Joanna CENT, Institute of Environmental Sciences, Jagiellonian University ; Malgorzata GRODZINSKA-JURCZAK, Institute of Environmental Sciences, Jagiellonian University

We aimed to investigate the spatial distribution of ecosystem services perceived in protected and adjacent non-protected areas. We analyzed the convergences and divergences in perceptions of two stakeholder categories: (1) professionals working on spatial planning and nature conservation (the "experts") and (2) local leaders not professionally involved, yet potentially interested in nature conservation (the "lay people"). We conducted our research on five study sites in Poland. The study sites differed in size, shape, as well as socio-economic and ecological aspects (e.g. population and land use characteristics or habitat structures). Using the CICES classification, we developed a list of ca. 20 ecosystem services potentially present in the study areas. During 10 facilitated workshops – one with experts and one with lay people on each study site – participants drew polygons of land that they perceived as providing particular ecosystem services. Each workshop aimed at finding a common vision of ecosystem services distribution and exploring the reasoning and argumentation behind particular opinions. As a result, two different ecosystem services maps were prepared for each site, one representing experts' view, and one representing lay people's perceptions. Using GIS software, we measured spatial correlations of various ecosystem services. Subsequently, we analyzed the extent to which experts' and lay people views were convergent in relation to types of ecosystem services and their distribution. As we hypothesized, most of ecosystem services were more widely perceived in protected in comparison with non-protected areas. We conclude

that the spatial distribution of the ecosystem services over protected and non-protected landscape as perceived by different stakeholders is crucial for spatial planning and nature conservation processes at both local and regional level.

THE MODERN CONSERVATION BIOLOGY INITIATIVES IN THE DEMOCRATIC REPUBLIC OF CONGO (DRC): THE EXAMPLE OF THE CONSERVATION OF BONOBOS BY THE NGO MBOU-MON-TOUR (MMT)

Valentin Omasombo Wotoko

Centre d'Ecologie Fonctionnelle et Evolutive
Claude MONGHIEMU, NGO Mbou-Mon-Tour ; Jean-Christophe BOKIKA NGAWOLO, NGO Mbou-Mon-Tour ; Jean MALEKANI, Université de Kinshasa ; Julien PUNGA, Université de Kinshasa ; Marc BONKOTO, NGO Mbou-Mon-Tour ; Aurélien BESNARD, Centre d'Ecologie Fonctionnelle et Evolutive ; Claude MIAUD, Centre d'Ecologie Fonctionnelle et Evolutive

The bonobo (*Pan paniscus*) is an endemic great ape of the Democratic Republic of Congo (DRC) that suffers a rapid decline due to the pressure induced by human demography, the abandonment of taboos on hunting, the economic and political crises, the epidemics and its habitat degradation by deforestation. This species is fully protected in DRC by Congolese laws and is cited in Appendix 12, Class A CITES and in the red list of the IUCN / SSN as « vulnerable » and « in danger ». The Grouping Mbee-Nkuru local communities in the Chiefdom of Batékés North, decided to protect by their own the bonobos populations occupying their surrounding area. To do this, in 1997, these communities have created a Non Governmental Organization (NGO) and asked the Congolese government to offer them a forest concession of 500 square kilometers in the forest-savannah mosaic area about 300 km north of Kinshasa, capital of DRC in order to develop the Bonobo conservation. In this area they promoted new methods of land use and agriculture, guard by themselves the Bonobos populations and developed a participative supervision of the area. In this context, we initiated a study that aimed at simultaneously acquiring the basic knowledge of ecology of the species in this area (population size, habitat use...) and the sociological factors related to this conservation action (factors that led this community to protect this species, but also consequences of this involvement). We also performed the same study on both the bonobos and humans in another reserve managed by the state only to compare the results. This approach that study the ecology but also the human dimension of species protection seems to be a promising way to develop an efficient and modern conservation biology in Africa.

EXPLORING MULTIDISCIPLINARY POSSIBILITIES IN UNDERSTANDING HUMAN-WILDLIFE CONFLICT ALONG A FOREST-AGRICULTURE FRINGE IN THE WESTERN GHATS HOTSPOT IN SOUTHERN INDIA

Meera Anna Oommen

University of Technology Sydney
Heather GOODALL, University of Technology Sydney ; William GLADSTONE, University of Technology Sydney

Lying at the nexus of farmland and forest, the fringe is a contact zone for people and wildlife. In the tropics, these productive zones are beneficial to wildlife such as pigs, deer, monkeys, elephants and carnivores. In this study, we explore the dynamics of a heavily populated forest fringe in Kerala, India, where extended periods of crop depredations and agrarian distress have resulted in an atmosphere of conflict resulting in retaliatory killings of wildlife and widespread opposition to forest protection. In this multidisciplinary enquiry, we use a mixed methods protocol ranging from Bayesian Belief Networks to oral histories and ethnographic enquiry to interrogate the interlinked components of conflict. Probabilistic networks are used to predict not only ecological suitability of different land use types for conflict, but are also useful in incorporating socio-economic and cultural components, linking decision-making frameworks and evaluating the effectiveness of predictions. Expanding these networks based on ethnographic enquiry shows that in addition to visible causal mechanisms (e.g. crop damage, direct attacks), opposition to wildlife is also a reflection of numerous typically unaccounted costs (e.g. opportunity costs, repercussions on food security), invisible impacts (e.g. emotional distress, poor physical health), historical contingencies (e.g. migration, agricultural choices) and consequent perceptions of distributive justice. Tracing the history of contrasting attitudes towards elephants and pigs in the region, we also emphasize the importance of species level differences especially in relation to their invisible impacts on psycho-social wellbeing. The negligible levels of conflict with indigenous forager-trader communities who live within the forest is in marked contrast to that of marginal farmers along the fringe indicating the critical role of differing expectations of place and lifestyles in determining human-animal relationships.

ECOLOGICAL RESEARCH ABOUT NATURA 2000 FOCUSES MAINLY ON FORESTS AND VASCULAR PLANTS

Ewa Orlikowska

Swedish University of Agricultural Sciences
Malgorzata BLICHARSKA, Swedish Biodiversity Centre (CBM) ; Jean-Michel ROBERGE, Swedish University of Agricultural

Sciences ; Grzegorz MIKUSINSKI, Swedish University of Agricultural Sciences

Natura 2000 is regarded as one of the most important and extensive nature protection networks worldwide, designated to support long-term survival of Europe's most valuable and threatened species and habitats. Based on the Birds Directive and the Habitats Directive, Natura 2000 is considered the key biodiversity conservation tool in the EU. Currently, the network encompasses 18% of Europe's landmass and over 251 000 km² of marine environment across all 28 EU member states. We conducted a literature review of the Natura 2000 topic using the Web of Science™ database for 1998-2014. We found 682 English-language publications relevant to Natura 2000, with focus areas of ecological (62%), social (21%), and socio-ecological (18%). Our review concentrates on in-depth analyses of the ecological publications. Spain, Poland, Italy and Greece produced the most articles of ecological scope. Scale-wise, the majority of publications focused on a region within a country or a single Natura 2000 site; most represented habitats included forest, undefined, freshwater and grasslands. Plants, abiotic factors, insects and birds were the most commonly-represented research subjects. Low elevation sites were considered more often than were montane sites. There was also an even split between community/guild versus ecosystem approaches, and fewer articles focused on a single species. Quantitative empirical study was the most common method used, followed by modeling and then by qualitative/analytical methods. Future research should investigate alpine, agricultural and marine habitats as well as taxonomic groups such as fish, reptiles and amphibians, and lichens. Furthermore, there are relatively few studies of northern and western Europe, or of EU-wide range, nor have the social and socio-ecological aspects of Natura 2000 been adequately investigated.

POPULATION EFFECTS OF TRANSIENT INDIVIDUALS AND CONSERVATION CONSEQUENCES FOR ENDANGERED SPECIES

Daniel Oro

IMEDEA (CSIC-UIB)

Daniel F. DOAK, UNIVERSITY OF COLORADO- BOULDER

We assess the implications that transient individuals can have on dynamics of local populations, with special attention to vertebrates. Transients are individuals that are detected only once in a population and then disappear. Despite being detected in many studies, the significance of transients for population analysis and the consequences for population stability have never been addressed before. In the capture-recapture (CR) modelling framework, transients have to be analyzed separately to avoid a bias in local survival estimates. Nevertheless, beyond the technical importance of taken this effect into account in survival CR analysis, transients have

also several biological meanings. A transient in CR may result from either an age effect (when newborns are marked) or by movement into the study area by adults or juveniles that is rapidly followed by permanent emigration. Alternatively, transience can also be true mortality (when adults are marked) when costs of first breeding are high and selection filters act on recruiting individuals. The occurrence of transients can be influenced by environmental stochasticity (e.g. increasing transience when conditions are harsh), population features (e.g. density-dependence) or individual covariates (e.g. age). We first assessed how frequent transience is in animal populations and which factors influence its magnitude. We then used stochastic population models to assess how the existence of transients influence population dynamics and the viability in endangered populations.

ROADS AND AFRICAN ELEPHANTS IN A SMALL SOUTH AFRICAN PRIVATE GAME RESERVE: A CALL FOR GREATER UNDERSTANDING OF THE IMPACTS OF ROADS ON SPACE USE OF WILDLIFE

Katherine Orrick

Columbia University

The ecological effects of roads are considered to be one of the most significant sources of ecosystem disturbance. As the human population continues to expand there is an increasing demand for more extensive road systems that overlap wildlife's home ranges. In many instances roads will constrict the movements of the wildlife. It is critical to recognize species true use of space versus available space, especially individuals already in small, protected areas. While many studies have observed the direct effect of road disturbance on wildlife, such as road mortality and fragmentation, few studies have looked at indirect effects, such as noise pollution and visual disturbance. This study analyzes the impact of public roads surrounding Karongwe Private Game Reserve, an 8000ha fenced reserve in the Limpopo Province of South Africa, on a herd of African elephants (*Loxodonta africana*). Six years of elephant data are examined to determine if the bordering roads within 50m of the reserve impact the individuals. GIS and Generalized Linear Mixed Effects models were created based on the distance of elephant locations from different anthropogenic disturbances (public roads, fences, lodges) and natural features (vegetation, rivers, water sources). Home ranges indicate a clear avoidance of the paved roads for all individuals. General trends suggest that public roads negatively impact both the breeding herd and the adult bulls. The research will provide vital information about the future of small, protected areas on large mammals such as elephants. If a species avoids roads due to disturbance, conservation measures must be taken to prevent further human-wildlife impacts and address infrastructure expansion near preserved

lands. The results of this study can contribute to improving development around conservation areas in South Africa as well as refine elephant-inhabited protected areas all over the world.

EVALUATING THREATENED SPECIES RECOVERY PLANS: PROPOSED FRAMEWORK AND UNIVERSAL LESSONS FOR MONITORING AND EVALUATION

Alex Ortega-Argueta

El Colegio de la Frontera Sur

Benjamin MORALES-VELA, El Colegio de la Frontera Sur

Recovery planning of threatened species is a complementary approach to establishing protected areas for biodiversity conservation. It is also incorporated into international treaties and the national legislation of several countries. Research and practice have shown that recovery planning is a very challenging task given the complexity of its ecological, socioeconomic, political and managerial aspects. One of the weakest aspects is the lack of a universal methodological framework and adequate criteria by which to assess recovery success. In this presentation, a monitoring and evaluation framework is illustrated with practical application in the Caribbean Manatee recovery plan in Mexico. A participatory evaluation framework was employed with support of the federal agency in charge of implementing recovery plans and the national manatee recovery team. Evaluation objectives comprised: 1) assessment of recovery plan progress and main achievements; 2) estimation of the degree of plan implementation towards meeting goals and objectives; 3) definition of the priority recovery actions and budget for the next five years; 4) establishment of the management mechanisms to strengthen coordination of the manatee recovery team and other stakeholders and 5) define a new five-year period work plan. Forty-four evaluated recovery actions were classified into six categories: species management, habitat restoration, protection, knowledge, culture, and operational management. Evaluation results indicated that 41% of recovery actions are behind schedule or remain to be addressed, 45% show medium progress and 14% have recorded significant progress. A discussion will address the facilitators and barriers that most influence recovery plan progress. General lessons were drawn from the analysis of this case study and comparison with similar evaluations in other countries.

LOCAL PEOPLE PERCEPTION ON FOREST GOVERNANCE IN PROTECTED AREAS IN NIGERIA

Israel Oluyinka Osunsina

Federal University of Agriculture, Abeokuta, Nigeria

Despite the fact that for a long time many local communities contributed to the conservation and protection of biological

resources, only recently has their importance in natural resources protection and the need for deriving benefits from protected areas has been recognised. Survey of the villageges around four Nigerian National Parks was carried out to determine the peoples' perception of purpose of establishment of Park and protection responsibility. Questionnaire were administered to respondents to elicit information from the villagers around the parks. CRNP(Cross River;985), Gashaka-Gumti(GGNP;1079);Kainji-Lake(KLNP;1134) and Old Oyo(OONP;1013) Natinal Parks. The result shows that many of the respondents in CRNP knew the purpose for the establishment of the Park(64.6%), while majority of the respondents in GGNP (66.7%), KLNP (51.1%) and OONP (57.3%) claimed not to know the purpose for the Park establishment. All the respondents in CRNP (100%) and more than half of the respondents in GGNP (65.3%) and KLNP (63.9%) reported that Park only advocates for the non intervention of the Park reources, while in OONP 57.8% reported that the Park authourity do request for their participation in the management of the Park. Respondents in CRNP indicated that the Park should be protected by the community because the land is closer and belongs to them. Respondents in GGNP and KLNP indicated that the Park should be protected by the Government that owns it. The result of the Chi-square showed that there was significant relationship ($p < 0.01$) between age, sex, occupation, income, educational qualification and the peoples perception on the parks protection responsibility. The issue of forest governance is an important aspect of the conservation which the people must be involved and hence the need to involved the local people in the management of the Protected areas

NEGATIVE INSECTICIDE IMPACTS ON POLLINATORS ARE REDUCED IN COMPLEX SMALL-SCALE AGRICULTURAL LANDSCAPES

Mark Otieno

Embu University College

Chanpreet Sheena SIDHU, Department of Entomology, University of California, Riverside ; Ben Alex WOODCOCK, NERC Centre for Ecology and Hydrology ; Andrew WILBY, Lancaster Environment Centre, University of Lancaster ; Ioannis N. VOGIATZAKIS, School of Pure and Applied Sciences, Open University of Cyprus ; Alice L. MAUCLINE, Centre for Agri-Environmental Research, University of Reading ; Mary W. GIKUNGU, Zoology Department, National Museums of Kenya ; Simon G. POTTS, Centre for Agri-Environmental Research, University of Reading

Pollinators face many challenges within agricultural systems due to landscape changes and intensification which can affect resource availability that can impact pollination services. This paper examines pigeon pea pollination and considers how

agricultural intensification affects the abundance of bees characterized by species guilds. The study was conducted on six paired farms across a gradient of habitat complexity based on the distance of each farm from adjacent semi-native vegetation in Kibwezi District, Kenya. The study revealed the strongest relationships between fruit set and bee abundance to be with the carpenter bee, social bee and solitary bee guilds, which are among the most abundant bees visiting pigeon pea flowers in this system. We found that farms which do not use insecticides in farm management, but are in close proximity to natural habitat have greater bee guild abundance, but at further distances, overall abundance is reduced with or without insecticide use. At 1 km landscape radius, the complexity of habitats but not patch size had a positive impact on the abundance of cavity nesting bees and mason bees, which can be attributed to the interspersed of the small-holder farms with semi-native habitats across the landscapes producing mosaics of heterogeneous habitats. Our findings provide the foundation for conservation efforts by identifying which bee guilds pollinated pigeon peas. From this study, we suggest managing the floral and nesting resources that would best support the most abundant crop pollinators, and also reducing insecticide application to the crop.

ECONOMIC VALUATION OF RICE CROP DAMAGE BY RED-BILLED QUELEA AND OTHER GRANIVOROUS BIRDS ON A RURAL IRRIGATION SCHEME IN WESTERN KENYA

Nickson Otieno

National Museums of Kenya

A MUTATI, National Museums of Kenya ; C AKOTH, National Museums of Kenya ; D OGWANG, Ahero Rice research Station ; P ALARO, Ahero Rice research Station

The study, conducted at Ahero Rice Irrigation Scheme in western Kenya from 2011-2012, aimed at estimating economic losses incurred by farmers from damage of rice crop by Red-billed Quelea *Quelea quelea* and other granivorous pest birds, assessing the implication of this for sustainable food security and exploring viable options to mitigate losses to pest birds. Pest bird densities were estimated from through sampling along varying-width line transect with spatial and temporal replications and their feeding rates determined per-season and per annum for valuation of rice damage rates. Total rice crop loss was then quantified from bird density and feeding rates for each bird group, calculated per season and annually. We then valued economic damage as a factor of the rice crop loss and prevailing paddy producer market price and finally estimated net economic loss by subtracting the cost of hiring labour to scare birds from damaging mature crop. The period of bird damage was restricted to the period between crop-maturity to harvest. Estimated total annual loss was 407 tonnes or 7.7% of potential yield for the whole

irrigation scheme excluding bird scaring costs. This was equivalent to Ksh. 40.7 million annually at 1 USD=87 Ksh. representing a 31.1% loss of net income. Inclusive of bird scaring costs, annual losses were Ksh. 20,763/ha equivalent to 39.5% of net income. Estimated annual rice damage due to *Q. quelea* was more than that due to the other granivorous birds combined (215 compared to 192 tonnes). We concluded that this loss magnitude considerably undermines efforts to reduce rural poverty and attainment of sustainable food security in the western Kenya region. In addition to the crop-guarding method, reducing losses from damage by the pest birds requires integration of several measures that have proved successful elsewhere, adoption of improved farming technologies and planting recently developed higher yielding rice varieties.

133 ASSESSING THE POTENTIAL OF INTERFAITH ENVIRONMENTAL NETWORKS IN CONTRIBUTING TO ENVIRONMENTAL CONSERVATION IN EAST AFRICA

Allen Ottaro

Catholic Youth Network for Environmental Sustainability in Africa

Since the 1986 gathering of leaders of the world religions in Assisi, Italy, religious communities have worked together on a variety of biological conservation issues from the perspectives of their particular sacred texts and traditions. These religious communities are regarded increasingly as key stakeholders in conservation efforts. Within the last two years, three faith and environment networks have been launched in Kenya, Tanzania, and Uganda, the three largest countries belonging to the East African Community. These networks seek to contribute to environmental conservation by influencing national, regional and international policy, education, awareness among their faithful, and sustainable land management practices. The contributions these interfaith networks make to the existing conservation efforts in East Africa will be underscored with focus on climate change, loss of biological diversity, and a rapidly growing population.

95" FISH, WATERWAYS AND ROADS - THE CHALLENGES OF COMBINING HYDROLOGY AND DYNAMIC SYSTEMS WITH STATIONERY AND STATIC INFRASTRUCTURE

Fabrice Ottburg

Wageningen UR, Alterra

Matt BLANK, Western Transportation Institute (WTI), Montana State University ; Paul WAGNER, Washington State Department of Transportation, Environmental Services Office.

This presentation focuses on fish that use fresh-water systems and provides solutions to minimise the effects of roads and road-stream crossings on fish and fish habitat. In order to complete their life cycles, fish need to move throughout waterways in their range to reach their spawning grounds, rearing areas or food resources. Streams providing necessary habitat are often in close proximity to or crossed by roads and railways, which can lead to habitat degradation and barriers fish movement. By degrading and isolating habitats, barriers can decrease fish populations and in some cases contribute to the total loss of a species. Steps typically taken to create and protect roads near streams include straightening channels or placing very large rocks or concrete reinforcement to stabilise banks. These generally result in loss of habitat and potential impacts to fish and wildlife populations. The dynamic character of streams and rivers and their changing nature needs to be accommodated in planning, expanding or operating transportation infrastructure where roads and other linear infrastructure cross water or occur in floodplain. This is necessary not only to minimise direct ecological effects to habitat and fish, but also to help reduce the potential damage to infrastructure from flooding, erosion and channel movement. Damage to infrastructure can often lead to additional environmental impacts. New infrastructure should avoid waterways where feasible and any crossings that are needed should be designed to allow the natural flow and function of the waterway. Existing road crossings that are barriers to the movement of fish should also be modified to be more natural and improve connectivity for fish and the support of natural stream function.

PARTICIPATORY ESTABLISHMENT OF FISH CONSERVATION ZONES IN THE MEKONG RIVER

Sinsamout Ounboundisane

FISHBIO Laos

Samuel LESLIE, FISHBIO Laos ; Erin LOURY, FISHBIO ; Shaara AINSLEY, FISHBIO ; Harmony PATRICIO, Griffith University [INSTITUTE] FISHBIO Laos

Human communities in the Mekong River Basin depend on fishing for food and income, but many species are declining. Because of the river's central role in livelihoods, many villagers support fish conservation. The national fisheries law in Lao PDR gives communities authority to establish Fish Conservation Zones (FCZs). While many community members possess relevant local ecological knowledge, they typically do not have the technical knowledge needed to design the FCZ effectively or the political knowledge to engage the government for formal establishment of new FCZs. We supported three villages

along the Mekong mainstream with the establishment of FCZs using a participatory approach and Knowledge, Attitudes, Practices (KAP) surveys. The FCZs were located specifically to protect the threatened Jullien's golden carp (*Probarbus jullieni*). Through consultations the communities helped design the FCZs and structured fishing restrictions based on what was feasible for their lifestyle. At three points during the project, a KAP survey was conducted with a subset of villagers to assess, 1) Local ecological Knowledge related to fish, aquatic ecosystems, and natural resource law; 2) Attitudes towards fish conservation strategies, government and NGO collaboration on local-level resource management; and 3) Current Practices related to aquatic resource use, food sources, income sources, enforcement of existing laws, and management strategies. 20 people were interviewed in each of the three villages, representing primary resource users (fishers), village elders, village committee members, and women's union members. Results from the initial survey revealed a strong knowledge of fish biology and a high level of support for conservation. The communities developed a strong sense of pride in their collective achievement, and unexpectedly chose to keep the areas closed to fishing year-round. This project can serve as a useful model for harmonizing human resource needs and conservation.

PSYCHOPHYSICAL ASSESSMENT OF GIANT PANDA HEARING SENSITIVITY: IMPLICATIONS FOR CONSERVATION AND MANAGEMENT

Megan Owen

*Institute for Conservation Research, San Diego Zoo Global
Jennifer KEATING, Southwest Fisheries Science Center-NOAA ; Samuel DENES, The Pennsylvania State University ; Angela FIORE, Collections Husbandry Science, San Diego Zoo Global ; Kathy HAWK, Collections Husbandry Science, San Diego Zoo Global ; Juli THATCHER, Collections Husbandry Science, San Diego Zoo Global ; Jennifer BECERRA, Collections Husbandry Science, San Diego Zoo Global ; Ronald SWAISGOOD, Institute for Conservation Research, San Diego Zoo Global*

Human generated noise may negatively impact wildlife, however the nature and severity of impacts are dependent upon the interaction of environmental, acoustic, and biological factors. Because regulatory and ethical constraints typically preclude controlled noise exposure experimentation with conservation-dependent species, there is a need to develop species-specific predictive models of disturbance. Fundamental to this approach is the inclusion of data describing a species' sensory ecology, including hearing sensitivity. As a first step towards developing a sensory-based model of noise disturbance in giant pandas, we have developed an audiogram for the species. We used psychoacoustic techniques to measure behavioral hearing thresholds of 5 captive giant

pandas between 0.125 kHz and 50 kHz. Our results suggest that giant pandas have good hearing sensitivity between 8 and 14 kHz, with best sensitivity centered at 12.5 – 14 kHz. Hearing sensitivity declined by about 8 dB per octave from 8 kHz to 125 Hz, 2.3 db per octave from 8 kHz to 1 kHz, and by 7.5 dB per octave from 12.5-50.0 kHz. Functional hearing was measured as high as 50 kHz, and we developed estimates of upper limits of hearing by extrapolation. These results suggest that panda hearing sensitivity is similar to that of other terrestrial carnivores, however, panda hearing thresholds above 16 kHz were significantly lower than those of the polar bear. Integrating sensory data, along with a broader understanding of how reproductive condition, body condition, and habitat characteristics act in synergy to produce both species typical noise reception and the range of potential responses to noise, is essential for developing a biologically rational, context-based model of noise disturbance.

ID 68 MANAGING INVERTEBRATE DIVERSITY IN CONTRASTING FOREST ENVIRONMENTS: LESSONS FROM NATURAL FORESTS IN CANADA AND IRISH PLANTATIONS

Anne Oxbrough

Edge Hill University

Sergio GARCIA-TEJERO, Edge Hill University ; John O'HALLORAN, University College Cork ; John SPENCE, University of Alberta

Typically, approaches to sustainable forest management that support biodiversity focus on maintaining large scale habitat heterogeneity (between forest stands) or promoting diversity of plants, mammals or birds. With the exception of saproxylic species, invertebrates are largely overlooked despite their importance to ecosystem function and resilience. This paper presents spider and beetle diversity data from contrasting managed forest types in the boreal mixedwoods of Alberta, Canada, and mixed spruce-ash plantations across Ireland, collected using the same sampling methods (pitfall traps and Berlese-Tullgren funnels). Analyses examine common responses in spider and beetle diversity to forest management and determine impacts on functional traits across both regions. Results are discussed with a focus on incorporating the needs of invertebrates in sustainable forest management in these contrasting forest environments.

SHORT TERM EFFECTS OF EARLY-SEASON FIRE ON HERBACEOUS COMPOSITION, DRY MATTER PRODUCTION AND SOIL FERTILITY IN NIGERIA'S GUINEA SAVANNA

Stephen Oyedeji

University of Ilorin

Friday Joseph ONUCHE, University of Ilorin ; Clement Oluseye OGUNKUNLE, University of Ilorin ; Oludare Oladipo AGBOOLA,

University of Lagos ; Augustine Onwuegbukiwe ISICHEI, Obafemi Awolowo University

The ecological impact of fire regimes on plant diversity and soil fertility has become subject of intense discussions, especially in savannas where recurring incidences are common. This study assessed the short-term effects of early-season fire on herbaceous composition, dry matter yield and soil fertility in the guinea savanna belt of Nigeria. Data on ground cover, dry matter yield (DMY) and concentration of C, N, P, K, Ca and Mg were collected from 10 delineated subplots in the burned and unburned zones of four sites after annual wildfire had occurred. Ground cover of species was significantly higher in the burned zones and increased progressively from January through April (dry season). Eleven (11) herbaceous species, in addition to 2 tree seedlings, occurred and were distributed among families of Asteraceae, Cyperaceae, Fabaceae and Poaceae. *Digitaria nuda*, *Brachiaria lata*, *Aeschynomene indica* and *Daniellia oliveri* were limited to the burnt zones while *Cyperus tuberosus*, *Mariscus alternifolius* and *Rottboellia cochinchinensis* were restricted to the unburned zones. Dry matter yield range between 0.32 g m⁻² (*Desmodium tortuosum*) and 52.96 g m⁻² (*Megathyrus maximus*). Average biomass was higher in the burnt sites (35.86 g m⁻²), but not significantly different from the unburned sites (28.42 g m⁻²). Soil C, N and P decreased (positive deterioration index - DI), while K, Ca and Mg improved (negative DI). No significant differences exist for soil nutrients in the burned and unburned zones of the sites. The study concluded that burning altered growth (ground cover) and composition of species in a short-term, but may significantly influence soil nutrient dynamics on a long-term, especially with recurring fire events.

BUILDING RESILIENCE WITH FOREST: INDIGENOUS KNOWLEDGE SYSTEMS IN SOUTH WEST NIGERIA

Oyetayo Oyelowo

Forestry Research Institute of Nigeria

Adegboyega ADURADOLA, Federal University of Agriculture ; Olayide OYELOWO, PT Skills Limited ; Akin OLOKETUYI, Forestry Research Institute of Nigeria

Local communities in Nigeria have successfully conserved natural resource of interest to them. This study was conducted to investigate existing indigenous knowledge systems adopted by 5 communities (Aye, Ibere, Oba-ile, Igbo-Olodumare and Igbara-oke) in South West Nigeria, where Igbo-Gbopo, Igbo-Ile, Igbo-Oba, Igbo-Olodumare and Igbo-Olua sacred groves are located respectively. Questionnaires were administered randomly to custodians (16), community heads (40) and residents (94). The results showed that the respondents were 72.82% males and 27.18% females. Local people, community leaders and custodians share the responsibility of protecting the sacred groves. Majority of respondents see the groves

as their heritage and protect it by not going against taboos. They all affirmed that the biodiversity within the groves are still intact because knowledge is being transferred to the next generation mainly through the parents. The indigenous knowledge has been preserved, transferred or adopted and adapted in all the communities. Apart from spiritual purposes, Aye community adopted the strategy of protecting the forest to the roles of the grove in providing more dependable source of water. Ibere community maintains the grove against heavy winds into the community (windbreaker). Laws and punishment varies among the sacred groves, but all affirmed that punishments of the intruders go beyond physical, but affliction through deities. Conservation policies should therefore acknowledge and incorporate values and local practices to reduce loss of both cultural and biodiversity. The country's ability to build and mobilize knowledge is essential for sustainable development.

DEVELOPING AN APPROACH FOR THE INTEGRATION OF FOREST BIODIVERSITY CONSERVATION INTO FOREST MANAGEMENT PLANNING IN TURKEY

Deniz Özü

Nature Conservation Centre

Uğur ZEYDANLI, Nature Conservation Centre ; Ayşe TURAK, Nature Conservation Centre

Forest ecosystems comprise nearly 65% of all terrestrial biodiversity worldwide but 90-95% of forests do not have any protection status. Therefore the future of forest biodiversity greatly depends on how unprotected forests are managed. One effective way to conserve biodiversity in the "managed forests" is by integration of biodiversity conservation into the forest management system. More than 27% of the land area of Turkey is within the forest regime, owned by the state and managed by the General Directorate of Forestry (GDF) through a 10-20 years cycle of planning and management by forest management directorates (FMD). Nature Conservation Centre has been working in collaboration with GDF since 2009, to develop a new approach for integration of biodiversity into forest management plans. The resulting work was applied in four pilot FMDs (Istanbul–Demirköy, Muğla–Marmaris, Trabzon–GümüÅ'hane, and Artvin–Å'avÅ'at). Our approach utilized five main steps for each FMD: i) determining of target species and ecological processes to be used in integration, ii) enhancement of the distributions of the select biodiversity targets by modeling of presence records, iii) creating a conservation zone map of the planning units using the distribution models and conservation goals for each biodiversity target, iv) evaluation and finalization of the conservation zones with the foresters in FMDs, v) preparing silvicultural prescriptions for conservation zones (in forest stand scale). In this presentation we submit the general outline of our approach and the results of the pilot studies,

which led to establishment of a total of 92,431 ha. of protected forest areas out of 782,093 ha. total area (12%) of four FMDs. No forestry practice is allowed in the core zones (3%) and a biodiversity-focused forestry is planned in the buffer zones (9%). A nationwide integration can create ~400,000 ha. of core conservation zones and 4,000,000 ha. of buffer zones within managed forests of Turkey.

ISCHIA SUBMARINE CANYONS, A CRITICAL HABITAT FOR CETACEANS ENDANGERED SPECIES

Daniela Silvia Pace

OCEANOMARE DELPHIS ONLUS

Angelo MIRAGLIUOLO, OCEANOMARE DELPHIS ONLUS ;

Barbara MUSSI, OCEANOMARE DELPHIS ONLUS

There is support within the international community for special consideration to be given for marine areas that are deemed significant ecosystems for particular species. Within Italy, Ischia Island is already acknowledged as a significant coastal/marine ecosystem, and habitat for seven cetaceans species, and is given special status through Regno di Nettuno Marine Protected Area. The region has been listed in the IUCN Cetacean Action Plan as a critical habitat for the endangered short-beaked common dolphin (*Delphinus delphis*) Mediterranean subpopulation, giving strong arguments for specific management strategies to be developed and applied for species that rely on this region for important biological processes (i.e. feeding/breeding). Herein, we present evidence that common dolphins occur year-round in the area (characterized by a submarine canyon system and high biodiversity), in contrast to other Mediterranean regions, providing also data to support the hypothesis that they use this region as a calving and nursery area. Observations of *D.delphis* were made in 2000-2013. We analyzed spatial patterns in occurrence and distribution, relative abundance, group size and composition. There were 62 encounters with 2222 common dolphins in a region corresponding to the central heads of two canyons, within a wide range of depth and middle-high slope. Common dolphins were predominantly sighted in groups containing ≤ 50 animals, frequently including immature individuals (juveniles/calves/neonates). The regular occurrence of *D.delphis* in Ischia waters is probably the result of a combination of factors, including prey availability and the need to meet the energetic demands related to calving and lactation. The consistent use of these waters by the species is of notable importance given the apparent susceptibility of the Mediterranean subpopulation to anthropogenic effects. Real conservation actions toward common dolphins around Ischia remains an issue.

ASSESSING THE SPATIAL EXTENT OF WOLF-DOG HYBRIDIZATION IN REAL-TIME AND AT A POPULATION LEVEL USING NON-INVASIVE DNA SAMPLING

Carolina Pacheco

CIBIO/InBio - Centro de Investigação em Biodiversidade e Recursos Genéticos, Universidade do Porto
José Vicente LÓPEZ-BAO, Research Unit of Biodiversity (UO/CSIC/PA), Oviedo University[INSTITUTE]Grimsö Wildlife Research Station, Department of Ecology, Swedish University of Agricultural Sciences (SLU); Emilio GARCÍA, A.R.E.N.A., Asesores en Recursos Naturales, S.L.; Francisco J LEMA, Fuentes Amarelle, Corcubion; Luís LLANEZA, A.R.E.N.A., Asesores en Recursos Naturales, S.L.; Vicente PALACIOS, A.R.E.N.A., Asesores en Recursos Naturales, S.L.; Vitor SAZATORNIL, Departamento de Biología Animal, Facultad de Biología, Universidad de Barcelona; Raquel GODINHO, CIBIO/InBio - Centro de Investigação em Biodiversidade e Recursos Genéticos, Universidade do Porto[INSTITUTE]Departamento de Biología, Faculdade de Ciências, Universidade do Porto

The crossbreeding between wild species and their domestic counterparts when followed by the introgression of domestic genes into the wild population may lead to disruption of local adaptations or genetic homogenization of the two gene pools. Recently, sporadic but spatially spread reports of wolf-dog hybridization events across European populations have led to a growing conservation concern. Yet, understanding the conservation and management implications of this process requires, for instance, knowing the spatial extent of this process at the population level; which remains largely unknown. During the 19th century, European wolf populations have suffered an intense regression, persisting only in some isolated regions, as in Northwestern Iberia, where the population persisted in a human-dominated landscape. In this work, we focused on assessing the geographical extent of hybridization in this region where sporadic hybridization events have been reported. This was accomplished through a non-invasive genetic survey of a 5000 km² area, covering the territory of 13 packs. Our results revealed a low hybridization rate between the two taxa (5%) and a clear differentiation between the two gene pools. Interestingly, the detected hybrids were found spread throughout the study area. Further, the identification of two distinct and spaced home-packs of two hybrids shows the spatial component of hybridization events in the study area. The results showed a previously unseen scenario of multiple and widespread hybridization events. However, they also support the hypothesis that wolf populations can present overlapping distributions with their domestic counterparts without having high hybridization rates or similar gene pools. Implications of our results are substantial for the management of this process, for instance to design and implement

management interventions, and therefore we recommend to continue improving our knowledge on the underlying process of hybridization dynamics.

ECOLOGICAL AND BIOLOGICAL CHARACTERISTICS EXPLAIN THE RESPONSE OF SPECIES TO RECENT CLIMATIC CHANGES

Michela Pacifici

Sapienza Università di Roma
Piero VISCONTI, Microsoft Research Computational Science Laboratory; James WATSON, University of Queensland; Carlo RONDININI, Sapienza Università di Roma

Species have evolved to live within certain temperature ranges, and many of them might simply be unable to adapt to the rapidly changing, probably unsuitable new climatic conditions and thus will be threatened with extinction. A variety of studies have stated that species displaying certain intrinsic characteristics are more vulnerable to extinction to climate warming than others, and authors have often assigned species to risk categories according to these characteristics based on expert opinion. However, the assumption of a relationship between species' characteristics and their response to climate change has never been validated against observed data. In this study we performed a meta-analysis of documented (published) responses of mammals and birds to past climate change to relate changes in climatic variables, such as annual temperature and annual precipitation, to changes in geographic distribution, abundance, body size, time of migration, and other life-history traits of mammal and bird species globally. We conducted a statistical analysis on the relationships between the type of response and each selected trait by building partitioning classification models and multinomial logistic regressions, and we found that intrinsic characteristics like activity patterns and reproductive traits play an important role in determining the responses of mammals, while those of birds depend primarily on external factors like the extent of the breeding range and the temperature experienced by the species in the area in which they live. To date, this is the first study investigating the quantitative relationship and the causality between biological and ecological characteristics of birds and mammals, and their observed responses to climate change. Additionally, this study may provide a data-driven validation of the expert-based criteria so far used to assess extinction risk from climate change of species based on their intrinsic characteristics.

ID65 CAN OPPORTUNISTIC OCCURRENCE RECORDS IMPROVE THE LARGE-SCALE ESTIMATION OF ABUNDANCE TRENDS?

Joern Pagel

University of Hohenheim

Barbara J. ANDERSON, Landcare Research ; Robert B. O'HARA, BIK-F ; Wolfgang CRAMER, IMBE ; Richard FOX, Butterfly Conservation ; Florian JELTSCH, University of Potsdam ; David ROY, NERC Centre for Ecology & Hydrology ; Chris D. THOMAS, University of York ; Frank M. SCHURR, University of Hohenheim

Data on spatio-temporal variation and trends in population abundance form a cornerstone of biogeography and also an important criterion for the assessment of a species' conservation status. Citizen-science projects can be a valuable data source, where in particular opportunistic occurrence records are collected in high numbers and across large geographic areas. While the interpretation of these data is usually handicapped by inhomogeneous sampling effort, they can still have the potential to inform about abundance variation, in particular when combined with data from more systematic surveys. A particularly well suited approach for the integration of data from multiple sources is provided by hierarchical Bayesian modelling techniques. We present a model framework that links annual population densities on a spatial grid to both long-term count data and to opportunistic occurrence records as they result from citizen science programs. Specific observation models for both data types accommodate uncertainties at all stages of the link between observational data and the modelled abundance and account for differences in the structure and quality of data from various sources. In a case study we combined opportunistic occurrence records from the British Butterflies for the New Millennium (BNM) project with systematic transect counts from the Butterfly Monitoring Scheme (UKBMS) for the estimation of long-term abundance dynamics across the range of the Gatekeeper (*Pyronia tithonus*) in Great Britain. The application of the hierarchical observation model facilitates the estimation of variation in abundances across space and time and thereby improves our ability to detect, partly opposing, regional trends in different parts of the butterfly's range. These spatially comprehensive estimates of abundance dynamics from citizen science data have not only implications for conservation monitoring but can also enhance the empirical basis for basic ecological and biogeographic research.

WHAT MOTIVATES CITIZENS TO TAKE PART IN THE MANAGEMENT OF AN INVASIVE NON-NATIVE SPECIES? THE CASE OF TREE MALLOW CONTROL ON THE ISLANDS OF THE FIRTH OF FORTH, SCOTLAND

Marie Pagès

University of Aberdeen

Anke FISCHER, The James Hutton Institute ; René VAN DER WAL, University of Aberdeen ; Xavier LAMBIN, University of Aberdeen

Invasive Non-Native Species (INNS) are seen as a major driver of environmental change and INNS managers increasingly seek to engage citizen volunteers in control and monitoring activities.

Because INNS management often require long-term control and surveillance, it is particularly important to understand why volunteers initially take part as well as their reasons for staying involved over time. We explore volunteers' motivations in the case of the SOS Puffin project, a seabird conservation initiative aiming to manage the invasive tree mallow (*Lavatera arborea*) on the islands of the Firth of Forth in Scotland. Taking a mixed qualitative and quantitative approach, we scope volunteers' motivations at two distinct points in time and examine changes in motives across the group of volunteers and for each individual participant. Preliminary results show that volunteers first got involved to contribute to a good cause and to help the puffins nesting on the islands. However, they also expressed self-interested motives, notably the desire to have a unique experience and to be in and learn about nature, and the enjoyment of other volunteers' company. These aspirations were positively met by specific elements in the project's social and environmental context, e.g. the views and wildlife on the islands and the presence of like-minded and knowledgeable volunteers. Longer term participants evoked the satisfaction of seeing progress and a sense of duty towards a well-organised project and a respected leader. The example of SOS Puffin, a volunteer-based initiative with remarkable success, illustrates the key role of special environments (uninhabited islands) and iconic species (the puffin) in drawing people towards conservation activities such as INNS management. It also shows the importance of the project organisation in keeping volunteers on board, particularly a strong leadership and an environment favourable to social interactions and learning.

HUNTING FOR ALIENS: A CONCEPTUAL FRAMEWORK TO ASSIST STAKEHOLDER ENGAGEMENT IN THE MANAGEMENT OF INVASIVE NON-NATIVE SPECIES.

Marie Pagès

University of Aberdeen

Anke FISCHER, The James Hutton Institute ; René VAN DER WAL, University of Aberdeen ; Xavier LAMBIN, University of Aberdeen

Invasive Non-Native Species (INNS) are seen as a major driver of environmental change. Top-down eradication programmes have proven effective at controlling certain INNS in insular systems but transposing such approaches to a mainland context may be less successful without the collective effort of local eyes and hands in detecting, controlling and monitoring INNS in the long term. Stakeholder involvement in INNS management can help deliver conservation objectives and motivate local communities to engage with and care for their natural environment. However, we need to better understand the factors that influence the social and ecological outcomes of volunteer-based INNS management. Using exploratory interviews with project officers and volunteer group coordinators in Great Britain, we propose a conceptual

framework mapping and linking the social, organisational and environmental factors underpinning stakeholders' engagement. Characteristics of the social context, such as leadership, land tenure and local views on INNS and nature conservation, influence the success of stakeholders' mobilisation. More surprising however is the role of biophysical conditions in local engagement, in particular the abundance of INNS, the proximity of the invasion and the technicality and physicality of control activities. Programme managers should take into consideration the specific social and ecological context of the project when designing approaches to stakeholder and community engagement. Importantly, environmental conditions and material aspects associated with hands-on control and surveillance activities should not be overlooked. Adapting public engagement and capacity building interventions to the characteristics and changing condition of the target species and habitat could therefore help recruit and retain a voluntary workforce.

ASSESSMENT AND MANAGEMENT OF MARINE LITTER POLLUTION IN THE SLOVENIAN PART OF THE ADRIATIC SEA

Andreja Palatinus

Institute for Water of the Republic of Slovenia
Elizabetha GABRIJELCIC, Institute for Water of the Republic of Slovenia ; Štefan TRDAN, Institute for Water of the Republic of Slovenia ; Mitja CENTA, Institute for Water of the Republic of Slovenia ; Manca KOVAC VIRSEK, Institute for Water of the Republic of Slovenia ; Monika PETERLIN, Institute for Water of the Republic of Slovenia

Marine litter has been defined as one of eleven descriptors evaluating good environmental status of marine environment under the EU Marine Strategy Framework Directive (MSFD, 2008/56/EC). Water Framework Directive (WFD 2000/60/EC) recognized litter as an important pressures that needs to be addressed as well. In 2013 EU Member States reported on first evaluation of status of marine environment according to Article 8 of the MSFD. Marine litter quantities and distribution in Slovenia were estimated for all required indicators with most comprehensive data on beach litter coming from clean-up activities and floating microplastic. Slovenia was one of the few countries in the Mediterranean sea with data set long enough to evaluate and report on trend of beach litter quantities. Data on beach litter weight from January 2009 until December 2014 showed that quantities of litter on the Slovenian coast were decreasing from 0.23 kg/m in 2009 to 0.09 kg/m in 2014. The negative trend of weighted beach litter could be attributed to the successful combination of regular monthly clean-up and sporadic raising awareness activities performed by public authorities, research institutes and non-governmental organizations. Plastic was most commonly found material on all locations. First assessment on floating microplastic (<5mm)

quantities in the Slovenian sea showed strong pollution with microplastic litter, ranging from 3.000 particles/km² to 140.000 particles/km². New measures dedicated to eliminating marine litter inputs at sources are identified in new Programme of measures in 2015 under MSFD process. Efficiency of existing measures is also presented in the article.

SUPPORTING A SCIENCE-BASED DIALOGUE AROUND WIDESPREAD SMALL HYDROPOWER DEVELOPMENT IN BRITISH COLUMBIA, CANADA

Wendy Palen

Simon Fraser University
Viorel POPESCU, Simon Fraser University ; Robin MUNSHAW, Simon Fraser University

The last decade has seen renewable electricity technologies surge as globally significant components of many regional and national energy portfolios. However, producing renewable electricity at scale requires that networks of many individual projects distributed over large areas be developed. Despite their low-carbon footprint, the potential for such networks to generate cumulative ecological effects, in addition to site-level impacts, challenges traditional environmental assessment and fuels rancorous public debate about the value of renewable energy. British Columbia (BC), Canada has a progressive carbon-neutral mandate as well as tremendous small hydropower potential, with >7000 technologically feasible development sites identified throughout the province. Using potential development locations, we created a non-technical web-based tool that melds strategic land use planning with cumulative impact assessment to quantify tradeoffs between renewable energy development and biodiversity conservation in BC. The tool is aimed at elevating the entrenched dialogue between diverse stakeholders, including private energy and public utility companies, government agencies, First Nations groups, and environmental organizations in the region. The web-tool provides the opportunity for users to explore a range of alternative scenarios that attempt to balance energy gains and species conservation, and highlights that despite sharp tradeoffs, energy-biodiversity conflicts can be partially mitigated by strategic spatial planning. While complex, time-consuming, and challenging, creating a stakeholder-driven framework for quantifying cumulative effects of renewable energy holds promise for identifying common ground as debate surrounding low-carbon energy production escalates.

INVASIVE MAMMALS IMPACT AT A BIODIVERSITY HOTSPOT SCALE: THE CASE OF FERAL CAT ON THE NEW CALEDONIAN ARCHIPELAGO

Biological invasions represent one of the main threats to biodiversity, especially on islands where invasive are the first cause of biodiversity loss. Alien mammalian predators have been responsible for numerous island species extinctions worldwide, and feral cats are among the most successful and damaging invaders due to their generalist predatory behavior and high reproductive success. This study focuses on cat predation at a biodiversity hotspot scale, the New Caledonia archipelago (south Pacific) harboring numerous endemic and endangered species. Feral cat have invaded these islands from seashore habitat to highest altitude forest (1628m). Cat diet was studied through scat analysis, collected on a wide range of representative habitats and during different seasons. We collected more than 6000 cat scats from 14 sites, during 4 to 6 sampling sessions and over 1 or 2 years. To understand this top predator impact on an ecosystem originally freed from mammal predators, we evaluated (i) cat population consumption of endangered prey species and also (ii) cat density estimation from capture-mark-recapture data with a

camera-traps set. At the archipelago scale cats preyed mainly upon introduced rats (Frequency of Occurrence, FO: 78%), that could increase cat population dynamics and their impact on native prey. However cats preyed strongly upon reptiles (FO: 40%) and flying foxes (FO: up to 30% in some humid forests), most of them being endemic, and petrels (FO: up to 25% in some mountain areas). However cat predation and its impact varied according to the different habitats where conservation management will be adjusted according to these differences. This study also confirmed the high diet plasticity of feral cat and highlighted original cat predation patterns upon alien and endemic species. This study will give recommendations to prioritize management and conservation strategies in a region where such actions are urgently needed.

108. ON-LINE TOOL TO MONITOR FIRES IN GLOBAL PROTECTED AREAS

Ilaria Palumbo

DG Joint Research Centre - European Commission
Bart VERBEECK, *Agentschap voor Geografische Informatie Vlaanderen* ; William TEMPERLEY, *DG Joint Research Centre - European Commission* ; Marco CLERICI, *DG Joint Research Centre - European Commission*

Fires are central in the ecology of tropical ecosystems: they can lead to habitat degradation but also help maintain habitat functionality and biodiversity in fire-adapted ecosystems. For these reasons park managers need up-to-date information on fire occurrence to take appropriate decisions in their day-to-day management (e.g. control of threats, law enforcement) as well as long-term planning. Field surveys and patrolling activities are key to effective management, but may not always be sufficient to monitor fires over large areas or long periods. Satellite observation offers a unique means to assess fire dynamics and it has been extensively used to map and understand the effects of burning over large regions and also globally. Although satellite products have been made more accessible, their use in conservation still requires specific processing and analysis capacity, which is not always available to end-users, like park managers. The aim of the on-line Fire Monitoring Tool we developed is to facilitate the use of EO products to assess fire activity and support conservation and decision making. We process MODIS fire products, distributed by NASA-FIRMS and University of Maryland, to provide near-real time and long time-series information of fire occurrence in and around the sites listed in the World Database on Protected Areas (WDPA, UNEP-WCMC). In addition to this we include conservation areas from other sources, forest reserves and concessions that are key to conservation. For a selected area of interest the tool calculates on-the-fly statistics, indicators and maps of fire using web-services; the fire metrics include fire density, intensity and the burned area extent in the main vegetation classes. The tool is being used in protected areas

and conservation programmes in support of decision making and planning. As many illegal activities, like poaching, are associated with fire, this tool can also be used to monitor human-induced threats and pressures.

DISTRIBUTION AND HABITAT PREFERENCE OF RED PANDA (AILURUS FULGENS FULGENS) IN JUMLA DISTRICT, NEPAL

Saroj Panthi

District Forest Office

Reliable and sufficient information regarding status, distribution and habitat preference of red panda (*Ailurus fulgens fulgens*) is lacking in Nepal. The research activities on red panda in the mid-western Nepal are very limited, so the status of red panda in the region is quite unknown. The study conducted during May, 2013 in three Village Development Committees (VDCs) namely Godhemahadev, Malikathata and Tamti of Jumla district was an important step for providing vital information including distribution and habitat preference of this species. The study included the reconnaissance, key informants survey, interviews and consultation for the most potential area identification, opportunistic survey comprising the direct observation and indirect sign count method for the presence and distribution, habitat assessment consisting vegetation sampling and ocular estimation. The study revealed the presence of red panda in three forests namely Bahirepatan, Imilchadamar and Tyakot of Godhemahadev, Tamti and Malikathata VDCs respectively. The species was found distributed between 2880 and 3244 m with an average dropping encounter rate of 1.04 per hour of searching effort and 12 pellets per dropping. Red panda mostly preferred the habitat in the elevation range of 2900 - 3000 m with southwest facing steep slopes (36° - 45°), associated with water sources at the distance of ≤100 m. Trees such as *Acer* spp., *Betula utilis* and *Quercus semecarpifolia*, shrub species of *Elaeagnus parvifolia*, *Drepanostachyum* spp. and *Jasminum humile*, and the herbs like *Polygonatum cirrhifolium*, *Fragaria nubicola* and *Galium asperifolium* were found to be the most preferred species by red panda. The red panda preferred the habitat with dense crown coverage (>20% - 100%) and 31% - 50% ground cover. Fallen logs (39%) were the most preferred substrate used for defecation.

BEE RICHNESS RESPONSE TO WARMING CAN BE MODIFIED BY LANDSCAPE STRUCTURE

Alexandra Papanikolaou

Helmholtz Centre for Environmental Research

Oliver SCHWEIGER, Helmholtz Centre for Environmental

Research ; Mark FRENZEL, Helmholtz Centre for Environmental

Research ; Ingolf KÜHN, Helmholtz Centre for Environmental Research

Climate change is expected to affect species communities. The effect of climate change on wild bee communities is of major concern since loss or decline of bee species could imperil the provision of pollination service. Meanwhile, habitat loss and fragmentation are considered threats to wild bees' populations as well. However, the interactive effects of climate and landscape structure on wild bee communities remain unknown. In the present study we aim to understand how the structure of agricultural landscapes can alter the effect of weather on wild bees. More specifically, we assess the potential of semi-natural areas to maintain robust communities under changing weather conditions. To this end, we use monitoring data from six different field sites analyzing 16 local pollinator communities per site. Abundance data for wild bees have been collected using pan traps annually since 2010 (six times per year). Species richness is estimated per trap and monitoring period as the number of species identified. A generalized mixed effect model is built in order to investigate how species richness is affected by the interaction between weather (temperature, precipitation) and landscape (landscape composition, connectivity, habitat diversity). Subsequently, a multimodel inference approach is followed to specify the most important landscape and weather variables, as well as interaction terms. All the plausible models are compared based on the second order Akaike Information Criterion (AICc) and a suitable set of models is selected. According to the selected set of models, favorable landscape composition could mitigate the detrimental effect of temperature increase on bee species richness. This finding could have important implications on conservation decision making, since it suggests that maintaining a fair amount of semi-natural areas could serve as a countermeasure against climate change for wild bees.

THE CONSERVATION VALUE OF PERIPHERALLY ISOLATED POPULATIONS OF MEDITERRANEAN ENDEMIC PLANTS: A COMPARATIVE ANALYSIS OF ECOLOGICAL NICHE VARIATION AND ORIGINALITY

Guillaume Papuga

University of Sassari & CEFE CNRS

Perrine GAUTHIER, CEFE CNRS ; Virginie PONS, CEFE CNRS ;

Emmanuele FARRIS, University of Sassari ; John D. THOMPSON,

CEFE CNRS

The geological and climatic histories of the Mediterranean have left a series of major traits in the patterns of contemporary species distribution. Well known for its high percentage of endemic plants, the region is also the scene for fascinating patterns of disjunct distributions and the occurrence of peripheral isolate populations in many species. This pattern is particularly apparent in Mediterranean France where a large

number listed (locally rare) species occur at their northern distribution limits. Such isolated populations may constitute an important demographic relay for northward colonization in a warming climate and may harbor a unique evolutionary potential. However, faced with an ever increasing human footprint many of these examples of peripheral isolates involve populations are in rapid decline. We show that these populations can occur in a different broad climatic niche compared to populations in the central part of their distribution. However, nothing is known about the fine-scaled ecology of these species in terms of their abiotic and biotic niche components. We have thus conducted a comparative field-based study of the ecological niche of 11 species (each in a different family and all rare with a listed status in France) in central (Spain/Italy) and peripheral (Mediterranean France) populations. The results provide interesting new insights into the potential for species persistence and evolution in peripherally isolated populations whose habitat is particularly endangered. Actually, thermophilous garrigues in France count as one of the most endangered habitats, particularly threatened by human population growth, tourism and development projects. Our study also informs site selection procedure and methods for reinforcement and reintroduction policy for many species whose populations are currently being destroyed.

161-DEFINING SEASCAPES: SOCIAL-ECOLOGICAL LESSONS LEARNED FROM FOCUS GROUP EXERCISES

Camille Parrain

Université de La Rochelle[INSTITUTE]Université de La Rochelle

Pascal Marty, Ecole normale supérieure de Lyon

Defining seascape is not only a matter of describing bio-physical factors. Human practices activities are key elements to understand seascape characteristic and transformations. Seascapes characteristics can also be defined by users. In this presentation we will address the issue of seascape perception by three categories of users during three focus group exercises. We will discuss to what extent terrestrial landscapes definitions and concepts can be used to define seascape.

DIFFERENT LAND USES ALTER THE ASSIMILATION OF 15N AND 13C BY MACROINVERTEBRATES IN NEOTROPICAL SAVANNA STREAMS

Diego Marcel Parreira De Castro

Universidade Federal de Minas Gerais

Débora REIS DE CARVALHO, Universidade Federal de Lavras ; Paulo POMPEU, Universidade Federal de Lavras ; Marcelo MOREIRA, Universidade de São Paulo ; Gabriela BIELEFELD

NARDOTO, Universidade de Brasília ; Marcos CALLISTO, Universidade Federal de Minas Gerais

To support management actions in aquatic ecosystems is essential to understand how changes in land use influence trophic relationships in headwater streams. Changes resulting from the replacement of native vegetation by cultivation and grazing systems have great potential to influence trophic relationships of aquatic ecosystems. They usually can lead to simplification and also promote changes in the food habits of different groups of macroinvertebrates. Our objective was to evaluate how the vegetation cover influence food resources for macroinvertebrates in streams under different land uses. We compared nine streams in three areas in the Brazilian neotropical savanna (Cerrado): streams surrounded by native vegetation (reference), pasture and sugarcane cultivation. Macroinvertebrates, categorized into functional feeding groups (FFG), and their possible carbon sources (CPOM, FPOM, seston, leaves, periphyton, algae), were sampled and evaluated for the isotopic composition of $\delta^{13}C$ and $\delta^{15}N$. Higher $\delta^{15}N$ values were found in streams under sugarcane or pasture influence, probably due to soil management that usually increase the $\delta^{15}N$ of the soil in the Cerrado region. The $\delta^{13}C$ values were different between predators and filterers, comparing the reference streams and the others. Finally, there was an increase in the niche size of macroinvertebrates in the streams under anthropic influence. This information could support proposals for watershed management measures in the Cerrado biome and contribute to the conservation of aquatic biodiversity in headwater streams.

APPLIED CONSERVATION LITERACY: FROM LOCAL LEARNING TO GLOBAL ACTION

Julia Parrish

University of Washington

Benjamin HAYWOOD, Allegheny College ; Shawn ROWE, Oregon State University ; Cynthia CHAR, Char Associates

Environmentally focused science education strategies have customarily placed substantial focus on the development of "critical thinking skills" with the hope that upon learning to think more critically "participants will be better able to analyze information about environmental issues and to make sound decisions about the environment" (Krasny and Bonney 2005, p 192). Within conservation, an assumption is that critical thinkers will be scientifically literate citizens who actively lobby for, and participate in, conservation-oriented change. However, the question remains: Does simply knowing more lead to a higher level of action, and if not, what other factors help to create citizen-based conservation change? We use data from both quantitative surveys and qualitative interviews of participants in the Coastal Observation and Seabird Survey Team (COAST) to explore how participation in biodiversity-

based citizen science can lead to conservation action. Specifically, we: propose a 4 step model of individual learning, link learning efficacy to locality via participants' sense of place and community, and examine the degree to which participants move from learning to action. Finally, we demonstrate that individual action can scale to conservation change through citizen science, exactly because these programs recruit and retain hundreds to thousands of people for years to decades. Our work suggests that rigorous citizen science programs providing a place-based, data-rich experience linked explicitly to local, regional and global issues can lead to measurable change in both understanding and action - the two components of applied conservation literacy - without imposing a pre-determined, normative vision of science (e.g., science is good, environment is good).

165 HISTORICAL TRENDS AND INSIGHTS FROM THE FIELD OF EVALUATION

Beverly Parsons
InSites

The formal practice of evaluation has been developing into a transdisciplinary field over the past 60 or more years in countries around the world. The first professional associations of evaluators were in Canada and the United States about 40 years ago. Associations in Europe, Australasia, Africa, and other parts of the world followed. By the end of 2013, over 188 regional, national, and international organizations for professional evaluation existed and the number continues to grow. Consequently, evaluation is a rapidly growing and maturing field with continually expanding theories, methodologies, and uses. Additionally in recent years, the evaluation field and the systems field have developed increasing connections that have strengthened the range of evaluation approaches now in use across many disciplines and sectors, for example, in health, education, human services, agriculture, criminal justice, governmental departments, the military and more. Increasingly the evaluation of human systems such as those just mentioned is connecting with the evaluation of natural resources and systems. In this session, the presenter will provide an overview of how the field of evaluation is developing in terms of its expanding theories, methodologies, uses, and attention to values across many disciplines. The variety of orientations provides expanded options for how conservation biologists might approach evaluation and applied research. Many of the advances in evaluation address the complexity of the issues that are being faced at the intersection of human and natural systems and resources. The presenter will describe how interdisciplinary collaborations in other fields have benefited from considering a wide range of evaluation practices. These examples are intended to stimulation ideas among the participants about

ways that conservation biologists may incorporate evaluation into their interdisciplinary collaborations and other activities.

NORTH AMERICAN PERSPECTIVES ON CLIMATE CHANGE ADAPTATION POLICY

Douglas Parsons
Society for Conservation Biology

Exploration of climate change adaptation in North America as a tool for conservation policy will be discussed, and how SCB members can lead in this emerging conservation field. As communities begin to grapple with the impacts of climate change, adaptation to these changes will become an increasing focus of conservation policy. Until recently, significant attention has been focused on climate change mitigation, the act of mitigating carbon emissions from human sources, and less on the impacts of climatic changes. Adaptation is defined as: Adjustment in natural or human systems in response to actual or expected climatic stimuli or their effects, which moderates harm or exploits beneficial opportunities (IPCC). Recently, governments and non-governmental organizations have begun to focus on adaptation to climate change impacts. It is uncertain how significant these impacts might be, but nations are beginning to develop policies in anticipation of these changes that are increasingly likely to occur, regardless of progress in mitigating carbon emissions. This oral presentation will highlight federal, state and non-governmental approaches to climate adaptation and how it will affect ecosystem conservation in North America. The presentation will discuss different approaches to integrating conservation into climate change adaptation policy and it will also explore near and long term challenges associated with this emerging field. The speaker has worked extensively in adaptation planning at both the state and federal government level, and now with the Society for Conservation Biology as the North America Policy Director.

#191 - HOW NOT TO GET AHEAD IN ADVERTISING - WHAT MANY CONSERVATION NGOS ARE DOING WRONG

Edward Christien Michael Parsons
George Mason University
Mel COSENTINO, Aberdeen University ; Andrew J WRIGHT, George Mason University ; Jenell WALSH-THOMAS, George Mason University

Studies show that the general public knows little about the conservation status of species or habitats. If NGO and Government Agency strategies were effective at outreach and engagement this would not be the case. Several NGOs have large memberships, in some cases exceeding the membership of all the political parties combined, which could be a major

lobbying tool or the basis for major shifts in public behavior. However, NGO materials to the general public are often geared towards recruiting members or funds, rather than actually educating the masses or eliciting more sweeping pro-conservation behavioral changes. NGOs, like most scientists, often cling to the “deficit” model: that simply providing information will lead to societal change. This is clearly not the case. What informational outreach materials that are produced are often “passive” (e.g. mailed letters, web-based fact sheets), rather than “active” outreach. Some NGOs have developed social media campaigns, such as online petitions, which are more active, but that typically have little long-term impact. Many people believe they have “done their bit” if they simply share materials (known as “slacktivism”). Conservation NGOs (and agencies) need to think beyond passive methods of education and stop using their marketing departments purely for fundraising. Learning from product advertising, conservation outreach could be more effective by (a) delivering simple messages, but with (b) accurate facts that (c) evoke surprise or emotion to (d) make messages more memorable by (e) providing information in an interesting “story” format, (f) motivating to learn more and (g) providing concrete actions for the public to do that could make a significant difference, be this supporting a specific election issue or boycotting goods, such as unsustainable palm oil. Out of the box outreach could be very effective (e.g. “product placement”, such as lobbying TV show writers to insert conservation story lines).

EFFECTS OF ARTIFICIAL CANOPY GAPS ON RESTORING TREE DIVERSITY IN BOREAL CONSERVATION AREAS

Hannes Pasanen

University of Eastern Finland

Seppo ROUVINEN, University of Eastern Finland ; Jari KOUKI, University of Eastern Finland

Creation of canopy gaps can be used as a restoration measure to diversify structural variability and tree species composition in forests. We examined tree seedling regeneration in 94 small canopy gaps that were established for restoration purposes in two protected Scots pine-dominated forests in eastern Finland. Diameter of the gaps was 0.5, 1, 1.5, or 2 times the height of the dominant trees. Both study forests were located on dry and nutrient-poor mineral soils (*Vaccinium*-type). In particular, we aimed at assessing the effect of gap size and soil preparation (exposing mineral soil) on post-disturbance seedling establishment ten years after the restoration measures. We found that tree species composition on the plots consisted mainly of *Pinus sylvestris* (73 %) and *Betula* spp. (16 %) seedlings. Most of the *Pinus* and *Betula* seedlings were growing on plots that were disturbed and only 6 % of the seedlings were found on undisturbed plots, reflecting the importance of regeneration microhabitats for the early development of

seedlings. The mean number of *Pinus* and *Betula* seedlings per disturbed plot (40 x 60 cm) was 0.5 and 0.1, respectively, and did not significantly differ in gaps of different size. As the mean height for *Pinus* was 9.2 cm and that for *Betula* 51.5 cm, development of the seedlings in the gaps seemed slow and hindered probably due to insufficient amount of radiation as well as due to root competition. Both factors are affected by the gap size, which in our study sites was probably not large enough to reach a threshold value that meets the requirements of *Pinus* and *Betula*. We conclude that very small gaps – in particular when implemented without soil disturbance – may not be the most effective method to restore tree diversity in boreal pine-dominated forests. Further studies that manipulate gap size more widely than what was analysed in the current study are needed.

BIODIVERSITY AND ECOSYSTEM SERVICES: META-ANALYSIS, MIND-MAPPING AND BAYESIAN BELIEF NETWORK MODELLING TO BETTER CAPTURE THE ROLE OF BIODIVERSITY ON ECOSYSTEM SERVICES.

Marta Pascual

Basque Centre for Climate Change (BC3)

Elena PÉREZ-MIÑANA, Basque Centre for Climate Change (BC3) ; Eva GIACOMELLO, Centre of IMAR of the University of the Azores, Department of Oceanography and Fisheries, and LARSyS Associated Laboratory

Biodiversity plays a wide range of functional roles in ecosystems and supports all ecosystem services to some extent. However, a quantitative understanding of the biodiversity-ecosystem functioning-ecosystem services relationships is still limited and the exact nature of the links between them is not well understood or easy to identify due to: the multi-layered biodiversity-ecosystem services relationship, and the complexity of the interactions between biotic and abiotic components in ecosystems influencing processes and services. Despite the extensive research on biodiversity, its impact on ecosystems, and its benefits to humans, many researchers across different scientific fields agree on the need for a better understanding of the functional links between biodiversity-ecosystem functioning-ecosystem services. To address this need, a meta-analysis of almost 300 peer-reviewed papers, including up-to-date contributions describing the links between biodiversity and ecosystem functioning and/or biodiversity and ecosystem services was carried out. The results show most effort has focused on investigating biodiversity and ecosystem functioning towards obtaining provisioning services such as food or raw materials, whilst the linkages concerning biodiversity, ecosystem functioning and supporting, regulating and cultural ecosystem services, albeit a slow growth, remain largely unexplored. Research results from the publications reviewed, information on the physical and

biological processes underpinning ecosystem services, their interactions and responses, was gathered and merged into a set of conceptual mind-maps. In certain cases, these mind-maps were translated into Bayesian belief networks in an effort to demonstrate, the explicit description and management of the uncertainty still evident. This contribution aims to expand the scope of research developing new ways of collaboratively representing and modelling these linkages to enable better informed decision-making.

STAKEHOLDER PERCEPTION OF CONFLICTS AND ECOSYSTEM SERVICES OF AN EXOTIC UNGULATE

Roberto Pascual

Universidad Miguel Hernández de Elche

Francisco BOTELLA, Universidad Miguel Hernández de Elche ; Sergio EGUÍA, Universidad Miguel Hernández de Elche ; Andrés CASALDUERO, Universidad Miguel Hernández de Elche ; José Antonio SÁNCHEZ, Universidad Miguel Hernández de Elche

Ecosystems provide humans with services that can be valued from the point of view of human well-being. Among the less studied group from this perspective are ungulates, currently expanding across Europe and North America due to rural abandonment, a decline in direct persecution and the introduction and reinforcement of native and exotic species for sport hunting. The increasing population trends of these ungulates has led to a widespread human-wildlife conflict derived from their effects on collisions with vehicles, crop damage, disease transmission. Thus the conflict perspective might be imposing over their functional role in ecosystems. We wanted to know the perception of conflicts and services of the Aoudad (*Ammotragus lervia*), an African ungulate that was introduced in 1970's in SE Spain. So we evaluated it by means of personal interviews with stakeholders (environmental groups, government, gamekeepers, game warden, hunters, farmers, scientific community) with special interests in Sierra Espuña Natural Park, Murcia, where Aoudad was released. Our results show that stakeholder perceptions are divided between negative (human-wildlife conflict) and positive (ecosystem services) visions according to their own interests. As principal conflicts we found damage crops, damage to native plants, competition with others ungulates (principally with Iberian Ibex) and the risk of collision with vehicles. As ecosystem services highlight tourism and hunting. Thereby we are facing a complex problem where coexisting positions ranging from eradicating the species to avoid negative effects until promote its populations for services it provide in the region, therefore would be recommendable elaborate a proper management plan for the Aoudad with the participation of stakeholders.

THE FIRST PARTICIPATORY MARINE MEGAFUNA BY-CATCH ASSESSMENT IN MAIO, CAPE VERDE

Leno Passos

Maio Biodiversity Foundation

Katia LOPES, Maio Biodiversity Foundation ; Amanda DUTRA, Maio Biodiversity Foundation ; Edita MAGILEVICIUTE, Maio Biodiversity Foundation ; Tamas SZEKELY, Maio Biodiversity Foundation

Cape Verde supports the third largest population of nesting loggerhead females, over 20 species of cetaceans and over 60 species of elasmobranch including whale sharks and manta rays. Those species are under growing pressure of illegal fishing and incidental take. Our goal was to investigate the prevalence and frequency of marine megafauna by-catch by Cape Verdean artisanal and semi-industrial fishing boats. To determine the level of by-catch off Maio's waters interviews were carried out with local fishers in spring 2014. Information was collected on fishing techniques, animals incidentally caught, mortality rate, attempts to release and local perceptions towards by-caught marine species. 71% of fishers reported catching sharks, 32% reported catching turtles and 9% reported catching dolphins (139 fishers were interviewed). Fishers who reported catching turtles also recorded catching sharks. Artisanal boats reported fewer dolphin and shark bycatch than non-artisanal boats ($p = 0.012$, $p < 0.001$, respectively), whereas there was no difference in turtle by-catch between artisanal and non-artisanal boats ($p = 0.823$). Together with local fishing community we will aim to identify cost-effective and locally acceptable methods to mitigate shark by-catch, and fill in knowledge gaps on the roles of top predators in maintaining healthy marine ecosystems.

175-IPBES GUIDE ON VALUES AND VALUATION

Gyorgy Pataki

Corvinus University of Budapest

What is the value of a songbird? What is the value of an ancient woodland? How to express and attribute value to nature and biodiversity? Values are multiple and diverse and many times contested by different stakeholders. Values are formed and nurtured within different worldviews held by individuals and populations, their interactions with biophysical environments, as well as socio-cultural and political contexts and institutions that facilitate their articulation. Values attributed to nature, biodiversity and ecosystem services change through time, across spatial scales and among type of social organization. Valuation methods are diverse and include biophysical and ecological, cultural and social, economic, public health, and holistic, indigenous, and local knowledge-based types of methods. Valuation is a culturally embedded process never independent from existing social structures and power relations. Which values, whose values and how should be

accounted for in a valuation process? Is it possible to be inclusive to the extent that makes justice to the multiple and diverse values and valuation methodologies different stakeholders nurture? The IPBES conceptual framework acknowledges the different paradigms and worldviews guiding the human expressions of value and aims to integrate definitions, classification of biodiversity and stakeholders, concepts and valuation methodologies as well as culturally rooted success criteria within this broader framework. The IPBES guide on values and valuation methodologies aims to provide conceptual and methodological support to integrate the diverse and multiple values and valuation methodologies into different assessments being conducted in the IPBES first work programme (2014-2018).

CONSERVATION OF TWO THREATENED AND MEDICINALLY IMPORTANT ASCLEPIADACEOUS SPECIES OF INDIAN THAR DESERT THROUGH IN VITRO TECHNOLOGY

Ashok Kumar Patel

JAI NARAIN VYAS UNIVERSITY, NEW CAMPUS, JODHPUR - 342 001, RAJASTHAN (INDIA)

Deepika LODHA, JAI NARAIN VYAS UNIVERSITY, NEW CAMPUS, JODHPUR - 342 001, RAJASTHAN (INDIA); Kheta RAM, JAI NARAIN VYAS UNIVERSITY, NEW CAMPUS, JODHPUR - 342 001, RAJASTHAN (INDIA); Narpal Singh SHEKHAWAT, JAI NARAIN VYAS UNIVERSITY, NEW CAMPUS, JODHPUR - 342 001, RAJASTHAN (INDIA)

Indian Thar Desert is one of the profusely populated hot deserts of the world. These populations (human and livestock) and anthropogenic activities exert various pressures on phytodiversity of desert and brought un-sustainability and therefore require immediate conservation actions. Indian Subcontinent is a secondary centre of diversity for Asclepiadaceae species. This abstract highlights in vitro techniques as a conservation tool applied to two threatened and medicinally important asclepiads of Thar Desert. *Caralluma edulis* (Edgew.), rich source of antioxidants, is an endemic, edible and nutraceutically important plant of the extreme arid regions of Desert. Collection of whole plant before attaining the maturity restricts its propagation through reproductive means. Furthermore, poor reproduction and absence of proper seed setting aggravate the problem and hence natural propagation is significantly affected. We developed an efficient in vitro multiplication system for large-scale plant production and conservation of germplasm of *C. edulis*. Another plant, *Pentstemon spiralis* (Forsk.), is a perennial climber and medicinally important tuberous plant. This is one of the "Life Supporting Plant" of Little Rann of Kachchh, Gujarat (a natural heritage place for wild ass, India), as this plant is an important source of food (root tubers are sweet

and edible), fruit and fodder/forage. Owing to edible nature of young seeds, local people collect them which aggravate the problem of natural propagation. We defined an efficient in vitro propagation system for *P. spiralis* using nodal segments as explant. Micropropagation protocols developed for both the species were followed by ex vitro rooting technique for making the protocols cost effective, less-labour intensive and for increasing their transplant survival rates. Both protocols may effectively be employed for large-scale propagation and conservation of these two threatened and medicinally important Asclepiadaceae species.

EFFORT TOWARDS GREAT APES CONSERVATION IN LOGGING FORESTS: TESTING ADAPTIVE SAMPLING TECHNIQUE FOR CHIMPANZEES IN CAMEROON

Mbosso Patrick Armel

Environmental Resources Management and Social Issue Centre

Conservation efforts to protect chimpanzees in their natural habitat are of the highest priority. Although the formal management of biodiversity in Central Africa countries is realised mainly through protected areas, forest companies, being beneficiaries of 39% of the forests against only 16% for protected areas remain an important hope for conservation issue. Therefore, logging companies who manage these concessions have the influence and opportunity to promote the long-term conservation of these apes, as in reality more than 80% of ape habitat lies outside protected areas. The objective of this study was to set up and test an adaptive sampling technique protocol in order to promote chimpanzees' conservation in logging forests. Since direct sightings of chimpanzees are rare, data were collected on the most obvious indirect observation – nests. We applied distance sampling methods to examine species abundance, and performed home range analysis with ArcView. We proposed a survey protocol where neighbouring units are added to the sample whenever the value of the variable of interest satisfies some criteria. On a basis of four predefined transects of 1.5 km each to cover, 63 additional transects of 250 m each were generated by adaptive sampling following the detection of new nesting sites. Thus spreading out the survey on 21.750 km instead of 6 km, 152 nests were detected on a total of 64 nest sites. We found an absolute density of 2 ind./sq-km (95% CI [1.40-2.93]; CV 18.8%) in a mapped area of 4.6 sq-km. On a positive note, the technique enables identification and mapping of core areas of chimpanzees' territories, which can then be assigned high conservation value status in order to adapt logging practices to minimise negative impact on the chimpanzees accordingly.

A GLOBAL META-ANALYSIS OF PROXIMATE CAUSES AND UNDERLYING DRIVERS OF TROPICAL DEFORESTATION

Stephanie Pau

Florida State University

Tropical deforestation simultaneously eliminates critical habitat for wildlife in world's most diverse locations and is the second largest contributor to greenhouse gas (GHG) emissions behind fossil fuel burning. There is increasing recognition that complex and interacting factors lead to land use change, nonetheless general patterns are emerging from different geographical locations. Of a total of ~1300 studies that address forest cover loss in tropical regions published between 2010-2013 (ISI Web of Science search), only 10% explicitly quantified forest cover change and attributed the change to at least one proximate cause or underlying driver. Fifty-five percent of studies focused on Latin America, 28% on Asia, and 14% on Africa (the remainder are global scale studies). In all three regions and at all spatial scales of study (local, regional/national, global) agricultural expansion was most frequently identified as a proximate cause and economic factors were most frequently identified as an underlying driver; in global scale studies, demographic underlying drivers were identified as commonly as economic drivers. Differences in the rate of forest cover loss were associated with particular proximate causes and underlying drivers in different regions. Agroforestry was addressed in less than 1% of studies. These results highlight the overwhelming consensus that agricultural expansion driven by economic incentives is the leading cause of tropical deforestation and should guide future conservation and management in tropical regions. Furthermore, agroforestry is a common agricultural land use in the tropics that can significantly alter forest cover, yet is seriously understudied.

UNDERSTANDING THE NEGATIVE IMPACT OF ILLEGAL WILDLIFE TRADE ON LOCAL COMMUNITIES IN ARANI-KO-TRAIL, NEPAL

Kumar Paudel

School of Environment Science and Management

Wildlife trade is the biggest threat to biodiversity conservation. China is an important source of demand for wildlife products and harvesting from its neighboring Asian states via Araniko-trail (Kathmandu-Kodari) and other routes, criminal organizations have developed to procure and dispatch wildlife products. Their organizational form adjusts to reduce the most significant transaction cost faced at each stage in the supply chain. Transport to the Chinese border is the tough job and local people has been using on scale economies to transport

wildlife products. This paper mainly focused to analyze the concept of Illegal wildlife trade & negative impacts on involved local communities in Araniko-trail Nepal. Household survey, key informant interview and interview with ex-poacher/trader have conducted on 6 most affected communities in Araniko trail. The total illegal wildlife trade phenomenon is widely supported by local people because of ease means of earning for them. Among the total arrested more than two third are the locals and never attended high school. The 20-35 yrs age group is most active in the wildlife trade. The every child of the region has experience wildlife crime one and another way. The illegal exploitation of wildlife has severe impacts on biodiversity and involved local indigenous communities are also suffering in long run. In the developing country like Nepal unemployment, illiteracy, poverty, resource scarcity has empirical relationship with poaching, illegal trade and habitat destruction of the wildlife. Conservation programs must able to create some additional visible economic benefits to local people. This can only save pangolins and other endangered species with the active participation of community citizen.

RECOVERING STRATEGY FOR THE MOST ENDANGERED REMAINING POPULATION OF GANGES RIVER DOLPHIN IN NEPAL

Shambhu Paudel

Kathmandu Forestry College

Grant Abel, Ocean Park Corporation

With the most endangered conservation status, Ganges river dolphin *Platanista gangetica gangetica* is now limited only in three river systems of Nepal with very questionably viable population. This small population is urgently seeking robust field based conservation strategies to recover into survival population. Our 2 years intensive study reported with the population less than 30 individuals in Nepal stressing urgent attention from concerned conservation authorities nationally and globally to recover this species into living planet for the next generation. Population abundance and occupancy was highly sensitive with season (pre monsoon) and habitat type (depth greater than 3m). Shifting southern distribution pattern (closer to Nepal/India boarder) with very sparsely sightings nature indicates the species at the brink of extinction from Nepal river systems. With the light of these behaviors, conservation on hotspots is strongly recommended with season specific conservation approaches involving local river dependent communities. But, national and international conservation agencies support is imperative to initiate meaningful conservation of this species by understanding spatial and temporal behaviors of this species using acoustic survey.

LOSING THE APEX PREDATOR: AN EVALUATION OF THE REMAINING JAGUAR POPULATIONS OF THE ATLANTIC FOREST OF SOUTH AMERICA

Agustin Paviolo

The Atlantic Forest (AF), a global biodiversity hotspot in eastern Brazil, eastern Paraguay and northern Argentina, has lost ≈90% of its range. In an international effort, we analyzed the AF's jaguar population status and proposed a spatial prioritization for conservation actions. We used jaguar records and Maxent

to develop a habitat suitability model and to estimate the area still occupied by jaguars. Using SECR models, we estimated jaguar densities from 29 camera-trap surveys in different areas, and calculated population size of the occupied fragments. We defined the AF Jaguar Conservation Units (JCU) based on size of the habitat fragment, presence of the species, confirmation of female presence, and population size. We developed a least-cost-corridor analysis to find the best options for corridors among the JCUs. Our analyses show that 85% of the original habitat has been lost, 8% is marginal, and only 7% of the AF is suitable for the species. The jaguar is present in only 2.8% of the region and potentially present in other 1.2%. Densities in areas where jaguar still occurs were low and varied from 0.62-2.41 ind/100km², but we could not estimate densities in 21 surveys due to the scarcity of records, suggesting even lower jaguar densities in some areas. We estimate the total jaguar population in the AF to be between 130 and 270 individuals. We identified seven JCUs and seven potential JCUs, but only three JCUs can sustain a population size of >50 individuals. Although some JCU could be connected by corridors, many of the remaining occupied fragments are isolated. We documented a dramatic jaguar habitat loss and fragmentation in the AF, but the species disappeared also in areas with good habitat, suggesting that human induced mortality is also a major drive for jaguar decline. The species is under high risk if urgent measures are not taken. Disappearance of jaguars and its ecological role will have unpredictable consequences for this biodiversity hotspot.

SYMPOSIUM ID CODE 191: DOES PRIDE WORK? AN APPLIED MODEL FOR INSPIRING BEHAVIOR CHANGE FOR CONSERVATION

Monica Pearce

Rare

As the conservation community begins to recognize that achieving positive change in human behavior is the key to protecting our natural resources, many are just scratching the surface toward implementing interventions that target social change coupled with biological change. Rare and its partners however have been conducting behavior change interventions for conservation (also known as a Pride campaign) for an extensive amount of time and is now completing its first comprehensive long-term impact study. This meta-analysis evaluates the long-term impact of the Pride campaign using both social and biological data from a significant sample size of 35+ sites, spanning throughout 13 countries, with some sites having begun their interventions up to 10 years ago. Through the evaluation of qualitative interviews that measure the level of continued intervention at each site post the initial 2-year intervention against quantitative data from social surveys and biophysical monitoring, this study seeks to answer the

following 3 questions: 1) Does Pride affect behavior change long-term? 2) Does the level of continued effort toward Pride post-two years affect changes in behavior change? 3) Do fluctuations in behavior change correlate to a conservation result? That quantitative data is measured along each aspect of Rare's Theory of Change that includes social indicators such as knowledge, attitudes and behaviors of the community to various biological indicators related to the site's conservation result. This study aims to statistically prove or disprove the assumption that the level of continued effort made toward the intervention post Rare's initial 2-year investment correlates to changes in behavior change and thus changes in conservation. The results provide comprehensive recommendations backed from scientifically valid data for how conservation interventions can achieve lasting impact.

181 ASSESSING SPECIES VULNERABILITY TO CLIMATE CHANGE IN AN UNCERTAIN WORLD

Richard Pearson

University College London

There is a pressing need to develop effective vulnerability assessments for evaluating the conservation status of species under twenty-first century climate change. Several modelling approaches have been used to predict responses of biodiversity to climate change, with recent developments offering several advances. In this talk I will provide a brief overview of alternative predictive approaches, with a focus on methods that couple ecological niche models (species distribution models) with demographic models. This coupled modelling approach estimates extinction risk as the probability of abundance falling to zero, rather than by inferring extinction risk from the contraction of bioclimate envelopes. Using case studies from the Arctic and North America, I will exemplify different methods and discuss some of their pros and cons. I will show how the attributes that cause species to be at high risk of extinction due to climate change may be estimated and how this information can be useful for vulnerability assessments. Set against a backdrop of multiple sources of uncertainty, I will argue that new methods provide increasingly robust predictions and I will point to important new research directions.

ONLINE PARTICIPATORY MAPPING OF ECOSYSTEM SERVICES AND LAND USE PREFERENCES IN THE POLISH TATRAS - EXPERIENCES AND CHALLENGES.

Barbara Peek

Institute of Nature Conservation Polish Academy of Sciences
Agnieszka OLSZANSKA, Institute of Nature Conservation Polish Academy of Sciences ; Agata PIETRZYK-KASZYNSKA, Institute of Nature Conservation Polish Academy of

Sciences [INSTITUTE] Institute of Environmental Sciences, Jagiellonian University ; Marcin RECHCINSKI, Institute of Geography and Spatial Management, Jagiellonian University ; Malgorzata GRODZINSKA-JURCZAK, Institute of Environmental Sciences, Jagiellonian University ; Joanna CENT, Institute of Environmental Sciences, Jagiellonian University

Online participatory mapping has been widely used in different research contexts, it is also applied to explore spatial distribution of the ecosystem services, yet it is still a fresh and challenging approach in Central Europe. Our study was the first attempt in Poland to use an online tool for collecting spatial data on ecosystem services from local society of non-urban territory. We used an internet public participatory geographical information system (PPGIS) mapping tool to gather and evaluate the spatial perception of ecosystem services and preferences of land use among residents and non-residents of the Tatrzyski county (southern Poland, Tatra Mountains and Tatra Foothills). The area is situated in the alpine biogeographical region and characterized by high biodiversity, having three Natura 2000 sites and Tatrzyski National Park within its borders. The application and web design was based on previous PPGIS studies and adjusted to the study site in Poland. To collect data, we set a website www.mapujTatry.pl that was open in December 2014 and January 2015. Data collection was based on random sampling of household addresses within five municipalities within the case study area (in total 3000 addresses), supported by an open invitation to participate in the survey, distributed via social media, municipalities offices and national park. We gathered responses from ca. 600 application users, who placed over 6000 markers and gave over 250 comments. Based on the markers distribution and densities, we created the ecosystem services and preferences hotspots maps and detected perceptual differences among various groups of respondents. We also analysed spatial correlation of generated hotspots with basemap features, with a special focus on borders of protected areas. Finally, we conclude that collecting preferences and values can be of use for planning or decision making process in conservation practice.

ID142 GREEN INFRASTRUCTURE, CONNECTIVITY, AND THE AGRICULTURAL LANDSCAPE: A STORY OF DEPENDENCY AND CONFLICTS

Guy Pe'er

UFZ - Helmholtz Centre for Environmental Research
Jennifer HAUCK, UFZ - Helmholtz Centre for Environmental Research ; Jenny SCHMIDT, UFZ - Helmholtz Centre for Environmental Research ; Klaus HENLE, UFZ - Helmholtz Centre for Environmental Research

The ideas of Green Infrastructure (GI) stem from the principle that a strategically planned network of natural and semi-natural

areas, combined with other environmental features, can provide a haven to biodiversity while delivering many benefits to humans. In 2013 the European Commission adopted a Green Infrastructure Strategy, “to promote the deployment of green infrastructure in the EU in urban and rural areas”. One key challenge of this strategy is the question how to maintain or enhance landscape connectivity, while agricultural expansion and intensification creates an increasingly hostile “matrix” separating natural and semi-natural areas from each other. The greening of the Common Agricultural Policy (CAP), which allocates almost 40 % of the EU’s budget to farmers, could provide some potential. However, despite much effort and the recent incorporation of three new greening measures, the reformed CAP for 2014–2020 seems to offer little benefits for biodiversity or means for the effective implementation of the GI strategy. Too many exemptions were made with regards to the requirement for 5 % “Ecological Focus Areas”; further losses of permanent pasture are permitted; and management criteria, to ensure habitat quality, are lacking in all greening measures. Effective GI would also depend on a spatial design that can maximises the benefits of environmental investments, but none such guidance was given so far. Agri-Environmental Schemes (AES) could still be used to support GI, but the budget for these is at risk of declining in many Member States. Despite these weaknesses, there are some improvements and reasons for hope. For instance, the requirement for a Farm Advisory System could facilitate a closer dialogue between (ecological) experts and farmers. Additionally, there is much flexibility to develop bottom-up initiatives that could pave the way for larger scale improvements. We conclude with some recommendations and integrative solutions.

ID #7: ZONOTIC ORIGIN OF HUMAN RETROVIRUSES AND IMPACT OF RETROVIRUSES ON SURVIVAL OF NON-HUMAN PRIMATES

Martine Peeters
IRD

Simian retroviruses (SIV, STLV and SFV) from non-human primates (NHP) have crossed the species barrier to humans at several occasions, leading to the HIV and HTLV epidemics and to sporadic cases of human infections with SFV. Efficient infection and spread in humans differs between SFV, STLV and SIV, but also among different viruses from the same simian lineage. SIV from chimpanzees and gorillas are at the origin of the four HIV-1 groups (M, N, O and P), but only HIV-1 group M has spread worldwide. Sooty mangabeys in west Africa, transmitted their virus on at least nine occasions to humans leading the nine HIV-2 groups. HIV-2 did only spread to some extent in West Africa. Simian counterparts of the four types of HTLV, type 1 to 4, have been identified in multiple NHP species (apes, cercopithecus spp, mangabeys, etc). HTLV-1

predominates in humans and is present throughout the world as clusters of high endemicity. Humans are susceptible to a wide variety of SFVs and seem to acquire these viruses more readily than SIVs or STLVs but no signs of disease in humans nor human-to-human transmission of SFV has been documented yet. Little information is available on pathogenicity of simian retroviruses in their natural NHP hosts and observations on captive NHP suggested until very recently that they are non-pathogenic. Today several studies showed clearly that SIV infection has a negative impact on health, reproduction and survival of chimpanzees in their natural habitat and immunological and clinical evidence for AIDS-like disease has been observed. Overall, our knowledge on cross-species transmissions of simian retroviruses and the impact of SIV infection in their NHP primate host are still incomplete.

CONSERVATION DEVELOPMENT: A WIN-WIN FOR DEVELOPERS, HOMEOWNERS AND BIODIVERSITY?

Liba Pejchar

Colorado State University

Sarah REED, Wildlife Conservation Society ; Cooper FARR, Colorado State University ; Steve LAPOSA, Alvarez and Marsal ; Chris HANNUM, Istanbul Technical University

The rapid conversion of private land to residential development and limited funding available for conservation make this a critical time to examine new tools that incorporate conservation objectives into development. Conservation Development (CD) is a private land conservation strategy designed to decrease the negative impacts of residential sprawl by clustering houses in a small portion of a property, while preserving the remaining land as protected open space. Although CD accounts for up to 25% of private land conservation in the United States, little is known about its contributions to biodiversity conservation and human well-being. We adopted a multi-disciplinary approach to evaluate the economic and ecological value of CD subdivisions in Colorado, USA. First, we used hedonic modeling and real estate transaction data for homes in 80 CD subdivisions and 125 nearby conventional subdivisions to assess the value of the conservation amenity to homeowners. We found widespread and significant sales price premiums of 25-29% for homes located in CDs relative to other types of rural residential development. Next, we investigated whether this strong economic benefit for developers and homeowners corresponds with an ecological benefit for biodiversity. Using point counts and remotely-triggered cameras, we examined the effects of subdivision design and open space stewardship on songbirds and mammals in 15 CD subdivisions. We found that CDs with a higher proportion of protected open space supported greater species richness; CDs with over 85% open space had 1.5 the number of bird species than CDs with less open space. Native plant cover was positively and housing

density was negatively associated with occupancy of human-sensitive bird and mammal species. Our findings suggest that CD can both provide economic benefits and support biodiversity if the protected open space is sufficiently large and contiguous, and if the property is managed to sustain natural plant communities.

SYSTEMATIC MONITORING PLANNING: OPTIMIZING WILDLIFE SURVEY SCHEMES

Jerome Pellet

N+p wildlife ecology

Gérard MAZE, Universität Zürich ; Yves GONSETH, CSCF/karch ; Benedikt SCHMIDT, CSCF/karch

Most biological monitoring programs rely on multi-species surveys (birds, amphibians, butterflies, dragonflies...). These programs usually rely on multiple visits during pre-defined, expert-based time windows. The goal of this approach is to encounter as many species as possible. Here, we present a novel method to optimize these time windows using a mathematical framework maximizing the detectable species pool. The approach is conceptually similar to spatial systematic conservation planning, but shifting from a spatial to a temporal perspective. We present an example using 20 years of butterfly records in Switzerland. We illustrate the link between financial investment in monitoring (number of visits) and loss of information (proportion of detected species), thus allowing for a rigorous return-on-investment analysis of monitoring scheme scenarios. The general framework offered by systematic monitoring planning can be used in a wide range of biological survey schemes and offers a new practical tool for adaptive monitoring.

MONITORING AND ASSESSING THE INTEGRITY OF A LARGE WORLD HERITAGE MARINE SITE USING UNBAITED VIDEO

Dominique Pelletier

French Institute for The Exploitation of the Sea
William ROMAN, French Institute for The Exploitation of the Sea ; Abigail POWELL, French Institute for The Exploitation of the Sea ; Thomas BOCKEL, French Institute for The Exploitation of the Sea ; Liliane FIANT, French Institute for The Exploitation of the Sea ; Charlotte GIRAUD-CARRIER, French Institute for The Exploitation of the Sea ; Charles GONSON, French Institute for The Exploitation of the Sea ; Jessica GARCIA, French Institute for The Exploitation of the Sea ; Thierry LAUGIER, French Institute for The Exploitation of the Sea

The World Heritage (WH) Convention adopted in 1972 protects natural and cultural sites considered to be of "Outstanding Universal Values" (OUV) and "worthy of special protection against the dangers that increasingly threaten

them". Management of inscribed sites must prove OUV conservation through periodic reporting. For WH natural sites where OUV is linked to biodiversity features, this is achieved through monitoring-based periodic assessment. In 2008, the New Caledonian lagoons were inscribed on the WH list in the light of the exceptional diversity of their reefs and associated ecosystems. They display intact ecosystems, with healthy populations of large predators, and a great number and diversity of big fish. This WH site covers 15743 km², thus requiring considerable monitoring effort. Since 2012, a series of surveys using a remote unbaited underwater video technique were conducted in a number of areas in the WH site, with the aim of assessing fish assemblage and habitats. The technique used enables a large number of observations to be collected per day, resulting in extensive geographical coverage and high local spatial replication of data. Data were analyzed to provide consistent assessments across areas. In addition, we investigated the effectiveness of Marine Protected Areas located within the WH site as conservation instruments. In this paper, we present the results of this comprehensive analysis. First, each sampled station was assigned to a habitat based on a multivariate typology of biotic and abiotic cover. A number of indicators describing fish assemblage were computed and we studied the influence of both habitat and protection status on these indicators. Our results show the overall good health of fish assemblages and living cover, while they reveal interesting qualitative and quantitative differences between sites. In many instances, protection effects were clearly evidenced for a number of indicators, in particular those involving fished species.

208 CITIZEN SCIENCE, SOCIAL LEARNING AND TRANSFORMING EXPERTISE

Taru Peltola

Irstea, Representative of AHIA group of ALTER-Net

Citizen science (CS) is currently gaining momentum in many different research fields, including biodiversity research, boosted by novel technologies that allow new modes of participation, inviting new social groups and extending the scope of collaboration between scientists and volunteers. CS is envisioned to bring mutual gains for the participants, as well as for society at large, facilitating, for example, 'scientific literacy', collaborative skills or empowering different social groups. While such learning processes taking place on an individual, collective or societal level are claimed to have high priority in CS projects, we provide a review of the development and state of the art of CS, focusing on the learning processes/arrangements and outcomes of CS projects. We critically assess how learning has been discussed in the context of CS, and how CS projects have been designed and implemented to facilitate learning. In this context we also discuss approaches,

such as public participatory GIS, which are not currently framed as CS but provide valuable experiences and methodological approaches for it. We also explore new cutting-edge collective learning processes such as Companion Modeling and Multi-Agent Behavioral Games. Through a number of case studies in the field of biodiversity research we explore the ways in which participants are involved, new knowledge is generated, and the potential benefits derived by different groups. We conclude with recommendations for the future development of CS processes to ensure mutual learning for improved biodiversity conservation and enhancing ecosystem services and suggestions on „appropriate avenue” for future biodiversity research that is relevant for addressing social challenges of collaborative knowledge production between citizens, scientists, and educators.

LAKE LERMA SALAMANDER (AMBYSTOMA LERMAENSE) OCCUPANCY IN THE NATURAL PROTECTED AREA CIENEGAS DE LERMA, MÉXICO

Karla Pelz Serrano

Universidad Autonoma Metropolitana Lerma
Rurik LIST, Universidad Autonoma Metropolitana Lerma ; Renata CHAVEZ VIZCARRA, Universidad Autonoma Metropolitana Lerma ; Odette ALCANTARA RAMOS, Universidad Autonoma Metropolitana Lerma

Lake Lerma salamander is an endemic species of the wetlands Cienegas de Lerma in Mexico, and is of remarkable importance for the wetlands and for human communities associated to this ecosystem. Unfortunately the Cienegas are still threatened by anthropogenic activities such as urbanization, water pollution, and introduction of exotic species. These activities have caused the reduction of the wetlands to 10% of their original size. Therefore many of the species that inhabit this ecosystem are threatened. *A. lermaense* is considered critically endangered by the IUCN and is under the category of especial protection of Mexican Environmental Law. Nevertheless, the lack of information about the status of the populations of *A. lermaense* limits the conservation efforts that can be applied to it. Therefore, the objective of this study was to estimate site occupancy of *A. lermaense*, as well as the relationship of occupancy and environmental variables (water turbidity, depth, and temperature) in order to contribute to the conservation strategy of this species. We conducted a single season survey in three wetlands (Almoloya, Guadalupe Victoria, and Capulhuac) within the natural protected area Cienegas de Lerma. We sampled 94 random points using minnow traps. Measurements of the environmental variables were taken at each point. Occupancy rate was 60% (95% C.I. from 0.39 to 0.81) for the study area, however, probability of detection varied across sites. Almoloya had a detection probability of 0.17, whereas Guadalupe Victoria and Capulhuac had a probability of 0.82, and 0.63 respectively. The findings of this study provide

insights into the status and distribution of the populations of *A. lermaense* in the Cienegas de Lerma. Furthermore, this study sets the baseline for the long-term monitoring of the species, which is part of the conservation strategy of *A. lermaense*.

#193 ECOLOGICAL REWILDING - OPPORTUNITIES AND CHALLENGES FOR A NEW APPROACH TO RESTORATION

Henrique Miguel Pereira

IDiv

Over the last few decades, landscapes in Europe have undergone major changes as people moved from rural areas to urban centers, marginal lands were abandoned and fertile soils were intensified. While, agricultural intensification has caused biodiversity declines in many places, farmland abandonment has opened the opportunity for biodiversity restoration elsewhere. But this is a controversial topic. Some conservationists see farmland abandonment has a major threat and something that should be stopped or even reverted. Others, have embraced the concept of rewilding abandoned landscapes and potentiating the return of biodiversity associated with forest and late successional stages, including some of the continent's megafauna. Here I discuss the concept of ecological rewilding. Ecological rewilding is distinct from other approaches to rewilding in that it does not use a specific baseline to which ecosystems should be restored. Instead, ecological rewilding is about decreasing the human control of landscapes and promoting natural ecosystem processes. I discuss the main opportunities and on-going initiatives on rewilding and present some of the main challenges. I conclude with a discussion on how the CAP subsidies could be reformed to promote rewilding.

INVESTIGATING THE SCALE DEPENDENT ROLE OF HERBIVORY AND SEED LIMITATION IN DETERMINING SUCCESSIONS IN EUROPEAN ABANDONED LANDSCAPES

Andrea Perino

German Centre of Integrative Biodiversity Research (idiv)
Laetitia Marie NAVARRO, German Centre of Integrative Biodiversity Research (idiv) ; Henrique Miguel PEREIRA, German Centre of Integrative Biodiversity Research (idiv)

In high-income countries, a decrease in land cultivation lead to large abandoned areas. Agricultural abandonment is associated with the transition from open areas to shrub-land and forest. This carries the risk of habitat homogenization but also has the potential to benefit biodiversity by providing habitats for species that have declined due to the loss of large natural areas. Restoring such landscapes to self-sustaining

ecosystems that are maintained without human interaction is the aim of the rewilding approach. One objective of rewilding is the recolonisation of abandoned lands by large herbivores to promote heterogeneous habitats suitable for a wide range of species. We investigate the dynamics of large mammals and their effect on natural succession across scales in the national park of Peneda-Gerês in Northern Portugal. The area is highly fragmented and comprises habitat patches at varying stages of abandonment. The cultivation legacy on the abandoned fields and the matrix of surrounding habitats may have important implication for the transitions subsequent to abandonment. We hypothesize that two opposing processes influence succession in abandoned landscapes: While seed availability in the surrounding habitats may influence succession processes, changes in density and activity of herbivores may alter disturbance via grazing or browsing, thus hindering succession. We present our approach to investigate the potential for ecological rewilding and the ecosystem response in Peneda-Gerês. Using a combination of camera trapping and herbivore exclosures, we will examine the influence of herbivore pressure and seed availability on abandoned fields and the scale at which these processes operate. Investigating the impact of these factors at different spatial scales will lead to a better understanding of the mechanisms driving succession and of the spatial extent at which they are effective.

THE USE OF RICE FIELDS BY WINTERING DUCKS: SEARCHING FOR MUTUAL BENEFITS TO DUCKS AND FARMERS

Claire Pernollet

Office National de la Chasse et de la Faune Sauvage, Centre de Recherche de la Tour du Valat

Michel GAUTHIER-CLERC, Centre de Recherche de la Tour du Valat ; Matthieu GUILLEMAIN, 1Office National de la Chasse et de la Faune Sauvage, CNERA Avifaune Migratrice

Rice is cultivated in 114 countries and represents the primary food source for over three billion people. Rice fields also represent foraging, roosting and nesting habitats for >50% of waterfowl worldwide. To better understand the interactions between rice farming and ducks, we first performed a literature review to identify the principal constraints and levers of action associated with the management of rice-production areas in a waterfowl-friendly way. Winter flooding of rice fields has been identified as habitat management providing potential benefits to ducks through its direct translation into wintering habitat creation, and to farmers through the increase of straw decomposition rate and the reduction of weed seed viability. To test this hypothesis, we first assessed if the average duck numbers at the flyway scale were positively explained by winter flooding areas in five main European rice-production regions. Once this was confirmed, we carried out four different analyses (two empirical and two experimental). In the first

two cases, rice field use by wintering ducks was assessed in the Camargue (France) and in Doñana (Spain), where post-harvest agricultural practices and the use of winter flooding are very different. In the two experimental studies, we tested the effect of winter flooding on the viability of three major rice weeds and the effects of attracting ducks by flooding on weed seed bank and straw stubble. All these tests suggested winter flooding of harvested rice fields were indeed a valuable management option benefiting both wild ducks and farmers. A cost-benefit analysis eventually allowed us to evaluate if such management could realistically be promoted in the Camargue considering the constraint of high flooding cost.

SYMPOSIA ID: 177. TACKLING ISSUES OF COEXISTENCE BETWEEN PROTECTED AREAS AND COMMUNAL LANDS: FROM A ROLE PLAYING GAME TO AN AGENT BASED MODEL

Arthur Perrotton

Cirad

Michel DE GARINE-WICHATITSKY, Cirad ; Christophe LE PAGE, Cirad

Coexistence between actors living in a common environment is a recurrent issue throughout the world. In southern Africa, issues at the interface between agriculture and conservation are inescapable. Livestock herding for instance is a particularly relevant phenomenon to consider if one wants to study coexistence between protected areas and farming households leaving on their edges. Role playing games and agent based model can be used both to elicit local knowledge and strategies, and also to simulate the possible evolution of a given system. In this presentation we propose to describe a work conducted with farmers and livestock herders living in what we define as the Hwange National Park-Sikumi Forest SES (HNP-SF-SES), Zimbabwe. In our study area, cattle are driven within one of the protected areas (SF) throughout the year, resulting in (i) cattle predation by wild predators, and (ii) concerns about the capacity of the SF to effectively conserve wild herbivores. In order to better understand herders' strategies, we co-designed a role playing game with 10 members of this community. Such game is a tool that allows us to elicit herding practices, and to test different scenarios (e.g. climatic variations, alternative governance rules). We assume that a co-designed game will better represent players' reality, thus enhancing appropriation and finally allowing us to collect relevant data. The design process is already a direct first step towards an agent Based model as we co-formalized the local environment with the design team. Results of the playing sessions will be presented, so will the process of translating them into an autonomous agent based model used to simulate possible trajectories of our studied system.

WHY ISN'T TANZANIA'S JOINT FOREST MANAGEMENT PROGRAM A TRIPLE WIN? CAUSAL MECHANISMS FOR GOVERNANCE, LIVELIHOODS AND FOREST CHANGE

Lauren Persha

University of North Carolina at Chapel Hill

Researchers and policymakers have long sought strategies to more effectively couple poverty reduction with sustainable forest use – particularly in the impoverished tropics where conservation and human development challenges continue to strongly align. Decentralized co-management policies are now widely implemented, with this aim, however there is surprisingly little consensus on their ability to meet any of their conservation, socio-economic or governance objectives. Here we use a quasi-experimental matching approach to determine average impacts of Tanzania's forest sector co-management program (JFM). Three questions drive the analyses: (1) What is JFM's average impact on forest governance and household livelihoods, and conditions in forest reserves? (2) How do governance and livelihoods impacts differ for poorest households? (3) What mechanisms and context factors drive these outcomes? We draw on data from 110 villages and forest reserves, and 3,363 households surveyed across eastern Tanzania. Results point to significant positive impacts of JFM, relative to the centralized alternative, on village governance of forests; but no impact on income or asset-based livelihoods or deforestation rates over the 12-years assessed. We find strong evidence for wealth-based differences, with the poorest quintile of households experiencing a smaller governance impact, and non-poorest households experiencing a negative impact on forest-based livelihoods. We test mechanisms for governance improvement, and livelihoods and forest change. Results contribute to a more nuanced understanding of the causal effects of forest sector decentralization, and policy-relevant knowledge on conditions under which such strategies can effectively meet their ambitious land use, governance and socio-economic goals. This manuscript is part of a set organized by L. Glew, M. Mascia and D. Miller. If accepted please include this paper in the program immediately following the presentation by Mike Mascia.

130-DEVELOPING IMPROVED FOOTPRINT ANALYSES TO ASSESS THE DISTANT DRIVERS OF BIODIVERSITY LOSS

Martin Persson

Chalmers University of Technology

Javier GODAR, Stockholm Environment Institute ; Toby GARDNER, Stockholm Environment Institute

With international commodity trade on the rise, local environmental impacts are increasingly being driven by the behavior of distant consumers. A better understanding of these distant drivers of environmental degradation is crucial for formulating effective conservation policy responses. However, footprint analyses to date omit land-use change—a key driver of biodiversity loss in the tropics—and are limited to country-to-country analyses, thereby failing to capture the fine-scale spatial heterogeneity of land-use change and associated biodiversity loss. Here we present advances in linking land-use change and associated biodiversity loss to consumption drivers across the globe, by combining a newly developed land-use change footprint methodology with a spatially-explicit trade model. The model links country level trade flows in agricultural commodities to sub-national level (e.g. counties) using customs, trade and production data. With the Brazilian Amazon as an example, we discuss options for assessing biodiversity impacts using a tiered approach, combining national and biome-wide data on global biodiversity patterns with remote-sensing and forest fragmentation metrics, as well as detailed biodiversity assessments from the Sustainable Amazon Network. We show that globally, a third of all tropical deforestation can be linked to the production of just four commodities (beef, soybeans, palm oil and timber products) in just seven countries, while results from the spatially-explicit trade model applied to Brazilian farming production reveals marked differences in the production areas that supply different consumers (e.g., the EU and China), leading to heterogeneous biodiversity impacts within and between regions. We interpret these findings in the context of how international and national conservation policies can be strengthened through an improved understanding of trade dynamics and the use of more spatially-explicit data.

CREATING A BUZZ IN THE CITY: AN EXPERIMENTAL CROSS-CITY COMPARISON OF THE PUBLIC'S PREFERENCES AND VALUES FOR CONSERVING URBAN POLLINATORS

Tristan J. Pett

Durrell Institute of Conservation and Ecology, School of Anthropology and Conservation, University of Kent
Martin DALLIMER, Sustainability Research Unit, School of Earth and Environment, University of Leeds ; Mark A GODDARD, School of Civil Engineering & Geosciences, Newcastle University ; David L ROBERTS, Durrell Institute of Conservation and Ecology, School of Anthropology and Conservation, University of Kent ; Zoe G DAVIES, Durrell Institute of Conservation and

Ecology, School of Anthropology and Conservation, University of Kent

Increasingly research is demonstrating that urban greenspaces (UGS), if suitably managed, have the potential to provide important habitats and resources for biodiversity, as well as improving the health and well-being of people living and working locally. However, the role that biodiversity plays in delivering such ecosystem services within UGS is poorly understood. Wildflower meadows can be implemented as a management initiative to support and augment pollinating insect populations. Such interventions could also provide co-benefits to park users in terms of increasing the opportunity and quality of interactions with nearby nature. This study used experimental meadow plots planted in UGS across three UK cities (Bristol, Leeds and Edinburgh), as part of a wider urban pollinators research project. Areas of UGS were assigned to one of three treatment groups: control sites constituting amenity grass, native perennial meadows and non-native annual meadows. Biodiversity surveys established the diversity and abundance of flowering plants and pollinators within meadows and control sites, and responses to questionnaires were collected in situ across 17 sites during the peak flowering period of summer 2014. We used a suite of methods to assess public preferences and values including psychological scales of connection to the natural world, choice modelling and items to establish perceptions of species diversity and function. These results indicate that the public are generally positive about the creation of flower meadows but that individuals value and prefer meadows for different aesthetic and functional characteristics, depending on the social profile of individuals, their perceptions of species richness and the ecological traits of the flower meadows (such as diversity, colour and nativeness). Our findings suggest that provisioning of wildflower meadows in UGS, as well as providing key resources for pollinators, enhance the value of UGS to park users.

ID34: SATELLITE REMOTE SENSING AND ENVIRONMENTAL POLICY

Nathalie Pettorelli

Zoological Society of London

Martin WEGMANN, University of Wuerzburg

Satellite remote sensing (SRS) provides a wealth of opportunities to monitor the different constituents of the planet's natural environment, allowing access to standardized, global, continuous data directly relevant to the monitoring of, and pressures on, biodiversity. Because of this, satellite-based information can underpin the construction of useful indicators of ecological change that measure past ecological impacts and provide early warning signs of impending change. Such information could facilitate the implementation of a number of international, regional and national environmental

agreements and policies, and various initiatives (e.g., essential biodiversity variables initiative from GEO-BON; Biodiversity task from the Committee on Earth Observations Satellites) are currently trying to maximise such a potential. The methods, costs and benefits of traditional biodiversity indicators are however relatively familiar to environmental decision makers, as opposed to the financial and technical challenges, as well as the complexity associated with the various components of SRS. This may ultimately preclude the adoption of SRS by environmental legislators. In order to gain widespread support for the use of SRS in management and conservation, satellite data and analyses need to become more accessible to the community of ecologists. Training opportunities in SRS tailored to the biodiversity and conservation community also need to become more common, as the current lack of training opportunities hampers the emergence of a new generation of scientists able to carry out integrated, multi-disciplinary approaches.

122 LEVERAGING THE POTENTIAL OF HIGH-YIELD FARMING TO MAKE SPACE FOR NATURE

Ben Phalan

University of Cambridge

Lynn DICKS, University of Cambridge ; Graziela DOTTA, Museu de Ciências, PUC-RS ; Claire FENIUK, University of Cambridge ; Toby GARDNER, Stockholm Environment Institute ; Rhys GREEN, University of Cambridge ; Anthony LAMB, University of Cambridge ; Bernardo STRASSBURG, International Institute for Sustainability ; David WILLIAMS, University of Cambridge ; Erasmus ZU ERMGASSEN, University of Cambridge ; Andrew BALMFORD, University of Cambridge

Evaluations of trade-offs between species populations and food production suggest that a promising way to reconcile these conflicting demands for land in many places is to increase yields while sparing land for nature. However, high yields are insufficient to protect natural habitats from conversion, and can even increase rates of conversion, unless they are introduced alongside specific policies and incentives to link yield increases with habitat protection. I will discuss a range of promising mechanisms that could help to create such a link, ranging from regional land-use planning to landholder knowledge-exchange networks. These mechanisms are most likely to succeed in the presence of certain enabling conditions, including conducive technology, inelastic demand, strong institutions, secure finance, stakeholder buy-in and political support. Furthermore, there is a need for such mechanisms to address other important objectives, such as reducing the negative externalities of farming. Notwithstanding these challenges, there is considerable potential to leverage the potential of high-yield farming to make space for nature, and we argue for greater efforts to test promising mechanisms that could assist this process.

LESSONS LEARNED FROM SEAGRASS RESTORATION IN THAILAND

Sathika Phaokanta

Phuket Marine Biological Center

Wirat SINBOOTSAKORN, Phuket Marine Biological Center ; Nopparat INCHUAN, Phuket Marine Biological Center ; Preecha NOOSAI, Phuket Marine Biological Center ; Khunchanaporn WUDDHIVORAWONG, Department of Marine and Coastal Resources ; Laddawan SAENGSAWANG, Marine and Coastal Resources Research and Development Center the Eastern the Gulf of Thailand ; Thakorn KHAKAIKITTAWAT, Kung Krabaen Bay Royal Development Study Center ; Karnda SUWANNACHOTTE, Marine and Coastal Resources Research and Development Center the Eastern the Gulf of Thailand ; Warut SUTTIWAIT, Marine and Coastal Resources Research and Development Center the Eastern the Gulf of Thailand ; Natthawadee BANTIWIWATKUL, Marine and Coastal Resources Research and Development Center the Center the Gulf of Thailand ; Papangkol ARREECHON, Phuket Marine Biological Center ; Peerasak MANOO, Phuket Marine Biological Center ; Wannakiat TAPTIMSAENG, Department of Marine and Coastal Resources ; Sombat POOVACHIRANON, Department of Marine and Coastal Resources ; Petchrung SUKPONG, P.O. Box 89 Phuket Post Office

Seagrass plays a valuable role in Thailand's coastal ecosystems, but it is facing particularly large threats from both natural disasters and anthropogenic activities. To restore lost habitat, six seagrass restoration projects have been initiated by the government since 2013. The aims were to establish seagrass in sea water pond habitat (abandoned shrimp ponds), or to restore seagrass to natural seagrass meadows. Eight species were transplanted into abandoned shrimp ponds. Plantings of seedlings of *Enhalus acoroides* into sea water ponds survived over one-year. Vegetative propagation of *E. acoroides* into natural seagrass beds survived eight-months. Other seagrass species did not survive over one year. Important factors affecting the restorations concerned: water current and flow, light, soil characteristics, season and transplantation techniques, and seagrass species. Overall, seagrass in Thai waters is in good condition and transplantation is unnecessary. Seagrass restoration efforts should shift to establishing seagrass conservation areas together with rules which emphasize protecting them from habitat loss, rather than investing in seagrass transplantation. Participatory seagrass planning with local communities is the key to sustainable seagrass management.

CAN CITIZEN SCIENCE YIELD CONSERVATION OUTCOMES? A FRAMEWORK DESCRIBING PATHWAYS TO CONSERVATION.

Tina Phillips

Cornell Lab of Ornithology

Heidi BALLARD, University of California, Davis

Citizen science projects focused on environmental or biodiversity monitoring, involving volunteers in any stage of the scientific research or monitoring process, have exploded in number in recent years, yet evidence of their impacts on conservation remain under-examined. While evidence is growing that these projects achieve science and environmental educational goals, many have explicit or implicit conservation outcomes as their goal, such as improved health of species and habitat. Few projects, however, evaluate or provide evidence of such outcomes stemming from citizen science. Through a critical examination of a range of projects, we suggest that citizen science affects conservation indirectly through application of research findings, education of stakeholders, implementation of policy or regulations, and individual and community-level actions, as well as, directly through traditional measures for site and species management (Kapos et al. 2008). This oral presentation introduces an evaluative framework for articulating and measuring intermediate but necessary outcomes that are prerequisites to achieving ultimate targets. By analyzing the pathways from citizen science activities to conservation outcomes across different projects, we will highlight evidence, strategies, and barriers that influence conservation outcomes. Our findings have implications for the field of conservation biology both in leveraging the ways in which citizen science can contribute to conservation outcomes, and elucidating challenges when incorporating citizen science into social-ecological systems.

SEA TURTLE CONSERVATION AND HATCHERY MANAGEMENT PRACTICES IN SOUTH AND SOUTH-EAST ASIA

Andrea D. Phillott

Asian University for Women

Nimisha KRISHNANKUTTY, Asian University for Women ; Jibymol MATHEW, Asian University for Women ; Rokhsana HASIB, Asian University for Women

Sea turtle hatcheries are common in South and South-east Asia, but their management practices are relatively undescribed and unregulated. We used a mixed-methods research approach, including a review of published literature and interviews with hatchery managers or owners, to identify hatchery practices that are likely to contribute to sea turtle conservation and negatively impact upon hatch success and hatchling survival. We present data about hatchery construction and practices for handling, transporting and incubating eggs, and releasing and holding hatchlings in South Asia (Bangladesh, India and its territories, Pakistan, and Sri Lanka) and South-east Asia (Malaysia, Myanmar, Philippines, Thailand, and Vietnam). While the goal of most sea turtle hatcheries is to protect nests

from poaching, predation, habitat loss and beach erosion, and/or promote public awareness about sea turtle biology and conservation through ecotourism, of great concern are practices (e.g holding hatchlings up to 3 weeks) and outcomes (e.g. low hatch success, sometimes <10%) that do not contribute to sea turtle conservation.

THE LAND ETHIC AND OLD, NEW, AND INCLUSIVE CONSERVATION

John Piccolo

Karlstad University

The past few years have seen a debate building within the field of conservation biology, between so-called "Old" and "New" conservation. Most recently, a call for Inclusive conservation was published in the pre-eminent journal *Nature*, which has resulted in a long list of signatories from around the world – myself included. Inclusive conservation highlights the common ground between Old and New conservation, despite apparent differences that pertain particularly to values in nature; Old conservation tends to expound intrinsic values in nature whereas New conservation tends towards instrumental values in nature. Conservation itself differs from ecology in that it is necessarily a subjective pursuit; it must include a normative base because we are called upon to make choices as to what ought we to do about a species decline or ecosystem impact. Old and New conservation stand on common ground in that both recognize that we ought to conserve nature. But they appear to differ as to why we ought to do so – for the good of nature versus for the good of humankind (our own "naturalness" notwithstanding). Since its inception, however, conservation biology has explicitly recognized intrinsic values in nature, as outlined in Micheal Soulé's defining 1985 essay in *Bioscience* (35:727-734). Inclusive conservation calls for "a unified and diverse conservation ethic; one that recognizes and accepts all values in nature". I argue that although this may be in practice the only realistic way forward, conservation biologists must continue to strive for recognition of what is right. Aldo Leopold's well-known Land Ethic, and the discipline of environmental ethics, provide an ethical argument that nature is good in its own right. I discuss why I think this is true, and how conservation biologists might come to better extoll nature's intrinsic value.

SPATIAL HETEROGENEITY IN ATTITUDES AND BELIEFS TOWARDS BROWN BEARS IN THE FRENCH PYRENEES

Blaise Piedallu

CEFE

Pierre-Yves QUENETTE, ONCFS ; Coralie MOUNET, PACTE ; Nicolas LESCUREUX, CEFE ; Olivier GIMENEZ, CEFE

The raise in awareness towards human-wildlife coexistence has led to studies focusing on the attitudes and beliefs of local populations towards species that have problematic interactions with human societies. Among them, large carnivores often generate a wide range of views, from strong support to complete opposition. However, studies on the perception of large carnivores have usually been limited to a few relevant sociological parameters (age, gender or life in rural vs. urban areas). Besides, these studies have not explored small-scale spatial variability in perception. Here, we studied the Pyrenean Brown Bear the coexistence between local people and the species raises concerns. We investigated the factors that influence the attitude and beliefs of local populations towards bear presence, controlling for many potentially confounding parameters. We sent a questionnaire to 3000 residents spread over the Pyrenees to investigate their perception of bear's presence. Our results confirmed the effect of factors that were found in other studies on attitudes towards large carnivores, such as age or hunting practice. The originality of our findings lied in attitude being significantly correlated to the administrative division the respondents lived in and their place of birth. People who were born in the Pyrenees had a more negative opinion on bear presence than people born away from the mountains, and residents of different administrative divisions displayed contrasted attitudes towards bear presence. We suggest that attitudes towards bear presence are affected by local geographical factors, and that being raised close to the conflictual area leads to develop a negative opinion on bears. Overall, we hope that our results will lead to a better description of conflicts surrounding bear conservation and will contribute to suggesting new management approaches in the future.

A GLOBAL ASSESSMENT OF THE CONSIDERATION OF GENETIC FACTORS IN THREATENED SPECIES RECOVERY PLANS

Jennifer Pierson

The Australian National University

David COATES, Flora Conservation and Herbarium Program, Department of Environment and Conservation ; J. Gerard OOSTERMEIJER, Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam

A fundamental goal of threatened species recovery planning is to recover species or populations to the point of being viable in the long-term. Ecologists have acknowledged for decades that long-term viability is a function of both demographic and genetic processes. We set out to determine 1) if genetic processes are considered in Recovery Planning, 2) If so, what type of genetic processes are considered, and 3) What factors

are associated with the inclusion of genetic factors in Recovery Planning? We designed a questionnaire and applied it to over 300 Threatened Species Recovery Plans in three distinct regions: Australia (n=108), USA (n=100), and Europe (n=111). In the USA and Australia, over half the Recovery Plans consider genetics a risk factor to population viability, however in Europe, only a third of plans considered genetics a risk factor. Overall, plant plans considered genetic factors a risk less often than animal plans ($P = 0.006$). A majority of the plans in the USA (82%) recommend collecting genetic data with fewer plans in Australia (52%) and Europe recommending genetic data collection (17%). Nearly half (46%) of plans in the USA included genetic data, while few plans in Australia (12%) and Europe included genetic data (11%). Population genetic factors (genetic variation, structure, gene flow), were most commonly considered. Effective population size was considered in Recovery Plans at a similar, but low rate, in the USA (13%), Australia (10%) and Europe (9%). Fitness-related (inbreeding, outbreeding, introgression) and life-history (mating system, chromosome variation, clonal propagation) factors were seldom considered regardless of region or taxonomic category. These results highlight that when genetic processes are considered, they are seldom processes that can be directly related to population fitness. Thus, more careful consideration of the genetic processes important to target for recovery planning may be warranted.

STRENGTHENING CAPACITY THROUGH A REGIONAL LEARNING NETWORK: A CORAL TRIANGLE CASE STUDY

Diana Pietri

University of Washington

Todd STEVENSON, University of Washington ; Patrick CHRISTIE, University of Washington

Conservation programs that promote building capacity and social learning among participants often lead to the formation of learning networks: social networks where learning is both a goal and potential outcome. Through forming relationships and sharing information, participants build social capital that can help a learning network achieve socio-ecological goals. We explored social capital in a network that emerged through a multi-country marine governance effort, the Coral Triangle Initiative on Coral Reefs, Fisheries, and Food Security (CTI-CFF). Through social network surveys and key informant interviews, we examined patterns of information exchange among participants in CTI-CFF regional learning exchanges (REXs) – ongoing meetings centered on CTI-CFF goals (e.g., marine protected areas). We evaluated whether the network's structure promoted information sharing and the role of key individuals in the network, and considered implications for strengthening network sustainability and learning. We found that the REX network fostered new pathways of information

sharing among participants across national and organizational boundaries. While some members were more central to information sharing, the network structure was generally decentralized, suggesting resilience to changes in leadership and membership. Participants stressed the importance of the knowledge and capacity they had acquired through the network; however, they expressed doubts regarding its sustainability and noted the need for a coordinating entity. Our findings suggest that conservation learning networks have the ability to bridge cultural divides and promote social learning; however, strong coordinators and continued efforts to support information sharing are crucial to a network's strength and sustainability. The tangible learning and capacity development outcomes cultivated through REX network underscore the value of and need to invest in conservation networks that support peer-to-peer learning.

HOW IS BIODIVERSITY FRAMED BY POLICY-EXECUTORS? INSIGHT FROM REGIONAL AND LOCAL PRACTITIONERS IN MAŁOPOLSKA REGION, POLAND

Agata Pietrzyk-Kaszynska

Polish Academy of Sciences

Malgorzata GRODZINSKA-JURCZAK, Polish Academy of Sciences[INSTITUTE]Institute of Environmental Sciences, Jagiellonian University

While many conservation initiatives is launched and promoted at the international level, there is still lack of comprehensive knowledge about their sub-national implementation. We highlight that one of the important elements of policy realization are decisions made by sub-national, executive administration employees. Yet, the knowledge on their attitudes and opinions is mostly based on incidental observations or secondary opinions of particular people or institutions. We contribute to fill this gap by presenting a quantitative, representative data on how practitioners from sub-national administrative levels actually frame biodiversity and how do they perceive factors influencing its state. The study was conducted among local authorities and regional nature conservation and environmental institutions (both having discretion over nature conservation realization) in Malopolska region, Poland. The total number of 219 questionnaires (144 from the local and 75 from the regional level) was collected with responses rates: 60% and 71% at local and regional level respectively. We investigated how biodiversity and biodiversity conservation are understood by people actually responsible for conservation realization and verified the extent to which there is a common or divergent opinion on local and regional scale threats to biodiversity. We revealed significant differences between local and regional policy-executors, indicating that local level representatives tended to think and perceive biodiversity and its threats in a very narrow, local scope only. Regional level representatives

instead lean toward seeing much more positives of both state and trends of change in biodiversity. Still, regional level policy executors much more often acknowledged various factors influencing biodiversity, such as habitat fragmentation, river regulation or monocultures in agriculture. Interestingly, only climate change was unanimously perceived as having low impact on biodiversity.

SYMPOSIUM ID: #191 CONSERVATION MARKETING: HOW TO PROMOTE YOUR RESEARCH OR CAUSE MORE EFFECTIVELY

Kathleen Pilfold

None.

Are you promoting your conservation research or cause to the entire general public? Are you having trouble quantifying tactics? If so, your strategy may need tweaking to be measurable and ultimately more effective. Marketing is both an art and a science. In essence, it is storytelling with three main objectives: 1) to create awareness and ensure the intended audience understands the basic concept behind an idea and its relevance to them; 2) to reduce or remove barriers surrounding the idea so that a proposed action takes minimal effort; and 3) to develop and manage relationships with the intended audience. Marketing always focuses on the audience's perspective. It begins with defining a communications objective that is separate from the conservation research objective. Then, an audience is segmented for specific sets of values and interests, including demographics, geographic segmentation, behaviors, political values, social status, and others variables. An ideal target audience is made of decision makers and/or influencers, who will ultimately be in charge of fulfilling a call to action. Clearly-defined messaging is then crafted for the audience by bridging psychology, sociology and often graphic design principles. A call to action is asking for a behavioral shift by the target audience, such as visiting a website, calling a number, buying a product (or not buying a product), switching brands, or sharing knowledge with friends. According to Schwartz's Norm Activation Model, behavioral change is influenced by the awareness of the need for change and the perceived notion that others are also acting. Attitudes can be shifted by targeting the right segment of an audience at precise moments that most influence decisions. Once attitudes change, actions can change. McKinsey's loyalty loop, or consumer decision journey is an industry standard in marketing, which can equally be applied to audiences regarding conservation topics.

DESPOTIC ANIMALS AND IDEAL DISTRIBUTION MODELS

Nicholas Pilfold

University of Alberta

Andrew DEROCHER, University of Alberta ; Marie AUGER-MÉTHÉ, Dalhousie University ; Evan RICHARDSON, Environment Canada

Identifying and protecting suitable habitat is a cornerstone of conservation. Species Distribution Models (SDMs) have become a preeminent method in quantifying habitat use and preference. SDMs are generally applied to the location patterns of individual animals, and the strong assumption underpinning these models is that density of use reflects habitat quality, also known as the habitat-matching rule. Habitat matching is a derived prediction of the Ideal Free Distribution (IFD), which suggests that if animals have perfect knowledge, are equal competitors, and can access high quality habitat with no cost, fitness will be homogeneous across a population and the density of individuals will reflect habitat suitability. Despite the acknowledgement that many animals have non-ideal distributions, limited study has occurred on how sensitive SDMs are to violation of IFD assumptions. We used a combination of simulation and empirical research on polar bears (*Ursus maritimus*) to investigate how metrics of habitat preference are influenced by despotic behaviour. In this presentation, I will discuss how robust SDMs are to violations in IFD assumptions, and examine practical ways of mitigating the influence of despotic behaviour on habitat quality metrics. Finally, I will relate these findings to the distribution of polar bears in the spring in the Beaufort Sea, Canada, and provide an empirical example of the effects of despotic behaviour on measuring habitat quality.

IMPACT OF FOREST EXPLORATION ON NATURAL REGENERATION OF AN ENDANGERED AMAZON SPECIES VIROLA SURINAMENSIS (ROL.) WARB: CONSEQUENCES FOR CONSERVATION

Fatima Piña-Rodrigues

Universidade Federal de São Carlos

José Mauro SANTANA DA SILVA, Universidade Federal de São Carlos ; Ivonir PIOTROWISKI SANTOS, Universidade Federal de São Carlos ; Barto LOPES, IDEPA ; Aparecida Juliana CORREA, Universidade Federal de São Carlos

Along 80-90 decades, plywood industries explored natural areas of *V. surinamensis* (Myristicaceae). Later that, a new exploration started after 2000 for seed harvesting to cosmetic productions. In order to propose a management for in-situ conservation, we surveyed natural areas with different intensity of exploration in the Amazon estuary as follow: (a) low (Gurupa) and high (Labrea) floodplain conserved forests; (b) explored areas in low (Laguna) and high (Anajas) floodplain zones and (c) floodplain forest with no wood exploration along the last 15-20 years (Abaetetuba). Perpendiculars to the tides we established transects (10 m x 100 to 300 m) and we evaluated seedlings

(0.20<H<1.0 m) in plots of 1 m², sticks (circumference < 0.30 m) in plots of 7.5 m² and adults (plots of 200 m²). We applied Paired Squared Variance (PSV) followed by Green Index (IG) to estimate spatial distribution among groups of individuals and T-square (C) to evaluate individuals inside the groups. In conserved areas (Gurupa and Labrea) the density of natural regeneration (seedlings and sticks) showed a "J" inverted distribution with a slight bottleneck from sticks to adults while in the explored ones (Laguna, Gurupa and Abaetetuba) there was a strong narrowing from seedlings to sticks, which were density-similar to adults. The type of forest affected spatial distribution; in lowland floodplain forest, groups were formed by 5 m distance adults-seedlings dispersed 80-120 m from each other, with sticks randomly distributed among them; in high floodplain forest, groups of adults and juveniles (seedlings and sticks) were distant from each other 40-80 m in Labrea and 120-240 m in the explored ones (Anajas and Abaetetuba). We suggest that species regeneration is more sensitive to exploration in high floodplain forests and that number of sticks can estimate endangered areas to potential conservation in-situ and management.

108 A DECISION SUPPORT SYSTEM TO MONITOR CHIMPANZEE HABITAT HEALTH IN AFRICA USING LANDSAT SATELLITE IMAGERY, CROWDSOURCING AND OPEN STANDARDS

Lilian Pintea

The Jane Goodall Institute

Samuel JANTZ, Department of Geographical Sciences, University of Maryland ; Janet NACKONEY, Department of Geographical Sciences, University of Maryland ; Matthew HANSEN, Department of Geographical Sciences, University of Maryland

The Open Standards for the practice of conservation is a science-based, collaborative and adaptive management framework that strategically focuses conservation decisions on clearly defined objectives and prioritized threats and measures success in a manner that enables adaptation and learning over time. However, to date, the process of setting and monitoring measurable goals can be particularly challenging. Recent developments in remote sensing and cloud computing enable the use of satellite observations to provide a synoptic view of habitats at fine spatial and temporal resolutions that are locally relevant and consistent across the entire species range. In this paper we present a practical Decision Support System to be used by the Jane Goodall Institute and partners to annually monitor and forecast chimpanzee habitat health in Africa. The system integrates Earth observations from 30-meter resolution Landsat data with a species-specific habitat model and a model forecasting future land use change, enhanced by crowd-sourced field data collected by local communities and rangers

using the Open Data Kit app and Android mobile smartphones and tablets. Current habitat health status of the chimpanzee in Africa between 2000 and 2013 and future habitat health until 2030 will be presented and discussed. While coarser-scale and static chimpanzee habitat models have been previously developed, this project is the first to develop a dynamic monitoring system updated annually via Earth observations data that will systematically monitor threats and changes in habitat over time. Since the chimpanzee is an important keystone, flagship and umbrella species, an annual chimpanzee habitat health index would support conservation goals of other species within its large 2.5 million sq km range and could be an important indicator of overall ecosystem health of tropical forests in Africa.

20 FOREST WATCHER MOBILE APP: A NEW TOOL TO INFORM HABITAT MONITORING AND LAW ENFORCEMENT

Lilian Pintea

The Jane Goodall Institute

Tanya BIRCH, Google Earth Outreach ; Jeff NAMNUM, Touch Lab Inc ; Kevin GALLIGAN, Touch Lab Inc ; Timothy AKUGIZIBWE, The Jane Goodall Institute ; Peter APEL, The Jane Goodall Institute ; Rachael PETERSEN, World Resources Institute

Deforestation is a key driver of loss of habitat, climate change, diminishment of ecosystem services, and destruction of the natural resources. The Global Forest Watch (GFW) platform represents a ground-breaking advance in democratizing satellite information by putting real-time, globally-consistent yet locally-relevant data on forest change into the hands of all. In this paper we present Forest Watcher, a new and free mobile app that enables users with limited and occasional Internet connectivity to access, navigate to and ground-truth GFW forest loss alerts using Android smartphones or tablets. Forest Watcher is developed by the Jane Goodall Institute, World Resources Institute, Google Earth Outreach and TouchLab. We will discuss the potential of the app and GFW forest loss alerts to conservation in practice using three user case studies as part of the joint efforts to monitor threats to chimpanzee habitats and forests in western Uganda. First we will present the results of using Forest Watcher app by the private forest owners associations to support accountability and transparency among its members and inform the collective management of the private forests in Budongo-Bugoma corridor. We will evaluate then the potential of the app to the local communities and National Forest Authority rangers to patrol Budongo Forest reserve and enforce the law. Finally we will discuss how the app can be used by other organizations and citizens to crowdsource forest monitoring worldwide. With some GFW forest loss alerts coming in monthly updates, decision-makers could potentially move from simply documenting the forests already lost toward

faster action to stop illegal activities on the ground, slowing and preventing habitat loss before it happens.

INTEGRATING STATISTICAL METHODS, DYNAMIC MODELS AND MULTIPLE DATA SOURCES TO INFORM CONSERVATION MANAGEMENT DECISIONS.

Cecilia Pinto

University of Aberdeen [INSTITUTE] Marine Scotland Science
Stephen PALMER, University of Aberdeen ; Francis NEAT, Marine Scotland Science ; Peter WRIGHT, Marine Scotland Science ; Beth E. SCOTT, University of Aberdeen ; Justin M. J. TRAVIS, University of Aberdeen

Understanding the spatial population dynamics of many species of conservation interest is often made challenging by sparse availability of data. This poses major challenges for developing robust conservation management strategies. Here, we demonstrate how by using and integrating multiple sources of data (each one of moderate information value) through a set of contemporary statistical methods we can gain improved insight into the behaviour and spatial dynamics of an endangered marine apex predator, the flapper skate (*Dipturus intermedius*). This species used to be a widely distributed species across the North East Atlantic, but suffered a 90% decline in the last 40 years due to high levels of by-catch by fisheries. The West Coast of Scotland still hosts a number of relict populations in its sea lochs which were studied in order to better understand the biology of this species and define effective conservation measures. Demographic parameters including survival and residency were estimated from a Bayesian multisite capture recapture model which accounted both for individual and effort heterogeneity. Habitat suitability was estimated from opportunistic scientific survey data analyzed with GAMs and it was validated from independent geolocation data obtained from data storage tags. Demographic parameters together with habitat suitability maps were used as inputs for RangeShifter (an individual based modelling platform) to define the species population dynamics and seascape respectively. The model was applied to explore potential outcomes of different plausible conservation scenarios. Importantly, we establish the degree to which model-informed management decisions are robust to the uncertainty in parameter estimates. Using the flapper skate as a case study, we have demonstrated how novel dynamic modelling approaches, coupled with emerging statistical methods can enable us to inform conservation management, even for data poor species.

THE EFFECT OF NEST BOX CLEANING ON THE BREEDING SUCCESS OF RED-FOOTED FALCONS (FALCO VESPERTINUS)

Imre Sándor Piross

Szent István University, Faculty of Veterinarian Sciences, Dep. of Biomathematics and Informatics

Péter FEHÉRVÁRI, Hungarian Natural History Museum ; Szabolcs SOLT, MME/BirdLife Hungary ; László KOTYMÁN, Körös-Maros National Park ; Éva HORVÁTH, MME/BirdLife Hungary ; Andrea HARNOS, Szent István University, Faculty of Veterinarian Sciences, Dep. of Biomathematics and Informatics ; Anikó Kovács-Hostyánszki, MTA Centre for Ecological Research ; Péter PALATITZ, MME/BirdLife Hungary

The Red-footed Falcon is a small raptor species of high international conservational interest. Like other falcons they occupy nests built by other species for breeding. Its main nest host species in the Carpathian Basin is the colonially breeding Rook. The Rook population dramatically decreased in Hungary in the late 20th century narrowing down the Red-footed Falcon's opportunities for breeding, and making their population in Hungary endangered. In the past decade circa 4000 nest-boxes were provided to overcome the lack of nesting opportunities, and nowadays approx. over two thirds of the Hungarian population breeds in these kinds of artificial boxes. In the current situation it is crucial to know what kind of maintenance these nest-boxes require to remain suitable for successful breeding. Due to their closedness a substrate made of mainly food remains and faeces piles up in these boxes. The goal of our study was to investigate whether the removal of this substrate have an effect on the breeding success of Red-footed Falcons. The study was conducted in 2012, at artificial Red-footed Falcon colonies located in the Körös-Maros National Park in southeast Hungary. After the breeding period, the substrate was removed and replaced with dry grass in 106 of 251 randomly selected nest-boxes in 7 colonies. We used the nest-box monitoring and nestling ringing data of 2013 to measure the breeding success of the Red-footed Falcons. Using Generalised Linear Mixed Models we found no difference in the number of eggs laid, in the proportion of nestlings fledged, in the wing length and mass of nestlings between clutches of cleaned and untreated boxes. Our results suggest that cleaning of the boxes doesn't improve the breeding success of Red-footed Falcons, so the efforts previously put in these kinds of activities can be used for other conservational actions. Although providing some kind of cushioning like placing dry grass in the boxes is necessary to prevent eggs from rolling around.

PREDICTING THE EFFECTS OF HUMAN DEVELOPMENTS ON INDIVIDUAL DOLPHINS TO UNDERSTAND POTENTIAL LONG-TERM POPULATION CONSEQUENCES

Enrico Pirotta

University of Aberdeen

John HARWOOD, University of St Andrews ; Paul THOMPSON, University of Aberdeen ; Leslie NEW, U.S. Geological Survey ; Barbara CHENEY, University of Aberdeen ; Monica ARSO CIVIL, University of St Andrews ; Philip HAMMOND, University of St Andrews ; Carl DONOVAN, University of St Andrews ; David LUSSEAU, University of Aberdeen

Human activities that impact wildlife do not necessarily remove individuals from populations. They may also sub-lethally change their behaviour. This has driven interest in developing analytical tools that predict the population consequences of these short-term responses. Recent research has shown that modelling behavioural dynamics that arise from underlying motivations is an effective way to simulate the processes affecting individuals' decision-making. However, there are relatively few examples where this was done using a robust evidence base. Here, we integrate empirical information on the ecology of a population of bottlenose dolphins in an individual-based model that predicts individuals' behavioural dynamics and any potential change resulting from the interaction with boat traffic and dredging activities. We simulate the effects of proposed coastal developments and show that the operational phase, but not the construction phase, is predicted to affect the animals' motivations. For such results to be relevant for management, the effects on individuals' vital rates need to be quantified. These are mediated by the animals' ability to maintain their condition. However, it remains challenging to measure changes in an individual's condition in the field. Alternatively, we investigate whether the relationship between an individual's exposure and reproductive success can be directly estimated using a Bayesian multi-stage model for calf survival. We carry out a power analysis to assess any bias, as well as the sample size and effect size required to detect an effect. The results suggest that this approach could only detect significant relationships in large, closely-studied populations. Our work can be used to guide management decisions, accelerate the consenting process for coastal and offshore developments and direct targeted monitoring. However, more proximate measures of female condition are needed if long-term population consequences are to be robustly predicted.

106 - MANAGING THE WILDLIFE TOURISM COMMONS

Enrico Pirotta

University of Aberdeen

David Lusseau, University of Aberdeen

The non-lethal effects of wildlife tourism can threaten the conservation status of targeted animal populations. In turn, such resource depletion can compromise the economic viability of the industry. Therefore, wildlife tourism exploits resources that can become common-pool and that should

be managed accordingly. We used a simulation approach to test whether different management regimes (tax, tax and subsidy, cap, cap-and-trade) could provide socio-ecologically sustainable solutions. Such schemes are sensitive to errors in estimated management targets. We determined the sensitivity of each scenario to various realistic uncertainties in management implementation and in our knowledge of the population. Scenarios where time quotas were enforced using a tax and subsidy approach, or they were traded between operators were more likely to be sustainable. Importantly, sustainability could be achieved even when operators were assumed to make simple rational economic decisions. We suggest that a combination of the two regimes might offer a robust solution, especially on a small spatial scale and under the control of a self-organized, operator-level institution. Our simulation platform could be parameterized to mimic local conditions and provide a test-bed for experimenting different governance solutions in specific case-studies.

LAND USE, HABITAT DEGRADATION, AND EASTERN HELLBENDER (*CRYPTOBRANCHUS ALLEGANIENSIS ALLEGANIENSIS*) DISTRIBUTION CONSTRICTION WITHIN THE SUSQUEHANNA RIVER DRAINAGE

Amber Pitt

Bloomsburg University

Jamie SHINSKIE, Bloomsburg University ; Sean HARTZELL, Bloomsburg University ; Joseph TAVANO, Bloomsburg University

Eastern hellbenders (*Cryptobranchus alleganiensis alleganiensis*) are long-lived, large-bodied, fully aquatic salamanders native to the eastern United States. Hellbender populations have declined precipitously throughout their range due to a variety of factors including habitat degradation, disease, and collection for scientific investigations, educational purposes, and the pet trade. Habitat degradation associated with land use changes continues to be a primary threat to hellbender populations, yet much of what is known about the impacts of habitat degradation on hellbenders has been derived from a few studies that have documented long-term trends in hellbender populations and their habitat within a single stream, or based on primarily anecdotal evidence of declines. We sought to examine the relationship among land use, within-stream characteristics (i.e., habitat), and hellbender population persistence and extirpation within the greater Susquehanna River drainage in Pennsylvania, USA. We surveyed streams from which historical hellbender populations were known, but for which no recent status assessments existed. We used remote sensing to categorize the land use surrounding each stream. We also evaluated the within-stream characteristics, including water quality and stream substrate composition. Our results indicated that only 10 of the 25 sites tested still contained hellbenders. Hellbenders have undergone

distribution constriction within the greater Susquehanna River drainage in Pennsylvania, USA, and this corresponded with changes in land use and habitat degradation. These results can be used to inform hellbender conservation and reintroduction programs throughout their range.

161 BIOGEOGRAPHIC ASSESSMENTS: AN INTEGRATIVE FRAMEWORK FOR INFORMATION SYNTHESIS IN MARINE SPATIAL PLANNING

Simon Pittman

NOAA & Plymouth University

Chris CALDOW, NOAA National Marine Sanctuaries ; Theresa GOEDEKE, NOAA Biogeography Branch ; Mark MONACO, NOAA Center for Coastal Monitoring and Assessment ; John CHRISTENSEN, NOAA Biogeography Branch

Spatial planning is a considerable challenge for marine stewardship agencies because of the need to synthesize information on complex socio-ecological patterns across geographically broad spatial scales. This challenge is compounded by relatively short time-frames for implementation and limited financial and technological resources. To address this pragmatically, NOAA in collaboration with marine managers have developed the Biogeographic Assessment Framework (BAF) which provides a rapid, flexible and multi-disciplinary approach to integrate geospatial information into formats and visualization tools readily useable for spatial planning. Central to BAF is four sequential components: (1) Planning; (2) Data Evaluation; (3) Ecosystem Characterization; and (4) Management Applications. The framework is continually evolving with technological advances, information availability and needs, but has already been applied to support the development of several marine spatial plans in the United States. This presentation describes the structure of the BAF framework, some of the associated analytical techniques with examples of how synthesis products have had real world impacts in marine spatial planning.

SURVIVING URBANISATION: AVIFAUNAL DIVERSITY IN MILLENIUM DRIVE, MALABE, SRI LANKA

Anushika Pitunugama Herath Mudiyansele

University of Sydney

Jayampathi HERATH, Sri Lanka Institute of Technology and Medicine

Increasing urbanisation poses a major threat to biodiversity. Even though a considerable amount of studies have been conducted on urban biodiversity, knowledge about how biodiversity respond to urbanisation is limited in Sri Lanka. Therefore this study compares the species richness and diversity of bird communities in remnant forest patches and exotic manmade landscapes in Millennium drive, Malabe Sri Lanka. Study site is located in a semi urban environment which

is undergoing rapid development and is surrounded by both manmade and natural wetlands and forest remnants. After a rapid recognisance survey 4 remnant forest patches and 4 exotic urban landscapes were selected within the millennium drive out of 2 were terrestrial and two were aquatic. In each site belt transects of 200X50 m were laid. Birds were identified using Line transect, opportunistic observations and point count methods. A total of 106 individuals which belongs to 53 bird species including 7 migrants, 4 endemic species, and 3 nationally threatened species were recorded in the study area. Total number of bird species observed in exotic landscapes and remnant forest patches were 37 and 45 respectively. High species richness in forest remnants may be due to the high availability of food and shelter in forest remnants than exotic landscapes. Thirty five bird species were recorded in both sites (urban adaptors) while 18 species (Urban avoiders) were restricted only to remnant forest patches and 5 species were urban exploiter only recorded in exotic landscapes. The species restricted to the remnant forest patches were native species which includes endemic and threatened species. In conclusion, even though rapidly urbanising Millennium drive comprises of a rich diversity of avifauna and it is clear that forest remnants support more native species diversity than new exotic landscapes. Therefore it is advisable to incorporate more native plants in future urban development

COLOMBO URBAN WATER CANAL SYSTEMS WATER QUALITY VARIATION DUE TO HUMAN ACTIVITIES IN SRI LANKA

Ranjana Piyadasa

University of Colombo

Asitha NANDASEELA, University of Colombo

Urban water canal systems faces challenges of a growing and urbanizing population, a changing climate, an increase in the frequency of extreme weather events. Understanding these challengers in the physical environment and determining whether such changes are natural or a result of anthropogenic influences can be a difficult problem. The study was conducted in Colombo urban canal system in Sri Lanka to identify the variations of water quality and to identify the human health impact of water quality. Field study was conducted in canal systems identify the waste dumping sites, locations and also to study the physical conditions of the canal. Then a water quality survey was conducted to measure the water quality parameters, with special focus to E-Coli test, pH, Electrical conductivity, Salinity, Turbidity, Dissolved Oxygen, Ammonia levels, Nitrate levels, Phosphate levels, Chemical Oxygen Demand, Biological Oxygen Demand. Tertiary the questionnaire survey was conducted based on people who live adjacent to the canal to identify their health conditions. Main analytical tools of the study were statistical, Arc GIS 10.1 and ERDAS 2011. According to the study the main causal factor

for pollution is identified as waste generated by the human activities and poor sanitary facilities. Therefore the levels of e-coli are around 10 per milligram where the recommended level is zero E-coli in water and other chemical parameters also above the recommended levels. Based rainfall analysis revealed that the clear relationship between rainfall variations and water quality parameters; especially the salinity variation due to sea water intrusion to the canal system.

EFFECTS OF OCEAN ACIDIFICATION ON CORAL REEF COMMUNITIES

Laetitia Plaisance

Smithsonian Institution

Nancy KNOWLTON, Smithsonian Institution ; Katharina FABRICIUS, Australian Institute of Marine Science

Coral reefs are the most diverse marine ecosystems and among the most threatened. It is now widely accepted that increasing levels of carbon dioxide (CO₂) in the atmosphere pose an enormous threat to coral reefs and ocean acidification (OA) has recently come to the forefront as a major concern in the coming decades. OA will have numerous consequences for both calcifying and non-calcifying species and will potentially significantly modify reef communities. Field experiments at sites with naturally-elevated CO₂ conditions, such as CO₂ vents, are potentially useful for investigating the effects of future acidification on coral reef associated biodiversity at the ecosystem level. To this end, we characterized the cryptic microfauna associated with naturally acidified coral reefs in Milne Bay, Papua New Guinea. Two pH conditions representing present day pH (8.1) and the estimated global ocean pH by the end of the century (7.8) were investigated for two sites in Dobu and Normanby Islands. We used standardized sampling techniques (ARMS) and molecular species characterization (DNA barcoding and metabarcoding) to quantify the taxonomic composition of the sessile and motile reef-associated cryptofauna. We will assess changes in diversity and community structure and will interpret the results in the light of changes in water chemistry and associated loss of habitat complexity to provide insights into future reef-community structure in a high CO₂ world.

CASCADING EFFECT OF PREY ABUNDANCE ON CARNIVORE MORTALITY NEAR MOTORWAYS

Aimara Planillo

Universidad Autónoma de Madrid

Cristina MATA, Universidad Autónoma de Madrid ; Beatriz FERNÁNDEZ-RUBIO, Universidad Autónoma de Madrid ; Pablo RUIZ-CAPILLAS, Obrascón Huarte Lain S.A. (OHL) ; Juan E. MALO, Universidad Autónoma de Madrid

Understanding effects of the human altered landscapes in wildlife is a priority to propose effective conservation measures.

Motorways are an interesting study case, as they not only create disturbance, but are also sources of extra mortality on many species. Some prey species have dense populations near these infrastructures which can attract predators to them. We analyzed changes in the predator-prey relationship in the proximity of motorways in comparison with control sites, with the prediction that prey populations beside the infrastructure will increase predator mortality. Our study model is a key prey species in Mediterranean area, the European rabbit (*Oryctolagus cuniculus*) and its carnivore predators - Red fox (*Vulpes vulpes*), Mustelids (several species, mainly *Martes foina*), and Cats (Feral and Wildcats, *Felis silvestris*), in a typical Mediterranean landscape of Central Spain. We conducted a survey of relative abundances and analyzed the effects of rabbit abundance and distance to motorway (motorway verges vs. control sites at more than 4 km away), on carnivore abundance. We also collected data on carnivore road mortality. We found that the carnivore abundance tend to increase with prey abundance, as expected. More interesting, we found that carnivore abundance was higher next to the motorway than in control sites, even for the same abundance of prey. As predicted, carnivore roadkills were related to the carnivore abundance in the verges. In the light of these results, we conclude that prey populations near risky anthropogenic areas, such as roads, can create a cascading effect that leads to increased carnivore mortality. These results will provide useful knowledge for future management actions, focused on reducing prey populations on road verges for carnivore conservation.

MULTI-SPECIES TRANSLOCATION STRATEGIES ARE HIGHLY INTERACTION-TYPE SPECIFIC

Michaela Plein

University of Melbourne

Michael BODE, University of Melbourne ; Melinda MOIR, The University of Western Australia ; Peter VESK, University of Melbourne

Translocating threatened species to prevent their extinction is commonplace. Although multiple species are being translocated to single locations such as fenced reserves or offshore islands, current translocation guidelines consider single species in isolation. This practice ignores important interspecific interactions and their influences on population dynamics, thereby risking translocation failure. To show if and how interspecific interactions influence translocation strategies, we modeled three two-species systems for consumer-resource, mutualism, and competition. We specifically focused on the influence of interaction types on the required founder population size, and the optimal order in which the species are moved (simultaneous or sequential) to achieve successful multi-species translocations. Further, we assessed the effect of increasing interaction strength in

simultaneous translocations, and increasing delay time in sequential translocations. Although we found few similarities between different interaction types, we identified a series of interaction-specific recommendations. Translocations of mutualists and competitors required a minimum founder population size, but consumer-resource translocations are more complex because they also exhibit a maximum founder population size. While simultaneous translocations improved the outcomes of mutualistic interaction partners, competitors and consumer-resource systems benefitted from sequential translocations. Interspecific interactions are important processes that shape population dynamics and should therefore be incorporated in the quantitative planning of each translocation, especially for multi-species translocations. Our findings not only apply to conservation translocations, but whenever interacting species are moved (e.g. biological control, restoration).

THE ROLE OF THE SEED BANK IN BUILDING UP A GENETIC EXTINCTION DEBT IN THE GRASSLAND PERENNIAL *CAMPANULA ROTUNDIFOLIA*

Jan Plue

Stockholm University
Katrien VANDEPITTE, *Katholieke Universiteit Leuven*; Olivier HONNAY, *Katholieke Universiteit Leuven*; Sara COUSINS, *Stockholm University*

Fragmentation of natural habitats is a global threat to biodiversity. Still, many species survive in habitat fragments past the point where their minimal viable population size has been reached. Plant species may postpone their extinction, due to persistent life-cycle stages involving prolonged clonal growth or seed banks, resulting in a species extinction debt. A delay in the expected loss of population genetic variation may be one of the mechanisms behind a species extinction debt. We examined the role of the seed bank in building up a genetic extinction debt in the grassland perennial *Campanula rotundifolia*. We used microsatellite markers to analyze the genetic make-up of 15 above- and belowground populations in relation to historical and current landscape configuration. Aboveground genetic diversity and composition were related to historical patch size and historical patch connectivity, respectively, and not to the current patch characteristics, supporting a genetic extinction debt. When the entire gene pool was examined by including the genetically diverse seed bank, the genetic extinction debt pattern became even stronger. We conclude that the seed bank contributes to the genetic extinction debt build-up, by delaying genetic diversity losses in small populations. This renders *C. rotundifolia* a species able to postpone its extinction, yet the question rises whether the extinction debt concept currently underestimates species losses, as long as underlying mechanisms are not fully understood. The genetic extinction debt nevertheless buys

conservation management the time needed to restore habitat area and connectivity, preventing expected erosion of genetic diversity, averting future species losses.

EFFECTS OF SILVICULTURAL PRACTICES ON ECOSYSTEM SERVICES FROM BOREAL PRODUCTION FORESTS

Tähti Pohjanmies

University of Jyväskylä
Maria TRIVIÑO, *University of Jyväskylä*; Adriano MAZZIOTTA, *University of Jyväskylä*; Eric LE TORTOREC, *University of Jyväskylä*; Mikko MÖNKKÖNEN, *University of Jyväskylä*

Forests are widely recognized as major providers of ecosystem services, including timber, recreation, regulation of water, soil, and air quality, and climate change mitigation. Boreal countries harbor some of the world's most extensive forest areas and have long traditions of production forestry. Extensive tracts of boreal forest are actively managed for timber production, but actions aimed at increasing timber yields also affect other forest functions and thus ecosystem services. Our review of the environmental and social impacts of prevailing practices reveals that management may have positive or negative effects on multiple ecosystem services provided by boreal forests. Similarly, actions aimed at tackling future challenges (increased wood production, climate change, and biodiversity conservation) may lead to both gains and losses in ecosystem services. The direction and magnitude of most of the effects are highly dependent on the properties of the site, suggesting forest management for diverse benefits should be context-specific. While some effects occur at spatial scales that are relevant for forest management (i.e. stand or forest holding), some are generated at larger scales (i.e. landscape). This suggests coordination of activities among forest owners may be necessary to secure diverse forest services. Conflicts among different interests related to forests are likely, but the concept of ecosystem services may provide a useful framework for identifying and assessing the conflicts and for finding optimal solutions for them.

SIMULATIONS BASED ON MOLECULAR-GENETIC DATA IN DETECTION OF EXPANSION *SALMO TRUTTA* ALLOCHTHONOUS POPULATION IN THE NERETVA RIVER'S TRIBUTARIES

Naris Pojskic

INGEB, *University of Sarajevo*
Belma KALAMUJIC, *INGEB, University of Sarajevo*

In Bosnia and Herzegovina, brown trout resides in both river basins. The Danube (Da) evolutionary lineage is native in the Black Sea basin, while the Adriatic lineage (Ad) is autochthonous to the Neretva basin. The survival of the local

gene pool of wild brown trout is threatened due to habitat degradation, overexploitation, inadequate stocking and hybridization. Control region of mtDNA together with LDH gene were used to assign samples to evolutionary lineages, while 13 microsatellite markers were genotyped to assess population genetic diversity. Total of 335 specimens of brown trout from the main flow of the River Neretva and 11 of its tributaries were sampled. Sampling locations on tributaries were located in hardly accessible areas in order to maximally reduce the possibility of stocking. Besides the indigenous Adriatic haplotype, the Danube and the Atlantic mtDNA haplotypes were detected, which clearly indicates that populations of brown trout in the Neretva river basin have been subject to translocation activities and stocking with allochthonous gene pool. Simulation based on molecular-genetic data clearly proves hybridization events and expansion of population with allochthonous haplotypes. The trend of expansion of allochthonous gene pool of brown trout was also detected in the most remote tributaries of the river Neretva. MCMC analysis indicated that the first introgression phase was represented by intraspecific hybridization between the Danube and the Adriatic brown trout, imposed by the process of restocking. The second phase of introgression is ongoing; it represents intraspecific hybridization between the first-phase-introgression hybrids (as well as "pure" Adriatic trout) and the Atlantic brown trout that were introduced primarily through inadequate stocking activities. Other simulations show that only 11% of the initial population (indigenous specimens from the tributaries) has the characteristics of the simulated autochthonous population.

HUMAN LEOPARD CONFLICT IN CAPITAL CITY OF NEPAL

Monsoon Pokharel Khatiwada

Tribhuvan University

Khadga KHADGA, Tribhuvan University; Ambika Prasad KHATIWADA, National Trust for Nature Conservation; Kyran KUNKEL, University of Montana

Common leopard (*Panthera pardus*) is a widely distributed large cat included in near threatened category of IUCN. In Nepal, common leopards are found in variety of habitats including protected areas and human dominated landscape. Human leopard conflict (HLC) is a major issue in capital city of Nepal (Kathmandu valley) recently with death of leopards, injuries to human beings, and livestock losses. The objectives of this study were to collect historical human leopard conflict data and to identify cause of conflict with its appropriate mitigation measures. HLC data including leopard death/rescue and human injuries were collected from primary (interview survey, n=110) and secondary sources. Satellite imagery of 2003 and 2013 were analyzed to understand land use land cover change to identify the causes of HLC. Thirty-two human leopards

encounter cases were recorded in 2010-2013 with more than 50% (17) of leopards found dead and sixteen leopards were rescued and released back to natural habitat. During 2003 - 2013 an area of 4011 hectare was converted from forest to barren land in Kathmandu valley. Most of the HLC cases occurred in forest cover change area i.e., forest cover converted into settlements or agriculture or barren land and the area where change is occurring gradually. Forest cover change into settlements, limited prey species in forest and insufficient awareness level of local communities were the major causes of HLC in Kathmandu valley. It is a daunting challenge to ensure the peaceful coexistence of leopards among high densities of humans. During encounter with leopards, human provocations have often resulted in aggressive nature of leopards. Such cases of HLC often remain unaddressed. Local education campaigns, improved livestock management, and enhancement of wild prey populations hold much promise for reducing and better managing conflicts.

SPATIAL PATTERNS OF VULNERABILITY TO EXTINCTION IN TERRESTRIAL MAMMALS: SPECIES TRAITS VS. ANTHROPIZATION

Ester Polaina

Doñana Biological Station

Manuela GONZÁLEZ-SUÁREZ, Doñana Biological Station; Eloy REVILLA, Doñana Biological Station

Traditionally, prioritization schemes for global biodiversity conservation are based on the amount of (endemic) species that inhabit certain areas or, less frequently, on the coincidence of species richness and some proxy of human presence (e.g. population density). However, nowadays there is more information available, which may help not only to establish schemes but also to understand the potential causes that make some areas a priority. In the present work, we introduce the concept of vulnerability to extinction into the prioritization framework. We focus on terrestrial mammals to predict extinction risk at the species level based on two well-known aspects influencing vulnerability: life-history traits and overlap with different human activities. Using this approach we identify areas requiring different conservation actions. In particular we recognized four types of areas: 1) urgency areas: where both the characteristics of the species and the existing human activities pose a threat and thus, action is urgently needed; 2) species-based vulnerable areas: where species are naturally fragile and human presence is scarce, thus specific management plans for mammals that also maintain natural habitats would be particularly efficient; 3) highly-anthropized areas: where human pressure is high but species are not intrinsically vulnerable; monitoring checks would be highly advisable, making the most of closeness of human populations; and 4) remote areas: relatively pristine areas where there are not remarkable threats for terrestrial mammals. We find that

our urgency areas largely overlap with previously identified hotspots, whereas, the other three types have been generally grouped and given low priority in literature. Our study allows for a finer-grain differentiation of conservation priorities, revealing areas where preventive and less-resources-requiring actions could be effective in avoiding future urgencies.

OPTIMAL PLANNING FOR MITIGATING THE IMPACTS OF ROADS ON WILDLIFE: A MULTIPLE SPECIES APPROACH

Tal Polak

The University of Queensland
Emily NICOLSON, The University of Melbourne ; Clara GRILO, Universidade de Aveiro ; Joseph BENNETT, The University of Queensland ; Hugh POSSINGHAM, The University of Queensland

Roads have a major effect on wildlife worldwide through habitat loss, habitat fragmentation and direct road-kill mortality. Two of the ways to mitigate these impacts are erect wildlife crossings and/or build fences. However, these techniques are expensive, and have varying levels of success. Thus, deciding where and how to act in order achieve the greatest return on investment is crucial. Here, we use a decision theory framework driven by a metapopulation process model to determine the most cost-effective combination of actions to mitigate the effects of roads on wildlife for multiple species. We illustrate our approach using two sets of species (from Australia and Europe) that cover a range of taxonomic groups and life history traits. We test the cost-effectiveness of spatially explicit combinations of three management options: 1) no mitigation, 2) erect fences without wildlife crossings, and 3) erect fences combined with wildlife crossings. We explore the trade-off between each populations' mean time to extinction and total mitigation cost, first on a per-species basis and then considering all species. For most species there are "win-win" mitigation solutions with high benefits for a relatively low cost. Among the species' attributes, home range (relative to the modelled landscaped scale) and road edge effect have the greatest impact on the optimal strategy. We find that, while a single species approach was less cost-effective than a multi-species approach to management, some species can be used as indicators, allowing mitigation planning to be based on a smaller suite of species and further increasing cost-effectiveness. Our method is adaptable to any road mitigation problem and illustrates the need to consider the entire system when planning mitigation measures in order to spend mitigation funds wisely.

EFFICIENT EXPANSION OF GLOBAL PROTECTED AREAS REQUIRES SIMULTANEOUS PLANNING FOR SPECIES AND ECOSYSTEMS

Tal Polak

The University of Queensland
James WATSON, The University of Queensland ; Richard FULLER, The University of Queensland ; Liana JOSEPH, The University of Queensland ; Tara MARTIN, CSIRO ; Hugh POSSINGHAM, The University of Queensland ; Oscar VENTER, James Cook University ; Josie CARWARDINE, CSIRO

The expansion of protected area networks at national scales to conserve species and represent ecosystems is recognized as a core conservation priority in the Convention for Biological Diversity (CBD). The CBD's strategic plan advocates the use of environmental surrogates, such as ecosystems, as a basis for planning where new protected areas should be placed. However, the efficiency and effectiveness of this ecosystem-based planning approach to adequately capture threatened species in protected area networks is unknown. We examine the impact of ecosystem-based planning on the representation of threatened species using Australia as a case study, a continent where ecosystem-based targets form protected area acquisition policy. We test scenarios for protected area expansion using two targets: 1) 10% coverage of each of Australia's 85 bioregions and 2) species-specific targets based on spatial range of all of Australia's 1320 threatened species. We measured the total land area required to meet the ecosystem and species targets independently, sequentially or simultaneously. Seeking ecosystem coverage alone is poor at meeting targets for threatened species, with less than a quarter of species targets being met, representing only a slight (3.2%) improvement to the current network. Planning simultaneously for species and ecosystems targets delivered the most efficient outcomes, while planning first for ecosystems and then filling the gaps to meet species targets was the most inefficient conservation strategy. Our analysis highlights the pitfalls of pursuing goals for species and ecosystems non-cooperatively and has significant implications for nations aiming to meet their CBD mandated protected area obligations.

USING UNMANNED AERIAL VEHICLES TO SURVEY FOR THREATENED GRASSLANDS SPECIES

Lucy Poley

University of Calgary
Greg MCDERMID, University of Calgary

Remote-sensing technology provides researchers the ability to survey large areas quickly and efficiently, collecting data needed to model species distribution and habitat features in a spatially explicit manner. When surveys are repeated over time, models can indicate changes in range occupancy,

habitat selection, and other information critical for wildlife conservation and management. Unmanned aerial vehicles (UAVs) are emerging as exciting new platforms for conducting ecological surveys: they are small, safe and maneuverable, and can fly autonomous missions at low altitudes with minimal disturbance to wildlife. UAVs can gather high-resolution data on wildlife and habitat, while low operating costs means they are ideal for conducting repeat surveys. Native grassland is amongst the most endangered ecosystem on Earth. In Canada, the largest contiguous area of native grassland is in southern Alberta and Saskatchewan, where a number of threatened species reside, including the burrowing owl (*Athene cunicularia hypugaea*), now found in only 36% of its historical range. Burrowing owls live in holes made by small mammals such as Richardson's ground squirrels (*Spermophilus richardsonii*), which play an important role in maintaining healthy prairie ecosystems. However, to date no large-scale surveys have been conducted for these species, and their habitat selection is not well-understood. Using low-flying UAVs, we repeatedly surveyed study areas in southern Alberta and Saskatchewan to collect data on burrowing owls, ground squirrels, and vegetation communities. We have developed and applied an automated method for identifying active burrows and vegetation classes in UAV imagery, and are using the resulting data to model changes in species distribution, habitat selection, and other aspects of burrowing owl ecology important to conservation. Our study shows how UAVs allow researchers to gather ecological data at previously unattainable spatial and temporal scales.

PRESERVING PAST EVOLUTIONARY DIVERSITY INTO THE FUTURE

Laura Pollock
CNRS

Evolutionary history is often considered in biogeographic studies, but rarely in conservation planning. Many studies map diversity across the landscape, but hotspots of diversity should not necessarily become conservation priorities. We also need to consider the diversity that has already been lost, the diversity that is protected, and the cost of conservation actions among other factors. Here, we demonstrate a recently developed method of including phylogenetic diversity in spatial conservation prioritization with ~700 eucalypt species that dominate forest canopies across Australia. Currently, 17% of the total eucalypt PD is protected in reserves (which cover 15% of the land area), whereas 60% of the PD could be protected if the same land area was optimally located to preserve PD. Importantly, with a small expansion of the current protected areas by 2%, we could include 70% more PD. The largest intact 'candidate' area for protected area expansion coincides with

both a world biodiversity hotspot and an area of active mining exploration.

MANAGING A KEYSTONE RODENT AND DOMESTIC CATTLE TO RESTORE SEMI-ARID GRASSLANDS IN MEXICO.

Eduardo Ponce Guevara

Universidad Nacional Autónoma de México
Ana DAVIDSON, Institute for Wildlife Studies ; Rodrigo SIERRA CORONA, Universidad Nacional Autónoma de México ; Gerardo CEBALLOS, Universidad Nacional Autónoma de México

A major challenge facing grassland conservation in North America is determining how wildlife and cattle can co-exist in a way that maintains grasslands, while also supporting human needs. Around the world, keystone rodents such as prairie dogs (*Cynomys* spp) have been considered as pest and eliminated in most of their native geographic range. Eradication of native species has resulted in a cascading decline in both native wildlife and livestock production, and consequent grassland degradation. We established a long-term manipulative experiment to evaluate the individual and interactive effects of black-tailed prairie dog (*C. ludovicianus*) and cattle (*Bos taurus*) on shrub encroachment in arid grassland of northwestern Mexico. After six years, cattle and prairie dogs impacted shrub encroachment. Both reduced mesquite density, but prairie dogs had the greatest impacts. On sites where both species were removed, shrub density increased by 3-fold following their removal, increasing from 7 to 28 shrubs per hectare in six years. Cattle also impacted prairie dog abundance, whereas sites with no cattle maintained a lower prairie dog density of 14 ind/ha, on sites with cattle prairie dog density increased to 38 ind/ha. Our results provide new insights for grassland management by showing that cattle and prairie dogs may co-exist, and if they are properly managed, they may interact synergistically to control mesquite encroachment and increase habitat heterogeneity on arid grasslands.

SYMPOSIUM ID 141: DO NATIVE PLANT HEDGEROWS IN CONVENTIONAL FARMING SYSTEMS HELP TO CONSERVE POLLINATORS AND POLLINATION SERVICES?

Lauren Ponisio

University of California Berkeley
Claire KREMEN, University of California Berkeley

To slow the rate of global species loss, it is imperative to understand how to restore and maintain biodiversity in agricultural landscapes. Widespread evidence of pollinator declines has led to policies that support habitat restoration, yet, little is known about the effectiveness of these restoration techniques for conserving pollinators, especially in intensively-

managed agricultural landscapes. Using seven years of pollinator collection records from the Central Valley of California, we evaluate the effectiveness of on-farm habitat restoration, in the form of native plant “hedgerows”, for supporting pollinator populations. We find that hedgerow restoration enhances colonization and persistence of pollinators, leading to the assembly of phenotypically diverse communities. This in turn leads to increased spatial heterogeneity between communities. By helping to restore phenotypically diverse pollinator communities in intensively managed agriculture, even small-scale restoration interventions like hedgerows are a valuable measure for conserving biodiversity and promoting the provisioning of ecosystem services.

SYMPOSIUM ID 208-POTENTIAL OF DIGITAL TECHNOLOGIES TO ENHANCE OPENNESS IN LEARNING AND SCIENCE

Marisa Ponti

University of Gothenburg

The Internet, open licensing, open access journals, and open educational resources (OER) provide the foundation for redefining the experience of consumer relationship that most people have with science into one of active engagement. Specifically, OER and open access scholarly articles used as OER are critical to ensuring and expanding access to knowledge. In this respect, they can facilitate citizen science in terms of making scientific ideas and practices accessible to everyone. It has been noted that OER can support citizen science in three ways. First, the free circulation of results in open access scholarly publication allows citizens to become informed and educated, and, possibly, motivated to engage actively in scientific research. Second, open access can contribute to recruit and train potential citizen scientists. Third, funders increasingly require that grant funded science be returned and repaid to the taxpayers partially through open access to research results. Based on these three premises, it can be argued that OER can be tied into citizen science projects to build scientific communities outside of institutional settings and support peer-to-peer learning practices, in which participants work together with scientists to address relevant problems, explore scientific concepts and research solutions to problems and/or study phenomena of interest. During the oral talk, some examples of citizen science projects connecting learners and scientists in fieldwork will be presented. These projects show the possibility of using OER to involve learners in forms of inquiry-based learning, while developing their appreciation of science to their lives.

106-VISUALISING AND ANALYSING DATA TO SAVE LIVES: HUMAN AND CROCODILIAN

Simon Pooley

Imperial College London

As human populations grow and transform undeveloped lands and waterways, human-wildlife conflict inevitably increases. This is particularly problematic for large predators and the humans who live alongside them. Relatively little research has been conducted on alleviating adverse human encounters with one of the most significant and widespread predator species on the planet, the crocodiles. In this talk I argue that while long-term data on crocodile attacks will always be incomplete, and prediction of future attacks difficult, we can learn much from collecting and analysing attack data. We should focus on accumulating long-term data, entered in standardised form on a freely available database; disaggregate data on human victims by age, gender, location and activity at time of attack, to enable targeted mitigation; and analyse long-term ecological and social data for both humans and crocodiles. Continuously updated databases will enable the identification emerging trends and problem areas, and the online CrocBITE database developed by Adam Britton and Brandon Sideleau aims to achieve this on local and regional scales. In developing countries with a range of pressing social, health and other needs, crocodile attacks are unlikely to be sufficiently serious on a national scale to attract funds for mitigation. It is more feasible for local authorities to raise funds to create awareness or provide safe water access in specific locales with a history (or emerging pattern) of attacks – and link this with other social benefits such as safe drinking water. Using my data for South Africa, I am currently developing interactive visualisations of CrocBITE data to allow users to explore the data without requiring research skills to do so. We aim to motivate busy conservation managers and the public to collect, contribute, and use crocodile attack data. This knowledge can then be mobilised to save lives – human and crocodilian.

RECONCILING BIODIVERSITY CONSERVATION AND RENEWABLE AND UNCONVENTIONAL ENERGY DEVELOPMENT

Viorel Dan Popescu

Simon Fraser University

Robin MUNSHAW, Simon Fraser University; Federico MONTESINO-POUZOLS, University of Helsinki; Wendy PALEN, Simon Fraser University; Pascale GIBEAU, Simon Fraser University; Evgenia DUBMAN, Simon Fraser University; Matt

HORNE, Pembina Institute ; Atte MOILANEN, University of Helsinki

Balancing biodiversity protection with economic development is a central tenet of conservation science, but local, regional, and global conservation priorities often differ. Driven by efforts to lower greenhouse gas (GHG) emissions, renewable energy sources and low-carbon fossil fuels are being adopted worldwide, but their rapid development often outpaces our understanding of biodiversity impacts. We examined opportunities and conflicts for biodiversity protection and future electricity generation from renewable sources (wind, small hydro) and shale gas extraction and combustion in British Columbia (BC), Canada using two metrics: spatial overlap with conservation priorities, and greenhouse gas emissions. We identified conservation priorities at three levels of biological organization, species (terrestrial and aquatic vertebrates, $n=370$), communities ($n=40$), ecosystems ($n=16$) using spatial conservation planning, and quantified the spatial overlap between the footprint of each energy type and conservation priorities. We contrasted the spatial overlap against GHG emissions from electricity generation. Small hydro had the lowest GHG emissions (1.5 – 65 kt CO₂-eq/year for 5000 GWh/year), yet its infrastructure overlapped with high conservation-ranked areas for species and communities. Conversely, GHG emissions from shale gas extraction and combustion were up to 1000 times higher than small hydro. Shale development overlapped with low conservation priority areas for species and communities, but occurred in less disturbed regions. Wind energy had little overlap with conservation priorities, and low GHG (15 – 225 kt CO₂-eq/year for 5000 GWh/year), suggesting that wind could reconcile conservation and electricity production. In summary, future electricity development in BC that meets biodiversity conservation targets with minimal GHG emissions needs to focus on wind, and limited small hydropower (in areas of low conservation priority).

ID134 THE FUTURE OF MARXAN

Hugh Possingham

The University of Queensland
Matt WATTS, The University of Queensland ; Maria BEGER, The University of Queensland ; Jennifer MCGOWAN, The University of Queensland ; Hawthorne BEYER, The University of Queensland ; Yann DUJARDIN, The University of Queensland ; Viv TULLOCH, The University of Queensland

During this session researchers have discussed diverse and interesting applications of Marxan, some of which were not entirely intended by the creators of Marxan. This shows the power and flexibility of decision support software that is founded in proper mathematical problem formulation and rigorous solution methods. Having a well-defined mathematical problem is essential for credible and flexible

decision-support application. In this talk I will discuss some of the new features currently being added to Marxan, in particular the capacity to deal with more complex objective functions. This will mean that Marxan can deal with the optimisation of issues such as: species viability, species demographic objectives (e.g. minimising mortality of migrants), maximising connectivity, and ecosystem services, more flexibly than in the past. These new objectives also enable us to explore trade-off frontiers. Further, we are introducing some new solution methods (algorithmic options), including optimal solutions to the linear programming variant of the spatial planning problem. This enables us to calculate the shadow price of the target for a conservation feature (Kaim et al., this conference). Finally I note that Marxan with Zones enables us to specify multiple action packages in any cell, making Marxan useful for any sort of spatially explicit action planning, such as anti-poacher patrols, invasive species management, grazing management, indeed any regional or national land-use planning, not just reserve system design.

ID197 MARINE AND TERRESTRIAL PROTECTED AREA SYSTEM DESIGN IN AUSTRALIA: SUCCESSES AND FAILURES

Hugh Possingham

The University of Queensland
Alienor CHAUVENET, The University of Queensland ; Vanessa ADAMS, The University of Queensland ; Kerrie WILSON, The University of Queensland ; Jennifer MCGOWAN, The University of Queensland ; Lissa BARR, The University of Queensland ; Richard FULLER, The University of Queensland ; James WATSON, The University of Queensland ; Oscar VENTER, The University of Queensland

“The National Reserve System is underpinned by a scientific framework to ensure that Australia progressively extends protection to examples of all our ecosystems. The scientific framework has a clear objective: to develop a ‘comprehensive, adequate and representative’ system of protected areas - commonly referred to as the ‘CAR’ reserve system.” This represents a clear statement of intent by the Australian government for over a decade. But given that intent, how well has Australia done in efficiently constructing a ‘CAR’ reserve system. Our analysis suggests that a focus on representation has delivered clear dividends over the past decade on the land – although land-based acquisition has stalled through lack of funds. That said, management is inadequate and major gaps in the reserve system remain. Australia’s marine protected areas system designations represent some of the worst, and the very best global examples of protected area system design. The rezoning of the Great Barrier Reef is a shining example of efficient representation of conservation features, as is the South Australian state marine reserve system. However the rezoning

of many commonwealth regions is very poor, especially in the south-east and north, because of a failure to use, or properly use, systematic conservation planning tools. Sadly there is often a failure to openly acknowledge what has, and has not, worked. Our analyses uses a new metric - "protection equality" - to assess representation. We argue that this metric should be a new global standard that sits alongside total fraction protected as a measure of conservation success. Much can be learnt from Australia's successes and failures.

OPTIMAL CONSERVATION OUTCOMES REQUIRE BOTH RESTORATION AND PROTECTION

Hugh Possingham

The University of Queensland

Michael BODE, The University of Melbourne ; Carissa KLEIN, The University of Queensland

Conservation outcomes are principally achieved through the protection of intact habitat or the restoration of degraded habitat. Restoration is generally considered a lower priority action than protection because protection is thought to provide superior outcomes, at lower costs, without the time delay required for restoration. Yet while it is broadly accepted that protected intact habitat safeguards more biodiversity and generates greater ecosystem services per unit area than restored habitat, conservation lacks a theory that can coherently compare the relative outcomes of the two actions. We use a dynamic landscape model to integrate these two actions into a unified conservation theory of protection and restoration. Using nonlinear benefit functions, we show that both actions are crucial components of a conservation strategy that seeks to optimise either biodiversity conservation or ecosystem services provision. In contrast to conservation orthodoxy, in some circumstances, restoration should be strongly preferred to protection. The relative priority of protection and restoration depends on their costs and also on the different time lags that are inherent to both protection and restoration. We derive a simple and easy-to-interpret heuristic that integrates these factors into a single equation that applies equally to biodiversity conservation and ecosystem service objectives. We use two examples to illustrate the theory: bird conservation in tropical rainforests and coastal defence provided by mangrove forests.

ASSESSING AT-RISK STATUS OF ATHABASCA RIVER RAINBOW TROUT WITH LOTS OF POOR RESOLUTION CATCH DATA

John Robert Post

University of Calgary

Hillary WARD, University of Calgary ; Eric TAYLOR, University of British Columbia ; George STERLING, Alberta Environment and Sustainable Resource Development

In most systems, there is usually not sufficient information to develop accurate predictions for assessing the rate of population change for a species across a wide spatial scale. However, managers and policy makers must be able to estimate demographic statistics and understand how uncertainty in the data affects uncertainty in policy advice. We use a system (Athabasca River Rainbow Trout) as an example of how uncertainty in demographic rates of change can be better included in policy making, with a specific focus on the quantitative criteria used by the Committee on the Status of Endangered Wildlife in Canada (COSEWIC). Athabasca river rainbow trout are one of the only native rainbow trout populations east of the continental divide and populations in this drainage are at reduced abundances due to natural low productivity, introgression with hatchery fish, competition with non-native species, habitat degradation from resource extraction and historical overfishing.

QUANTIFYING POPULATION RECOVERY AFTER FOREST FIRES: A MULTI-METHODOLOGICAL APPROACH

Dominique Potvin

University of Helsinki

Kirsten PARRIS, University of Melbourne ; Katie SMITH, Museum Victoria ; Jane MELVILLE, Museum Victoria

Sampling animals in the wild in order to make population-wide estimates is a task fraught with difficulty. Studies have shown that using multiple sampling methods can be beneficial, especially if such methods are complementary. This approach not only increases accuracy, for example when making calculations regarding population size, but can also provide additional information useful in population viability analyses, or estimations of population recovery. We demonstrate a case study where we used multiple sampling methods to quantify the recovery of frog metapopulations in the years following the devastating 2009 bushfires in South-eastern Australia. In particular, we demonstrate how using a combination of direct hand-capturing, acoustic sampling and genetic sampling can contribute to creating a more informed and useful assessment of species' recovery after a significant natural disaster.

BEHAVIOURAL CHANGES IN HIMALAYAN MARMOTS IN RELATION TO HUMAN ACTIVITIES ASSOCIATED WITH TRADITIONAL PASTORALISM

Buddi Poudel

Institute for Land, Water and Society

Peter SPOONER, *Institute for Land, Water and Society*; Alison MATTHEWS, *Institute for Land, Water and Society*

The Trans-Himalayas is among the world's largest pastoral ecosystems and has a long history of pastoralism. Climate change is predicted to enhance opportunities for high altitude rangeland grazing, however there is a paucity of information of potential conflict between human activities and local wildlife. We studied the behaviour of the Himalayan marmot, a common rodent that co-occurs in areas grazed by domestic livestock. In 2014, we used instantaneous scan and focal animal sampling methods to observe marmot behaviours at 30 sites located in the Upper Mustang region of Annapurna Conservation Area, Nepal. An index of pastoralism intensity, based on the presence of livestock, herders, guard dogs, distance from pastoralist camps, and density of major tracks was developed to compare marmot behaviour between high and low pastoralism sites. Using a linear mixed modeling approach, we found that the vigilance behaviour of marmots was significantly influenced by pastoralism. Marmots looked up more often and devoted more time in vigilance in areas of high pastoralism as compared to low pastoralism. Marmots also adjusted their diurnal patterns of activity (temporal niche adjustment), and the distances moved from their burrows, in relation to the timing of pastoralist activities. In general, marmots were less active and foraged near to the burrows during periods of high risk when livestock and their herders were in the vicinity, but compensated by increasing activity and foraging further away from their burrows when pastoralist activity was less. These results suggest marmot experience increased wariness and fearfulness when pastoralist are near, which in turn, may reduce their fitness in terms of decreased opportunities to forage and fatten for winter hibernation. These changes in marmot behaviour could have important ecological ramifications in relation to predicted expansion of pastoralism in the region and associated likely increases in human-wildlife conflict.

110 TREE CHIEFS OF NORTHERN GHANA: CAN LOCAL RESOURCE GOVERNANCE INSTITUTIONS HELP SOLVE GLOBAL ENVIRONMENTAL PROBLEMS?

Mahesh Poudyal
Bangor University

Agroforestry parklands are one of the main features of the landscape in West African savannas where mature trees of a few economic species occur scattered across the cultivated fields or fallows. These trees form a vital part of the socio-ecological systems providing not only material benefits to the local inhabitants, but also help in improving soil fertility, moisture retention and in reduction of erosion. Recent studies have suggested that these trees could be vital in the retention

of carbon in these parklands, a service that could be exploited for the benefits of the local population through mechanisms such as REDD+. The appropriation of economic and other benefits from these trees in the parklands, however, depends in large part on the institutional arrangements in place - such as various tenure regimes. In many parts of the rural West Africa, resources such as land and trees are still managed under the traditional institutional arrangements, often referred to as the customary laws. One of these traditional systems is the separability of land and tree tenures whereby rights over a parcel of land does not necessarily guarantee the rights over the trees on that land. Indeed tree tenure systems are often just as complex, a case highlighted by the special tenure arrangements for locust bean trees (*Parkia biglobosa*) - including chiefs for these trees among many ethnic groups. Field studies in Northern Ghana have shown that tree tenure arrangements could have significant impacts not just on how indigenous economic trees are exploited, but also how they are managed, ultimately impacting on the environmental conditions of the parklands. Using this unique case as an example, I discuss if and how local resource governance institutions can contribute to solving environmental problems - local and global.

SYMPOSIUM #90: INDIRECT EFFECTS OF MOSQUITO CONTROL ON THE NON-TARGET FAUNA IN THE CAMARGUE

Brigitte Poulin

Tour du Valat Research Center

Gaëtan LEFEBVRE, Tour du Valat Research Center; Laurence DESPRÉS, Laboratoire d'Ecologie Alpine, LECA-UMR 5553, Université de Grenoble 1; Christiane JAKOB, Libelo; Claire TÉTREL, Parc Naturel Régional de Camargue

Bacillus thuringiensis var. *israelensis* (Bti) is the most commonly used agent to control mosquitoes worldwide. This soil-dwelling bacteria is considered non-toxic to most organisms, at the exception of non-biting-midges (chironomids), a major prey item in wetland food webs. Yet, few studies have addressed the indirect effects of Bti through trophic interactions. This topic was addressed within a control program encompassing 2500 of the 25,000 ha of mosquito larval biotopes in the Camargue. Since 2006, Bti spraying occurs whenever *Aedes* larvae appear in water bodies, totaling 30-60 aerial treatments annually. Various impact studies were implemented, being systematically based on the comparison of treated and untreated areas. A detailed investigation on breeding colonies of house martins revealed a shift in chick diet with less nematoceraans, spiders and dragonflies taken in treated areas, translating into a 33% decrease in breeding success and a 26% decrease in colony size at treated sites. Likewise, reed-dwelling invertebrates serving as food to passerines suffer a 34% decrease, while richness and abundance of Odonata is reduced by 50%. Comparison of

long term trends in water bird and passerine counts revealed a significant decline in 11 species amongst the most abundant, not observed at untreated sites. These multi-trophic impacts suggest a strong dependence of the non-target fauna on Bti-sensitive prey, while the observed persistence and proliferation of Bti spores in some marshes (up to 8 500 000 spores per gram of soil) suggests impacts on chironomids well extending the period of Bti spraying. Efficiency of alternative techniques to reduce mosquito nuisance adapted to the specific context of the Camargue (ie. small villages surrounded by wetlands covering large areas) are currently being tested. These include mosquito trapping in inhabited areas and increased awareness of wetland managers to reduce unintentional production of mosquitoes.

SEARCHING FOR HOTSPOTS WITHIN A HOTSPOT: STACKED SPECIES DISTRIBUTION MODELS PROVIDE NEW OPPORTUNITIES TO MAP SPECIES RICHNESS IN NEW CALEDONIA

Robin Pouteau

Institut Agronomique Néo-Calédonien (IAC)
Elise BAYLE, Institut de Recherche pour le Développement (IRD) ; Elodie BLANCHARD, Institut Agronomique Néo-Calédonien (IAC) ; Philippe BIRNBAUM, Institut Agronomique Néo-Calédonien (IAC) ; Jean-Jerome CASSAN, Province Nord ; Vanessa HEQUET, Institut de Recherche pour le Développement (IRD) ; Thomas IBANEZ, Institut Agronomique Néo-Calédonien (IAC) ; Herve VANDROT, Institut Agronomique Néo-Calédonien (IAC)

A critical prerequisite to implement efficient conservation actions in biodiversity hotspots is to understand how biodiversity varies in space. Stacked species distribution models (S-SDMs) provide new opportunities to describe patterns of species richness (α -diversity). In previous attempts to map richness through S-SDM, the accuracy of the method was assessed using global metrics. Here, we ask whether the reliability of S-SDMs varies along environmental gradients. We used an S-SDM to predict tree species richness in rainforests of New Caledonia (South-West Pacific Ocean). We built an individual MAXENT model for 743 species combining eight fine-scale environmental variables with c. 10,000 occurrence records derived from herbarium collections and plot inventories. For each species, a distribution map was produced at a 100 m-scale indicating the suitability of each site. All models were then summed up and we compared the resulting richness estimates with the number of species measured in independent one hectare inventories. Overall, we noticed that the S-SDM increasingly overestimated richness as elevation increased. We demonstrated that this pattern stems from two features related to mountain morphology that S-SDMs disregard: (1) the conical shape of mountains provides

a decreasing area at increasing elevation which influences the regional pool of species found in elevational bands; (2) the connectivity of mountain habitats ('sky islands') decreases at increasing elevation which affects the equilibrium between species and their environment, and exacerbates commission errors. Despite remaining difficulties to predict richness when accounting for the effect of mountain morphology, our findings represent a significant step forward towards improved S-SDM designing.

INTERSPECIFIC COMPETITION BETWEEN RESIDENT AND MIGRANT BIRDS IN JAMAICAN MANGROVE FORESTS: EVIDENCE FROM A REMOVAL EXPERIMENT

Luke Powell

Smithsonian Migratory Bird Center
Nathan COOPER, Smithsonian Migratory Bird Center ; Peter MARRA, Smithsonian Migratory Bird Center

Every autumn, billions of migratory songbirds depart North America for the Neotropics, where they spend ~7 months wintering alongside ecologically similar year-round residents. In the Caribbean, the winter influx of migrants coincides with low arthropod abundances, and food shortages limit wintering songbird populations. Despite recent progress, the question remains: how do so many ecologically similar migrants and residents coexist during the most resource-poor time of year? Here we test the hypothesis that interspecific competition exists between resident Yellow Warblers (*Setophaga petechia*; hereafter "yellows") and wintering American Redstarts (*Setophaga ruticilla*). We performed two experiments in Jamaican mangrove forests: 1) a removal experiment in which we 3D-mapped yellow territories (n = 14) and overlapping redstart territories (n = 24) before and after removal of yellows, and 2) a natural experiment in which we compared redstart presence with and without territorial yellows (n = 10 territories). In the removal experiment, male redstarts expanded their 3D space use into the core of the (vacated) yellows; female redstarts moved away from the core yellow territory—probably due to intraspecific competition from males. In the natural experiment, when the yellows were on the opposite sides of their territories from redstarts (i.e. absent) redstarts were 2.3 times more likely to be present than when yellows were present, indicating that yellows constantly but temporarily exclude redstarts from space. The relentless aggression of larger yellows towards smaller redstarts almost certainly denies redstarts access to otherwise obtainable resources: space and insect prey. Only by understanding interspecific competition between migrant and resident birds can we quantify the challenges that migrants face throughout the annual cycle.

DO PRIMARY FOREST PARKS IN CENTRAL AFRICA PROTECT RAINFOREST BIRD COMMUNITIES BETTER THAN UNPROTECTED SECONDARY FORESTS? AN EXPLORATION, EDUCATION AND ECOLOGY PROJECT FROM THE EQUATORIAL GUINEA BIRD INITIATIVE.

Luke Powell

Smithsonian Migratory Bird Center

Jared WOLFE, US Forest Service, Redwood Sciences Lab ; Jacob COOPER, University of Kansas

Equatorial Guinea is a small, poorly explored Central African nation along the Gulf of Guinea. With the highest GDP per capita in Africa, Equatorial Guinea is developing quickly, with major highways now crisscrossing primary forests. In December 2014, The Equatorial Guinea Bird Initiative conducted our second expedition with three primary objectives: 1) exploration: work towards completing a country list of bird species, 2) education: train local biologists to do ornithology and, 3) ecology: determine how primary and secondary forest bird communities differ. First, we documented the first country records of 8 bird species—all on the mainland. Second, we trained two government biological technicians and four university students on basic ornithological techniques, including the safe capture of birds using mist nets. Third, we spent eight days capturing and surveying birds in Altos de Nsork National Park with the goal of understanding differences in the avian community between primary and 15-20 year-old secondary forests. Primary forest communities were more diverse (Chao II estimate = 94 species) and had more specialized forest interior species. Secondary forests were less even and less diverse (Chao II estimate = 74 species), with captures dominated by the generalist species Western Olive Sunbird (*Cyanomitra obscura*) and Yellow-whiskered Greenbul (*Eurillas latirostris*). During audiovisual surveys, we detected 24 species in primary forest that we did not detect in secondary forest, highlighted by Lesser Bristlebill (*Bleda notatus*; n=10). The prevalence of this species and others in primary but not secondary forest suggests that they can be used as indicators of intact primary forest bird communities, thus giving local biologists a tool with which to quantify the quality of forest. Only by continuing a campaign of education, exploration and ecology can we hope to protect rainforest wildlife in this Central African nation during this critical period in its history.

DEVELOPMENT AND APPLICATION OF A SPATIAL IBM TO FORECAST GREATER PRAIRIE-CHICKEN POPULATION RESPONSES TO LAND USE IN THE FLINT HILLS REGION OF KANSAS

Breanna Powers

U.S. Environmental Protection Agency

Nathan SCHUMAKER, U.S. Environmental Protection Agency

Greater prairie-chicken (*Tympanachus cupido*) populations have been on the decline for decades. Recent efforts to reverse this trend are focusing on two specific disturbance regimes, cattle grazing and field burning, both prevalent in the Flint Hill region of Kansas -- an area of critical prairie-chicken habitat. Field burning and grazing are necessary for arresting the transition of prairies into shrublands and forests, but fire application (frequency and timing) is managed to optimize livestock production, and thus may not be ideal for prairie-chicken preservation. Not surprisingly, it is completely infeasible to perform real-world tests that might quantify the relationship between fire management and prairie-chicken population trends at large spatial scales. We addressed this constraint by developing a spatial IBM (individual-based model) capable of forecasting prairie chicken population trends and their responses to multiple interacting disturbance regimes. Here, we report on our initial results from this work, in which we have examined how sensitive prairie chicken population trends are to changes in landscape structure.

LOOKING FOR (THE ORIGIN OF) HEC IN THE OKAVANGO DELTA

Rocío Pozo

University of Oxford[INSTITUTE]Ecoexist Project, Botswana
Anna SONGHURST, Ecoexist Project, Botswana[INSTITUTE] University of Oxford ; Graham MCCULLOCH, Ecoexist Project, Botswana[INSTITUTE] University of Oxford ; Amanda STRONZA, Ecoexist Project, Botswana[INSTITUTE] Texas A&M University, Applied Biodiversity Sciences ; Tim COULSON, University of Oxford

In Botswana's Okavango Delta panhandle, fifteen thousand people share and compete for resources with a population of more than fifteen thousand African elephants (*Loxodonta africana*). Unsurprisingly, this area represents a real hotspot for human-elephant conflict (HEC), which manifests itself in the form of elephant crop-raiding (i.e. the destruction and damage to crops). Using historical data on human and elephant population size, as well as on allocation of agricultural land collected over the past 40 years, we first assess the likely drivers of human-elephant conflict in the eastern Okavango Panhandle. We then evaluate trends in the level of conflict over the last seven years when mitigation strategies were put in place by our project. We find that human and elephant population sizes have been growing exponentially and logistically, respectively, and that the land allocated to human activities across the study area has also been increasing steadily. In the absence of mitigation, we therefore predicted an increase in HEC in recent years. Surprisingly, however, we find that the level of HEC has been decreasing over the past seven years. We discuss these results in terms of recent

mitigation strategies, changes in elephant spatial behaviour and environmental factors.

UNDERSTANDING WILDLIFE-PEOPLE INTERACTIONS THROUGH MULTIDISCIPLINARY APPROACHES FOR APPROPRIATE PATHWAYS TO CONSERVATION IN THE DARJEELING HIMALAYAS, INDIA

Sunita Pradhan

ASHOKA TRUST FOR RESEARCH IN ECOLOGY AND THE ENVIRONMENT

Sarala KHALING, ASHOKA TRUST FOR RESEARCH IN ECOLOGY AND THE ENVIRONMENT; T GANESH, ASHOKA TRUST FOR RESEARCH IN ECOLOGY AND THE ENVIRONMENT; Sanjay NEPAL, UNIVERSITY OF WATERLOO; Vincent VON DOSKY, UNIVERSITY OF HEIDELBERG; Shekhar BHUJEL, ASHOKA TRUST FOR RESEARCH IN ECOLOGY AND THE ENVIRONMENT

Darjeeling Himalayas is a significant bio-geographic link between Nepal, Indian state of Sikkim and Bhutan extending into Assam and Arunachal Pradesh of North east India in the biodiversity hotspot of the Eastern Himalaya. Darjeeling, with an indicated forest cover of 40 percent of its geographical area (3149 sq km), has icon species such as the globally threatened Rufous-necked Hornbill (*Aceros nipalensis*) along with four other hornbill species, the critically endangered Chinese Pangolin (*Manis pentadactyla*), and the vulnerable Red panda (*Ailurus fulgens*), indicating the conservation significance of this region. Even though the region is a global biodiversity hotspot, the linkages and interactions among cultural, social and natural elements are poorly understood in context of biodiversity conservation. Hence Ashoka Trust for Research in Ecology and the Environment (ATREE) in an effort to fill this gap in knowledge, has taken up initiatives on Red panda conservation and tourism in the Subalpine Conifer forests, Chinese pangolin in the inadequately protected Areas Outside Protected Areas of Tea plantations in Darjeeling and dietary use of wild fruit resources by the local communities and the hornbills in the Subtropical lowland forests of Darjeeling Himalayas, to better understand wildlife-people interactions and linkages with the existing social elements. These initiatives are an attempt to understand and analyse aspects of nature-society relationships to seek pathways to conservation and sustainable use of forest resources in these regions, which supports 1.85 million people with recorded poverty rate of 56 percent - highest in the entire Indian Himalayas. Preliminary findings and appropriate interventions being taken up, from these initiatives are presented and discussed here.

PROTECTING THE FRAGMENTS - AN ANALYSIS OF MANDARIN ORANGE AND POLLINATOR DEPENDENCE ON FRAGMENTED FOREST PATCHES IN SIKKIM, EASTERN HIMALAYAS

Urbashi Pradhan

Ashoka Trust for Research in Ecology and the Environment(ATREE)

Soubadra DEVY M, Ashoka Trust for Research in Ecology and the Environment(ATREE)

In the Himalayan state of Sikkim 50% of total forest area is fragmented lying outside protected area network in dynamic human dominated landscape. We take an interdisciplinary approach in understanding the role of these fragments in provisioning pollination service and its impact on socioeconomic welfare of farmers in Sikkim. Detailed RS/GIS method was used to study landscape composition in orange belt of Sikkim. Result shows various landscape matrices determine the rate of pollinator visitation to mandarin oranges, the major cash crop of Sikkim. Manual pollination treatment shows increase in fruit set number by four times, highlighting importance of pollinators and pollination service to Sikkim mandarin oranges. Our vegetation sampling shows that forest patches in the vicinity act as resource reservoir for pollinators during non orange flowering season and help sustain pollinator population in the landscape. Therefore, pollination service has direct impact on the income of famers in Sikkim which surprisingly is less perceived by them. Open pollination resulted in fruit set similar to pollinator exclusion treatment which hints at a possible dearth of pollinators for mandarin oranges. This issue needs attention especially considering the decreasing number of pollinators worldwide. Pollinator composition shows drastic change with increase in elevation. Lower altitude orange belt is dominated by 80% of *Apis cerana* visitation but high altitude belt shows more Dipterans. As a policy intervention to increase yield of oranges, installation of domesticated honey bee boxes may be an option to compensate for lower pollinator visitation in the lower belt. But the only way to sustain viable Dipteran population in the upper belt is by conserving its habitat, which are fragmented forest patches along with the matrix in human dominated landscape. We discuss management measures that can be taken in a lived-in landscape like Sikkim Eastern Himalayan Biodiversity Hotspot.

3.09 MOLLUSKS ASSEMBLE DIVERSITY IN THREE LANDSCAPE UNITS OF DRY FOREST WITH DIFFERENT LEVELS OF TRANSFORMATION IN THE VALLE DEL MAGDALENA IN VICTORIA AND LA DORADA (CALDAS-COLOMBIA)

Angélica Prado-Ospina

Universidad del Valle

Alan GIRALDO, Universidad del Valle ; Wilmar BOLIVAR, Universidad del Valle ; Jaime CANTERA-KINTZ, Universidad del Valle

The dry forest in Colombia has lost its vegetation cover at an accelerated rate, being heavily transformed and fragmented. In the remnants, the flora, insects and some vertebrate groups have been intensively studied; however, the knowledge regarding mollusks inhabiting this ecosystem is scarce. The ecological attributes of the mollusks' assemblage, may be significantly affected by the transformation of the dry forest. This research describes the taxonomic composition of the mollusks' assemblage in three dry forests with different degrees of transformation located in the municipalities of La Victoria and La Dorada, Caldas: natural secondary forest succession (BSSN), intervened forest for silvopastures-livestock operations (BSSG), and forest intervened for mining activities (BSIM). Systematic sampling was conducted during the first rainy season and the second dry season of the year, taking records of temperature, relative humidity, soil humidity, luminosity, altitude and vegetation cover. 120 parcels were checked, at each parcel, two quadrats of 50 x 50cm were used to remove leaf litter and soil. 678 specimens belonging to 32 species were collected, of which 55% were associated to BSSN, 40% to BSSG and 5% to BSIM. The highest species richness (30 sp) was recorded in the BSSN, followed by the BSSG (8 sp) and the BSIM (4 sp). Despite the high temperature and low humidity conditions in the study area, the presence of tree cover in the BSSN provides suitable microhabitats for the presence of mollusks. According to the results, processes of transformation of dry forest involving a reduction in tree cover causes a significant reduction in the diversity of mollusks assemble in this ecosystem.

FOOD-WEB MODELLING: A POSSIBLE ECOSYSTEM MANAGEMENT TOOL FOR MEDITERRANEAN MPAS?

Giulia Prato

Université de Nice Sophia Antipolis
Celine BARRIER, Université de Nice Sophia Antipolis ; Jean-Michel COTTALORDA, Université de Nice Sophia Antipolis ; Vasiliki MARKANTONATOU, Università politecnica delle marche ; Valentina CAPPANERA, Area marina Protetta di Portofino ; Patrice FRANCOUR, Université de Nice Sophia Antipolis ; Didier GASCUEL, Agrocampus Rennes

Mediterranean coastal ecosystems support a great diversity of habitats, species and communities, being a major challenge for an ecosystem management approach. In particular, management of Marine Protected Areas should be informed about the possible effects of protection on often complex food-webs. The application of food-web modelling through the Ecopath with Ecosim software (EwE) may allow to unravel

such a complexity and could thus help to better pursue the conservation and management objectives of Mediterranean MPAs. Unfortunately, whilst widely applied at larger ecosystem scales where the presence of industrial fisheries allows for large data availability, EwE has not yet gained full attention as a possible tool for the management of smaller and highly diverse coastal areas. Main drawback is the difficulty of obtaining local biomass data for all functional groups in such areas. Here we propose a standardized and simplified model structure developed for Port-Cros MPA (France) and present its application in two case-studies that are well representative of Mediterranean data availability: the relatively well-studied Portofino MPA (Italy), where available local biomass data was used; the poorly studied Cap Roux fishery reserve (France), where biomass data was collected in the field. We show that using a standardized model strongly reduces the data requirement and the time spent for model building and allows for comparisons between ecosystems. We identify the possible management applications of such tool, focusing in particular on indices useful for the monitoring of ecosystem functioning and on the assessment of the ecosystem impacts of multiple and interacting fisheries. We conclude that this standardized approach could provide a well-defined framework for integrating available (but often dispersed) data on Mediterranean coastal ecosystems into a coherent picture of ecosystem functioning, allowing also to identify important monitoring gaps.

21-UBUNTU AND THE BALANCING OF DIVERSE ENVIRONMENTAL ETHICS AND VALUES TO ACHIEVE ENVIRONMENTAL JUSTICE IN THE MAASAI MARA, KENYA

Francisca Pretorius

Strathmore University
Jeffrey SU, Plains Conservation Center

Justice, as a moral and philosophical concept, is rooted in fairness. Depending on the desired goal, justice is meted out in four different ways: retributively (fairness in punishment), restoratively (fairness in correction), distributively (fairness in equal distribution), or procedurally (fairness in just process). Environmental justice, being the intersection between human rights, the environment, and the equitable access the resources people need to survive, constitutes a complex set of ethics and values. To fully explore environmental justice we must recognize the often competing environmental ethics and values of the constituents in an environmental conflict. These values can be broadly defined by the philosophies and work of John Muir (preservationist), Gifford Pinchot (conservationist) and Aldo Leopold (ecological). We contend that environmental justice can only be achieved by striking a balance between these concepts of justice and competing environmental values. We apply the uniquely African concept of justice, "Ubuntu",

to demonstrate the balancing of these complexities in the Maasai Mara, Kenya. We specifically examine the challenges of the competing needs of a thriving wildlife-tourism industry, the semi-nomadic pastoralist lifestyle of the Maasai tribe and the preservation of the increasingly fragile ecosystem of the Mara region. We demonstrate how these challenges can be successfully addressed through private conservancies that combine community-based agriculture, sustainable livestock enterprises and private land conservancy to effectively preserve wildlife (preservationist), the rich Maasai heritage (conservationist) as well as the ecosystem of the Mara region (ecological). We show the importance of understanding the diversity of environmental ethics and values, underpinned by the different concepts of justice, to find an equitable solution for competing needs and rights of interested parties, ensuring that justice is attained for all involved.

HOW FAST ARE THEY REALLY MOVING?

Sonja Preuss

Swedish University of Agricultural Sciences
*Matthew LOW, Swedish University of Agricultural Sciences ;
Anna CASSEL-LUNDHAGEN, Swedish University of Agricultural
Sciences ; Åsa Berggren, Swedish University of Agricultural
Sciences*

Species range shifts associated with environmental change or biological invasions are increasingly important study areas. However, quantifying range expansion rates may be heavily influenced by methodology and/or sampling bias. We compared expansion rate estimates of Roesel's bush-cricket (*Metrioptera roeselii*) a nonnative species currently expanding its range in southcentral Sweden, from range statistic models based on distance measures (mean, median, 95th gamma quantile, marginal mean, maximum, and conditional maximum) and an area-based method (grid occupancy). We used sampling simulations to determine the sensitivity of the different methods to incomplete sampling across the species' range. For periods when we had comprehensive survey data, range expansion estimates clustered into two groups: (1) those calculated from range margin statistics (gamma, marginal mean, maximum and conditional maximum: 3 km/year), and (2) those calculated from the central tendency (mean and median) and the area-based method of grid occupancy (1.5 km/year). Range statistic measures differed greatly in their sensitivity to sampling effort; the proportion of sampling required to achieve an estimate within 10% of the true value ranged from 0.17 to 0.9. Grid occupancy and median were most sensitive to sampling effort and the maximum and gamma quantile the least. If periods with incomplete sampling were included in the range expansion calculations, this generally lowered the estimates (range 16-72%). Care should be taken when interpreting rate expansion estimates from data sampled from only a fraction of the full distribution. Methods based on

the central tendency will give rates approximately half that of methods based on the range margin. The gamma quantile method appears to be the most robust to incomplete sampling bias and should be considered as the method of choice when sampling the entire distribution is not possible.

ENVIRONMENTAL CONCERN IS NOT MEDIATED BY UNIVERSITY EDUCATION

Anne-Caroline Prevot

Museum National d'Histoire Naturelle
*Susan CLAYTON, College of Wooster ; Raphael MATHEVET,
CEFE-CNRS*

In the current biodiversity crisis, increasing individual awareness of conservation issues becomes of prominent importance. Education is proposed as an important way to increase environmental concern by many authors and conservationists. In this study, we explored the relative roles of environmental education at university, personal experiences of nature and social identity on the level of individual environmental identity (EID), which is an important component of environmental concern. Environmental identity is a stable sense of oneself as connected to the natural world, and has been found to predict a wide range of environmental attitudes and behavior. To study its correlates, we proposed a questionnaire to more than 1200 students in different academic curriculum in France (ecology, other sciences and political sciences). We showed significant difference in levels of EID for students in ecology compared to others (students in political sciences having the lowest level), but also that EID was strongly influenced by personal experiences of nature and social context regarding conservation. Our results suggest therefore that academic curriculum is more a result than a cause for high environment identity. We discuss these results in terms of education and access to nature for children and young people

SYMP97-SHORT AND LONG TERM CONSEQUENCES OF URBAN CITIZEN-SCIENCE PROJECTS TO INDIVIDUAL CONNECTION TO NATURE

Anne-Caroline Prevot

Museum National d'Histoire Naturelle

Citizen science programs are first devoted to collect large amounts of data on large temporal and spatial scales, in order to survey biodiversity dynamics. The second objective of these participative observatories is however to encourage laypeople to interact with nature, in order to increase individual awareness on biodiversity and conservation issues. In this presentation, I present two studies that tested the consequences of participation on individual relation to nature. These studies were conducted in France, in the Vigie-Nature

program. First, we showed with a conservation psychology approach that 10-11 year old pupils which conducted a very short citizen-science program at school have a different way to represent ordinary nature than pupils that did not have this experience. Secondly, we showed with an anthropological approach that adult volunteers that surveyed butterflies in their garden during several years did change their relations and practices towards their garden. I discuss these results in terms of individual connection to nature.

THREATENED SPECIES CONSERVATION: CHALLENGES AND OPPORTUNITIES FOR FLAGSHIP TREES

Victoria Price

Fauna & Flora International/Global Trees Campaign
David GILL, Fauna & Flora International/Global Trees Campaign ; Georgina MAGIN, Fauna & Flora International/Global Trees Campaign

Halting the loss of threatened species is a major priority for the conservation community and was highlighted as an area for action under Aichi target 12. The challenge is of particular relevance to the world's tree species, of which more than 9,000 are threatened with extinction. This is despite the key ecological role played by many tree species and the goods, services and cultural values they provide. In addition to habitat loss, exploitation and climate change, increasing action for threatened trees faces a number of challenges. Firstly, there is a lack of information on tree species themselves. For example, 100% of the world's known bird species have been assessed on the IUCN Red List, but merely 12% of trees have been assessed under the same criteria. Secondly, there is insufficient awareness of the need for species specific tree conservation, and finally, so few organisations currently integrate tree conservation into habitat management strategies. This talk will explore whether the current pace of tree conservation is moving rapidly enough to keep up with the scale of the threats. There are opportunities to tackle these challenges, and upscale intervention efforts including; exploiting open source data to rapidly increase assessment effort, sharing skills through multi-disciplinary, regional networks and embedding threatened tree conservation into widely practised landscape approaches. Using case studies from our various field sites and activities across the globe, the Global Trees Campaign (GTC) will showcase examples of practical interventions to both address these challenges and exploit the identified opportunities. Recommendations will be made for embedding a species based approach to tree conservation into existing programmes and, into the wider conservation rationale.

THE IMPORTANCE OF CONSERVATION MANAGEMENT FOR LAKE OHRID TROUT

Viola Prifti

University of Korça
Arefi CAKE, University "A.Xhuvani",

In the past, trout and other fish introductions were made primarily by federal and state management agencies and less commonly through accidental releases and individual enterprises by anglers. Stocking can have a multitude of impacts on aquatic communities and it is conducted for the social and economic benefits provided to anglers and communities. The main purpose of this paper is to describe the importance of conservation management for Lake Ohrid trout. Lake Ohrid trout is an endemic species and very important in the context of cultural heritage for both states, Albania and Macedonia. For several years the increase of its conservation is associated with the social and economic benefits. What about the biological impact in the wild form of the Lake Ohrid trout? In recent years, stocking of trout have been left to persist with individual enterprises. We suggest that these activities should be well supervised by the government. In many cases not professional persons at the same pond made the farmed of similar species. And if the spawning period complies the natural hybridization is a random event. This is a very important point of our study because we think that the main reason of Lake Ohrid trout conservation should be the protection of this endemic specie.

A GENOME-WIDE ASSOCIATION STUDY (GWAS) OF AGE AT MATURITY IN ATLANTIC SALMON: IMPLICATIONS FOR CONSERVATION AND MANAGEMENT

Craig Primmer

University of Turku
Susan JOHNSTON, University of Turku ; Tutku AYKANAT, University of Turku ; Panu ORELL, Natural Resources Institute Finland ; Eero NIEMELÄ, Natural Resources Institute Finland ; Matthew KENT, Centre for Integrative Genomics ; Sigbjorn LIEN, Centre for Integrative Genomics

In wild Atlantic salmon (*Salmo salar*), there is variation in the age at maturity within and between populations, as individuals can spend anywhere between one and five years feeding at sea before returning, often to their natal river, to spawn. The larger, late-maturing 'multi-sea winter' (MSW) individuals are highly sought after by anglers. This life-history strategy has also been shown to be important from a biodiversity perspective, thus creating a management conflict. Knowledge of the genetic basis of age at maturity would provide a foundation for developing effective management strategies for conservation of this important life-history trait. The Atlantic salmon

population of the Teno River in northern Finland is arguably the most biodiverse salmon population in the world from a life history strategy perspective, with more than 100 different life history strategies (combinations of river years, years at sea and repeat spawning) being recorded. It also has immense socioeconomic importance, both due to fishing tourism (15,000 anglers visit this remote region annually) as well as local and indigenous fisheries, with up to 60,000 individuals (60% of the annual run of ascending salmon) caught annually. Alarming, the proportion of late-maturing MSW fish has been declining in recent decades. A long term scale archive combined with the availability of Atlantic salmon SNP arrays provides opportunities for conducting genome-wide association studies (GWAS) to identify genomic regions associated with age at maturity. By implementing genome-wide relatedness information to account for unexpected population structure, we identified several genomic regions harbouring loci significantly associated with age at maturity. The implications of the findings for conducting GWAS in wild populations, as well as for the practical management and conservation of exploited salmon populations will be presented.

165 FROM EVALUATING BIODIVERSITY CONSERVATION TO EVALUATING BIODIVERSITY CONSERVATION POLICY AND ECOSYSTEM SERVICE GOVERNANCE

Eeva Primmer

Finnish Environment Institute

Biodiversity conservation policies are justified with arguments about the intrinsic value of nature and backed up with science. The outcomes are evaluated by tallying extinctions, endangered species as well as the conservation status of species and habitats. As outcomes of habitat and species conservation policies remain disappointing, attention is increasingly placed on broader arguments and broader science. The idea is that a systemic approach to ecosystems must save more ecosystem features and functions. How has this broadening of policy goals and scientific basis of conservation changed conservation policy itself? How have the institutions, processes and practices changed to make use of the new approach? In conserving biodiversity and securing ecosystem services, little empirical attention is paid to ways in which different types of decisions are made, to what arguments are effective in turning policy into practice and into conservation outcomes and, in general, to how ecosystem services are governed. The limited attention to ecosystem service governance is surprising, given the empirical evidence base that the conservation and management analysts have accumulated over the last 50 years. To close this gap, this paper identifies the different modes of governance and incorporates them in a conceptual model of ecosystem services

commonly utilised at present. The conceptual framework encompasses: 1) hierarchical governance; 2) scientific-technical governance; 3) adaptive collaborative governance; and, 4) governing strategic behaviour. This framework provides a structure for empirical analysis of ecosystem services governance, which takes into account the people and organizations making decisions, and the different arguments that are used when implementing policies. The framework will facilitate holistic ecosystem service analyses and support policies in generating conservation and sustainability impact.

ID #188: SALT WATER BARRIERS IN A TROPICAL ESTUARINE SYSTEM: IMPACTS ON BIODIVERSITY AND HUMAN LIFE

Dharma Rajan Priyadarsanan

Ashoka Trust for Research in Ecology and the Environment (ATREE)

Lying below mean sea level, tropical estuaries stand drastically impacted by global warming and salinity ingression. Salt water barriers and flood gates are built extensively throughout to prevent the increasing salt water ingression to agricultural fields on the estuarine flood plains. Vembanad estuary (Kerala, India), a Ramsar site, is the largest humid tropical wetland ecosystem in the south west coast of India. The estuary is fed by six rivers flowing towards west originating from the Western Ghats and forms the lifeline of the villages on its banks. Apart from providing feeding, spawning and rearing areas for a very large proportion of commercial fish and shellfish, this estuary is supporting a highly productive agricultural system also. A barrier was constructed at Thanneermukkam in 1976 to prevent saline water intrusion into paddy fields during the dry season, and thus to bolster paddy cultivation. But the closing of barrier stops the tidal effects, stagnates water movement and hinder the natural mechanism to flush out contaminants. It obstructs the migration of marine species to the upstream areas, the resultant salinity alteration has significantly impacted the breeding of fresh water prawns and clams. We have also noticed a significant spatial relationship between the barrier and the diversity of zooplanktons. Annual fish landing has been reduced to half after the construction of the barrier and has been causing conflicts between fishermen and farmers. This paper discusses the impacts of Thanneermukkam salt water barrier in Vembanad estuary on aquatic biodiversity and human life.

185. MANAGING INTERACTING SPECIES WITHIN FOOD WEBS THROUGH TIME

William Probert

The Pennsylvania State University

Nathalie PEYRARD, INRA ; Regis SABBADIN, INRA ; Eve MCDONALD-MADDEN, The University of Queensland

The study of ecological food webs is useful for gaining insight into optimal management practice. Computational methods for finding optimal management strategies, however, face the challenge of overcoming computational bottlenecks inherent in evaluating all management options that are possible on large food webs that, themselves, may exist in a huge number of different states. To overcome this problem, we investigate the performance of several network metrics from the literature that are easily calculated on large food webs as tools to guide management by ranking species based on metric value. We view ecological food webs as directed acyclic graphs and use Markov decision processes to model management. Using dynamic programming we optimally solve the management of moderately sized food webs through time so as to maximise the expected number of species surviving. We use simulation to compare the performance of managing using several metrics with this optimal solution. For larger food webs, the size of the state and action spaces make dynamic programming computationally infeasible so, at this scale, we extrapolate our results from smaller food webs and investigate the performance of the network metrics for management. Our results show that network metrics which manage the simulated systems well, resulting in high numbers of species surviving, are generally those that highly rank the conservation of predator species. Our analysis illustrates computational techniques that allow management experiments to be performed on food webs of respectable size while using techniques that have been benchmarked against the exactly optimal solution on smaller food webs.

LAND SHARING FOR LAND SPARING: THE CASE OF SOWN BIODIVERSE PASTURES IN MEDITERRANEAN ECOSYSTEMS

Vânia Proença

University of Lisbon

Ricardo F. M. TEIXEIRA, University of Antwerp ; Marjan JONGEN, University of Lisbon ; Tiago DOMINGOS, University of Lisbon

The concept of Sown Biodiverse Permanent Pastures Rich in Legumes (SBPPRL) was initiated in the 1960's as a response to the low productivity and feed quality obtained in semi-natural pastures (SNP) in Portugal. The poor performance of SNP derives from endogenous low fertility and historical land use practices causing soil nutrient mining and erosion but also plant community impoverishment. The SBPPRL system is based on sowing up to 20 species/varieties of legumes and grasses, correcting soil conditions by applying phosphorus and limestone, and adequate grazing management. Seed mixtures are tailored to each site to best cover the available environmental niches and enhance resilience to

environmental variation. Compared to SNP, SBPPRL provide higher quantity and quality of food for animals (without the need for nitrogen fertilizers or annual soil mobilization), permit increasing sustainable stocking rates, and promote soil carbon sequestration through soil organic matter (SOM) increases. Enhanced SOM contributes to control water runoff and soil erosion, and the increased stocking rates contribute to control fire risk. Sustainable intensification has been criticized for narrowing its view towards productivity. However, SBPPRL offer an alternative for sustainable intensification by combining higher pasture productivity, i.e. socio-economic benefits, with environmental benefits that emerge as positive externalities, namely soil carbon sequestration and soil restoration. Also, the use of phosphorus is more than compensated by the avoided impacts of nitrogen fertilizers (otherwise required either to produce concentrate feed or fertilize pastures), while potential leaching of phosphorus is mitigated by increased SOM. Hence, SBPPRL are a land sharing system that combines conservation (e.g. soil restoration) and production goals, and which may enable land sparing due to high productivity.

LANDSCAPE HETEROGENEITY IS CRUCIAL FOR SPECIALIST INTERIOR SPECIES IN ECOLOGICAL NETWORKS

James Stephen Pryke

Stellenbosch University

Landscape ecological networks (ENs) are an important mitigation measure in agriculturally transformed landscapes. Understanding the multitude of pressures influencing the presence/absence of species is important when planning effective ENs. Arthropods are effective bioindicators for measuring these pressures, as many are habitat sensitive. However, in sub-tropical grasslands caution is required, due to a high incidence of singletons (one individual recorded) in sampling regimes. Here we take a multi-taxon approach to determine how a variety of variables influence the spatially sensitive interior species of both EN corridors and adjacent reference sites in protected areas (PAs). At each of the 48 sites selected, nine stations were sampled for arthropods, with six stations in either wooded patch (i.e. plantation block or indigenous forest) or associated edge zone and three stations in EN corridor or PA interior. Eleven variables were measured and classed into environmental, design, and current and historical management variables. Data were split into: the overall data, recording all species found in the interior zones, and datasets containing only species that had more than 50% or 75% of their abundance sampled in the interior zone. These datasets were split into total species and singleton-removed datasets. Overall, species richness of the singleton-removed datasets and assemblage composition were most responsive to the natural background environmental variables,

while the design and management variables were the most important variables for datasets with the singletons included. When planning the ENs within future production landscapes, we first need to conserve the natural range of landscape heterogeneity, especially for the interior specialists. It is important that this spatial heterogeneity is incorporated into design and management planning to maintain the full range of biodiversity.

ROADLESS AREAS IN THE SERVICE OF THE EUROPEAN NATURA 2000 NETWORK

Maria K. Psaralexi

ARISTOTLE UNIVERSITY OF THESSALONIKI

Nefta-Eleftheria P. VOTSI, ARISTOTLE UNIVERSITY OF THESSALONIKI ; Antonios D. MAZARIS, ARISTOTLE UNIVERSITY OF THESSALONIKI ; John D. PANTIS, ARISTOTLE UNIVERSITY OF THESSALONIKI

Road Ecology has indicated transportation network as one of the most prevalent drivers of habitat fragmentation and biodiversity loss. In addition, Conservation Biology, through the establishment of protected areas, attempts to mitigate these detrimental impacts to the natural environment. Roadless Areas (RAs) have recently been identified as important sites to be protected due to their role in providing multiple ecosystem services, protecting biodiversity and offering economic profit. At political level it is of vital importance to investigate the potential complementarity of RAs and European N2K network with view to ensuring biodiversity conservation. Here, we present a Geographical Information System (GIS) methodological approach of broadening the surface of the existing European Natura 2000 network by overlapping RAs. Applying a buffer zone (1 km) around the road network of Europe and excluding these sites from the total surface of Europe, we resulted in RAs. We, then, superimposed Corine Land Cover 2000 database in order to remove any human induced area. The next step comprised the extraction of areas smaller than 100 km². Lastly we investigated the spatial overlap of RAs and Natura 2000 network, giving special attention to adjacent areas. We calculated the spatial intersection, as well as expansion, of adjacent areas of RAs and Natura 2000 network. RAs (18% of Europe) and Natura 2000 network overlapping divulged some interesting findings, showing that countries with the highest percentages of RAs coverage occupy the lowest percentages of roadless Natura 2000 sites. The potential expansion of Natura 2000 network, by appending intersected or tangent RAs, could lead up to a 63% increase of the European Natura 2000 network. Discovering new means of conserving biodiversity -like integrating RAs and Natura 2000 network- in a time-and-cost-effective way, could contribute to a more environment-friendly Europe under a socio-political and economic framework.

INVESTIGATION INTO THE ORIGIN AND IMPACTS OF THE CAUSATIVE AGENT OF WHITE NOSE DISEASE ON BATS

Sébastien Puechmaille

Greifswald University

Marcus FRITZE, Greifswald University ; Stefania LEOPARDI, Royal Veterinary College ; Damer BLAKE, Royal Veterinary College ; Winifred FRICK, University of California ; Marm KILPATRICK, University of California ; Hugo REBELO, University of Porto

White-Nose Disease (WND) is an infectious disease of hibernating bats that has killed millions of bats since it first emerged in eastern North America in 2006. The disease is caused by a pathogenic fungus, *Pseudogymnoascus destructans* that was suspected to be introduced to North America by human trade or travel. We applied eDNA analyses from bat hibernacula to demonstrate the widespread presence of the fungus across Europe and used genetic data from North American (suspected introduced) and European (suspected source) populations of the fungus to confirm the introduced origin of this invasive species in North America. This scenario explains the lack of associated mass mortality among European bats while the naive North American populations are collapsing. To investigate the consequences of the disease on bat populations, we assembled four decades of population counts from 1108 populations to compare the local abundances of bats in North America before and after the emergence of the disease to the situation in Europe, where the disease is endemic. We demonstrate a 10-fold decrease in the abundance of bats at hibernacula in North America, eliminating large differences in species abundance patterns that existed between Europe and North America prior to disease emergence. We also document extensive local extinction in many species in North America. As the fungus range is still expanding year after year in North America, we used a species distribution modelling technique – maximum entropy modelling – to predict its potential future distribution. Results indicated that the fungus is currently occupying only half of its potential distribution in North America, suggesting that the disease will soon threaten many more bat populations and species. Our results provide insights into the devastating outcome of alien species introductions, and highlight once more the critical need for the application of tighter control of international transfer and trade in biological material.

USING TECHNOLOGY TO IMPROVE COEXISTENCE BETWEEN HUMANS AND KANGAROOS

Melanie Purdy

The University of Technology Sydney

Daniel RAMP, The University of Technology Sydney

Human-wildlife conflict is common where both parties compete for resources. The city of Bathurst in New South Wales is the oldest inland settlement in Australia and has witnessed stark changes in kangaroo abundance since. The last remnant population close to the city persists on Mount Panorama, also home to a car racetrack, shooting ranges, permanent residents, agriculturalists, and a historic goldfields site. This small kangaroo population is largely closed to migration due to the inhospitable nature of the surrounding land. Attempts to reconcile conflicting use of space have been largely implemented through culling and fencing, which resulted in international criticism and tainted the image of the Bathurst 1000 car race on which the local economy relies. To provide new insight into sharing space on the Mountain, we chose to implement a compassionate conservation approach to encourage coexistence with kangaroos. Compassionate conservation promotes the inclusion of individual welfare in conservation practice and thereby reframes how conservation targets are established and envisioned. We installed a range of monitoring technologies to collect information on kangaroo numbers, movement and demography that simultaneously provided the Bathurst community with a means of connecting to individual animals and the population as a whole. We actively involved the community in our research and provided regular online and media reports. Despite entrenched perceptions of conflict and negative attitudes towards kangaroos permeating the Bathurst community, we found broad acceptance for the use of technology to assist with demystifying science and a thirst for overcoming traditionally combative interactions with kangaroos. By collecting cheap, reliable and transparent data we were able to create accurate maps of kangaroo space use to identify the principal areas of human-wildlife conflict. This in turn may be used to establish sustainable and compassionate management strategies.

MULTI-SCALE DISTRIBUTION MODELS FOR CONSERVING WIDESPREAD SPECIES: THE CASE OF SLOTH BEAR IN INDIA

Mahi Puri

Wildlife Conservation Society-India[INSTITUTE]Centre for Wildlife Studies

Arjun SRIVATHSA, Wildlife Conservation Society-India[INSTITUTE]Centre for Wildlife Studies ; Krithi K. KARANTH, Wildlife Conservation Society[INSTITUTE]Centre for Wildlife Studies[INSTITUTE]Nicholas School of Environment ; N. Samba KUMAR, Wildlife Conservation Society-India[INSTITUTE]Centre for Wildlife Studies ; Ullas K. KARANTH, Wildlife Conservation Society[INSTITUTE]Centre for Wildlife Studies

Information on patterns and determinants of spatial distributions remains poorly available for many widespread

species of conservation importance. The sloth bear *Melursus ursinus*, in the Indian subcontinent exemplifies this requirement. We aimed at assessing (1) distribution patterns of sloth bears at two spatial scales, (2) ecological and anthropogenic factors that determine bear occupancy. We estimated sloth bear habitat occupancy at a countrywide scale across India and at the landscape scale in the Western Ghats of Karnataka, India. We used a grid-based occupancy approach to determine sloth bear distribution patterns. At the countrywide scale, we used data from questionnaire-surveys of field experts. At the landscape scale, we conducted field surveys of bear signs. Detection/non-detection data from both surveys were analysed using occupancy-modelling methods that account for imperfect detection. Countrywide, sloth bears occupied an estimated 67% of plausible bear habitat in contrast to 46% derived from methods that disregard detectability. Bear distribution was positively influenced by deciduous forests, scrub and barren areas, regions with high human densities and cultural tolerance. At the landscape scale, bears occupied 61% of the area versus 54% estimated from methods ignoring detectability. Occupancy probabilities increased with forest cover and topographic heterogeneity, whereas annual precipitation and human disturbance showed negative effects. Our study underlines the need to integrate human-modified areas with existing conservation landscapes. Given its widespread nature, functional role, conservation status and relatively benign interactions with humans, we propose recognizing sloth bear as an umbrella species for securing unprotected habitats in India. Protection of widespread species like the sloth bear in other landscapes may complement current conservation strategies for large mammalian communities.

REVERSING THE DECLINE OF SHARK POPULATIONS IN RAJA AMPAT, EASTERN INDONESIA

Purwanto Purwanto

The Nature Conservancy[INSTITUTE]Faculty of Fisheries and Marine Science Diponegoro University

Nur Ismu HIDAYAT, Conservation International Indonesia ; Sangeeta MANGUBHAI, Wildlife Conservation Society ; Dheny SETYAWAN, The Nature Conservancy ; Lukas RUMETNA, The Nature Conservancy ; Andreas Hary MULJADI, Coral Triangle Center

The high marine biodiversity and natural beauty of Raja Ampat, Indonesia attracts not only dive tourism, but also outside fishers, who often engage in destructive and illegal fishing, including the targeting of sharks for their economically valuable fins. This is driven by international markets. Indonesia is the number one exporter of sharks and shark products in the world. The local government made several efforts to improve shark conservation in Raja Ampat, including: campaigning about the importance of shark for ecosystem function and economic

benefits through ecotourism; consistently enforcing no-take-zones in the MPA network; implementing an integrated routine surveillance system that includes monitoring shark fishermen activities; and supporting efforts by the Raja Ampat local government to develop regulations that prohibit shark fishing throughout the area's waters. The declaration of 46,108 km² marine areas as a Raja Ampat shark sanctuary in December 2012 was the first of its kind for Indonesia and for the Coral Triangle. Since the declaration of the shark sanctuary, the Indonesian government has been supporting the enforcement of the shark finning ban, with several illegal fishers being caught and prosecuted. Shark populations have been surveyed approximately annually from 2009 to 2014 as part of routine reef fish monitoring. Preliminary results indicate shark populations are already recovering in MPAs since implementation of the shark sanctuary. This is further reinforced by anecdotal evidence from local patrol team observations on the reappearance of juvenile shark populations in several areas. Amidst an overall trend of shark population decline in Indonesia, this shark sanctuary is showing a promising outlook for the recovery of shark populations in Raja Ampat, providing a model for other regions in the Coral Triangle and beyond.

RHINOS IN THE PARKS: OCCURRENCE AND ABUNDANCE INDICES OF THE LAST WILD POPULATIONS OF SUMATRAN RHINOCEROSSES

Wulan Pusparini

WCS

Todd K. FULLER, University of Massachusetts Amherst ; Paul R. SIEVERT, University of Massachusetts Amherst ; Timothy RANDHIR, University of Massachusetts Amherst ; Noviar ANDAYANI, WCS

In the 200 years since the Sumatran rhinoceros was first scientifically described (Fisher 1814), the range of the species has contracted from a broad region in Southeast Asia to three areas on the island of Sumatra, Indonesia. Little information on the factors influencing the distribution of rhinos on Sumatra has been gathered since the study of van Strien's 1986 in the Mamas Valley of the Leuser Landscape. Using a hierarchical modeling approach, we estimated proportion of area occupied (PAO) and indices of abundance (IA) for Sumatran rhinos at the only sites in the world where they are known to occur: Leuser Landscape [2007: PAO = 2.8%, IA = 26 (CI = 12-61)], Way Kambas National Park [2008: PAO = 33.6%, IA = 27 (CI = 14-50)], and Bukit Barisan Selatan National Park [2010: PAO = 36.4%, IA = 31 (CI = 19-66)]. In the Leuser Landscape, rhino PAO was positively associated with primary dry land forest, and rivers, while IA was influenced by deforestation (-), landscape roughness (+), and vegetation indices (+). In Way Kambas, PAO was related to the amount of deforestation (+) and IA was associated with the presence of major roads (-), brush (+), and

savanna (-). In Bukit Barisan Selatan, PAO and IA were both influenced by presence of secondary dryland forest (+), regular roads (+), and deforestation (-). Using the above predictors of PAO and IA, we developed spatially explicit maps that can be used to outline intensive protection zones for in-situ conservation efforts. In addition, reducing deforestation and maintenance of dry land forests in sensitive areas are needed to protect last remaining habitats of Sumatran rhinos.

IMPROVING THE EVIDENCE BASE OF CONSERVATION INTERVENTIONS: WHAT ROLE SHOULD RANDOMISED CONTROL TRIALS HAVE?

Edwin Pynegar

Bangor University

James GIBBONS, Bangor University ; Nigel ASQUITH, Harvard Forest ; Julia JONES, Bangor University

Robust evidence of the effectiveness of socio-ecological conservation interventions (such as agroforestry projects or Payments for Ecosystem Services schemes) is widely considered necessary for improved land management. Randomised Control Trials (RCTs), in which experimental units are randomly allocated to intervention or control groups, are increasingly promoted as a tool for evaluating an intervention's impact. They have received notable recent support from governments and there are number of high-profile examples currently underway, but they are currently not widely used in conservation. Here we use lessons from RCTs' implementation in other fields to examine their potential for more widespread use in conservation. RCTs have a number of advantages as a method of impact evaluation. They offer a straightforward, intuitive means of calculating the average treatment effect of an intervention through establishing a reliable counterfactual, avoid many pitfalls of the commonly used quasi-experimental approach (particularly poor matching between intervention and comparison groups), and the method's clarity is likely to appeal to those aiming to translate evidence into policy. However, there are a number of issues to be considered when designing an RCT which may not be immediately obvious to researchers and practitioners. Randomisation may not always be practical for large-scale interventions, and outcomes may spill over between experimental and control groups. Interventions seeking to change human behaviour may be affected by psychological effects arising from participants knowing they are in an experiment, and often additionally raise ethical dilemmas. The question of the extent to which knowledge obtained from an RCT is relevant to other contexts must also be considered. RCTs must therefore be designed carefully, incorporating knowledge from other fields where their use is established. If this is done they have a key role in evaluating conservation interventions.

MAPPING BUNDLES OF ECOSYSTEM SERVICES REVEALS DISTINCT TYPES OF MULTIFUNCTIONALITY WITHIN A SWEDISH LANDSCAPE

Cibele Queiroz

Stockholm University

Megan MEACHAM, Stockholm Resilience Centre ; Kristina RICHTER, Stockholm Resilience Centre ; Erik ANDERSSON, Stockholm Resilience Centre ; Albert NORSTRÖM, Stockholm Resilience Centre ; Jon NORBERG, Stockholm Resilience Centre ; Garry PETERSON, Stockholm Resilience Centre

Ecosystem services can be a valuable tool to be used in the planning and management of social-ecological landscapes. However, the understanding of the determinant factors affecting the interaction between services in the form of synergies or trade-offs is still limited. We assessed the production of 16 ecosystem services across 62 municipalities in the Norrström drainage basin, Sweden. We combined GIS data with publically available information for quantifying and mapping the distribution of services. Additionally, we calculated the diversity of ecosystem services for each municipality and used correlations and k means clustering analyses to assess the existence bundles of ecosystem services. We found five distinct types of bundles of ecosystem services spatially agglomerated in the landscape that could be explained by regional social and ecological gradients. Human dominated landscapes were highly multifunctional in our study area and urban densely populated areas were hotspots of cultural services.

GLACIER RETREAT EFFECT ON PEAT LAND POOL METACOMMUNITIES IN THE HIGH BOLIVIAN ANDES

Estefania Quenta Herrera

Institut de Recherche sur la Biologie de l'Insecte (IRBI),
Université François-Rabelais

Karina GONZALES, Unidad de Limnología, Instituto de Ecología. Universidad Mayor de San Andrés. ; Jorge MOLINA, Unidad de Limnología, Instituto de Ecología. Universidad Mayor de San Andrés. ; Jérôme Casas CASAS, Institut de Recherche sur la Biologie de l'Insecte (IRBI), Université François-Rabelais ; Dean JACOBSEN, Freshwater Biological Laboratory, Department of Biology, University of Copenhagen ; Olivier DANGLES, Institut de Recherche pour le Développement, UMR EGCE

High altitude Bolivian peat lands concentrate many services such as high biodiversity and support of endangered wildlife, support of livestock production especially during the dry season, regulation of organic matter decomposition influencing regional carbon cycle, and filtering and regulation of water for hundreds of thousands of people. These peat lands are also one of the most threatened ecosystems of the world as they are extremely sensitive to climate change, due to change

in water provision from melting glaciers and the impact of temperature rise on biodiversity, and human disturbance, due to land transformation, burning, mining activity and drainage. As peat land habitats can be viewed as green islands in the arid environment of the Bolivian Cordilleras, several studies have shown that their biodiversity is tightly related to their size and habitat heterogeneity, which depends on the provision of melt water from surrounding glaciers. Here we investigated the relationship between glacier influence, peat land area and environmental heterogeneity on the organization of aquatic metacommunities living in pool networks characteristic of Bolivian peat lands. We select 200 pools of 20 peat lands in the Cordillera Real (above 4500 m. asl) where we analyzed the metacommunity structure of zooplankton, macrophytes, algae and macroinvertebrates at different levels of spatial scale (α , β and γ diversity). We found that the aquatic environmental heterogeneity of peat lands was positively correlated with the percent of glacier cover in the catchment and positively affected β and γ diversity. Local diversity in each pool was best explained by the percentage of macrophytes cover and water conductivity. The turbidity levels of the peat lands were positively correlated to the percent of glacier cover in the catchment.

124 THE CHALLENGE OF ACHIEVING NO NET LOSS IN THE FORESTS OF CENTRAL AFRICA

Fabien Quétier

Biotope

Pauwel DE WACHTER, WWF ; Hélène DESSARD, CIRAD ; Laurène FEINTRENIE, CIRAD ; Claude GARCIA, CIRAD [INSTITUTE] ETH

The Tri-National Dja - Odzala - Minkebe Forest landscape (TRIDOM) covers 178000 km² across the borders of Cameroon, Gabon and the Republic of Congo. Almost 97% is covered by sparsely populated lowland tropical rainforest and is globally important for the conservation of large mammals (elephants, gorillas, chimpanzees). It is also an emerging iron ore province with several deposits currently being explored and two mining projects ready for exploitation. Encouraging investment while respecting the legal and customary rights of local populations and conserving biodiversity represents a major challenge. Conservationists fear that the needed infrastructure (railroads, roads, transmission lines, hydropower dams) and the associated impacts (especially from the influx of population) will lead to the fragmentation of TRIDOM. It risks being reduced to a mosaic of vulnerable, isolated protected areas, no longer fit to conserve its mega-fauna or maintain large scale ecosystem processes, but developing mining projects with a no-net loss (NNL) or even a net gain (NG) biodiversity objective as a condition for access to finance raises considerable technical and institutional challenges. A landscape-level approach is needed to take into account and mitigate indirect and cumulative impacts. Land-use rights are granted through

sector-specific concessions that have varying requirements in terms of biodiversity and rural livelihoods. Elaborating long-term arrangements for implementing and financing biodiversity offsets will thus require close collaboration between financial institutions, mining companies, conservation NGOs and government bodies from different sectors. We investigate the opportunities and obstacles for achieving NNL/NG objectives in the TRIDOM and draw lessons for other biodiversity-rich landscapes faced with the perspective of large-scale environmental and socio-economic changes.

CAVE DISTURBANCES AND ITS EFFECTS TO CAVE-DWELLING BATS IN A SMALL ISLAND IN SOUTHERN PHILIPPINES

Ma Nina Regina Quibod

Adamson University

Anna Pauline DE GUIA, University of the Philippines Los Banos ; Virginia CUEVAS, University of the Philippines Los Banos ; Ireneo LIT JR, University of the Philippines Los Banos ; Phillip ALVIOLA, University of the Philippines Los Banos

Caves are among the habitats and/or resources that are critically important to the ecology of a number of species, especially cave-dependent species like bats. These habitats are utilized by bats as sites for roosting, courtship and mating, maternity, and hibernation. More than 2,000 caves have been documented in the Philippines, yet cave research is very poor. To address and fill the gaps of knowledge on caves and cave bats in the country, a baseline study on the ecology of cave-dwelling bats in a highly disturbed small island in the southern region was conducted. Thirty caves with different diversity, architecture, microclimate, and disturbances were surveyed, wherein the types and degree of disturbances were correlated to the species richness and abundance of cave-dwelling bats. A total of 16 anthropogenic disturbances were identified outside and inside the caves surveyed, including proofs of bat hunting activities. The survey showed that most caves in the island are moderately to highly disturbed. Important disturbances to consider are visitation/tourism, guano harvesting, and proofs of bat hunting such as bamboo poles, remains of bonfires, torches, and nets. A positive and significant relationship was determined with species richness, abundance, and degree of disturbance in this study. Statistical results showed that disturbed caves have high species richness and abundance. However, the architecture of the cave plays an important role on the presence of high species richness and abundance in disturbed caves. These findings also pose alarm as it reveals that disturbances are concentrated in species rich and abundant caves. Hence, conflicts between cave use (especially tourism) and cave conservation are perceived, as caves with high species richness and abundances (often large caves) are also the most prized tourist destinations.

MODELLING HYBRIDIZATION WITH DENSITY-DEPENDENT RANGE EXPANSION AND ITS IMPLICATIONS FOR CONSERVATION

Claudio S. Quilodrán

University of Geneva

Béatrice NUSSBERGER, University of Zurich ; Juan I. MONTOYA-BURGOS, University of Geneva ; Mathias CURRAT, University of Geneva

The dynamics of range expansion need to be taken into account when studying the genetic consequences of an invasive species spreading and interbreeding with native populations. This is also critical when interbreeding results from shifts in the natural distribution of species due to climate change. Among the species interactions that take place during range expansions, hybridization is of growing concern in conservation biology. Models aimed at studying the genetic consequences of species range expansion have been recently developed but usually assume dispersal to be independent from local population densities. However, organisms may disperse because they are attracted by conspecifics, or to the contrary because they prefer depopulated areas. These behaviours are referred to as positive or negative migratory responses toward conspecifics. Here, through spatially explicit simulations, we assess the effects of various forms of density-dependent dispersal during range expansion on the genetic introgression between two interacting species. We show that massive introgression of neutral genes in the invasive species occurs in all the density-dependent dispersal models (positive and negative), even when hybridization is relatively low. For a given hybridization rate the levels of introgression are lower when dispersal is negatively related to local densities and higher under positive density-dependent dispersal. Our results suggest that organisms that tend to disperse due to conspecific attraction are more affected by genetic introgression. As a consequence they are more threatened by hybridization, which in turn is enhanced by anthropogenic factors and global climate change. We applied our theoretical framework on a real case of hybridization between European wildcat and domestic cat in Switzerland. We highlight that considering density-dependent dispersal in the models has the potential to improve their predictive power and has evident species management implications.

CONSERVATION OF ENDANGERED MARINE SPECIES AND TRADITIONAL ECOLOGICAL KNOWLEDGE: CASE STUDY OF HIPPOCAMPUS INGENS "PACIFIC SEAHORSE" IN PERU.

Marina Quiñe

Laboratoire d'Excellence "CORAIL", USR 3278 CNRS EPHE UPVD. Centre de Recherche Insulaire et Observatoire de l'Environnement (CRIOBE), CBETM - UPVD. Ecole Pratique

des Hautes Etudes. EPHE-Sorbonne.

In order to implement and develop a program to protect endangered marine species, gathering information about these species is a priority. Additionally, traditional ecological knowledge (TEK) represents an extremely useful tool when the distributional area of the species is largest and the economic means limited. This is the case of the assessment of *Hippocampus ingens* in Peru. The study presented here took place in the Northern shore of Peru, between 3° 30' and 6° 30' LS. Six field works were made and 15 fishermen communities were visited. A total of 88 individuals (fishermen principally) were interviewed. Information related to distribution, size, reproductive biology, species association, extraction, commercialization and population shift was collected. This data was crossed with that obtained through ecological assessment. Both data collection were performed in parallel. Fishermen TEK allowed principally: (1) To identify key points of marine extraction and marketing, then allowing the design of the commercial circuit. (2) To show the accuracy of the information related to the spatial distribution and size of specimens in these areas. (3) To determine modes of marine extraction and which of them has the highest impact on populations of *H. ingens*, in this case the bycatch (4) To chronologically know about the shift situation (such as population density and distribution) of *H. ingens* and some other traded species associated with it. Throughout the three years that lasted this assessment, TEK of fishermen, constituted an invaluable tool in the development of the field study and the way to establish links with fishermen, facilitating the process of sensitization pro-conservation, in this case, of *H. ingens*. In conclusion, this study highlights the importance of involving the fishery communities to enrich conservational studies.

SCENARIO PLANNING FOR COUPLED HUMAN-NATURAL SYSTEMS IN A RAPIDLY URBANIZING ANTHROME

John Quinn

Furman University

Melanie COZAD, Furman University ; Jenny WARNKEN, Furman University ; Dainee GIBSON, Furman University

Anthromes link human and natural systems by characterizing terrestrial ecological patterns in terms of human populations and how these populations use the land. Thus biogeographical descriptions of regions like the eastern United States shift from temperate deciduous forest to a heterogeneous mix of semi-natural woodlands and dense settlements. One area of rapid change is the Piedmont ecoregion of the eastern U.S. where an expected >100% increase in urbanization will likely drive continued loss of forest cover, resulting in a regional transition to a homogenous anthrome of dense settlement.

This simplification of the coupled human-natural system necessitates integration of data and perspectives to effectively prepare for future change. Here we present the results of an interdisciplinary effort to link local and regional data to design and test, with the program InVEST, future scenarios of land use change in anthromes. Ecological and economic input data sets were collected at multiple spatial scales. Scenarios prioritized bird conservation, retention of agriculture, timber harvest, carbon regulation, and storm water control. Importantly, while conservation scenarios are sometimes based on conservation ideals and ignore economic constraints, these scenarios reflect measured values of willingness to pay. Specifically, we consider the amount and spatial arrangement of land that could be retained as forest in semi-natural and used anthromes. Evaluation of scenarios suggests that optimizing multiple services at the local scale is challenging, for example the difficulty of maximizing both bird richness and carbon sequestration, but regional coordination, within economic constraints, can improve the future flow of services. Ultimately, by connecting ecological value to economically viable scenarios, we can better assess where biodiversity conservation and ecosystem services retention would successfully occur in shifting anthromes.

THE EFFECT OF ENLISTING SPECIES ON THEIR CONSERVATION STATUS: A MEXICAN CASE STUDY

Esther Quintero

Conabio

Angélica CERVANTES, Conabio ; Adriana VALERA, Conabio

Mexico is one of the few megadiverse countries of the world, however, not all of its biodiversity is well known, documented, and protected. For instance, there is a good level of knowledge for some groups such as mammals and birds, but other such as fishes, invertebrates and even plants are poorly known. For instance, there is not a comprehensive taxonomic treatment for the Mexican Flora. Aichi Biodiversity Target 12, derived from the Convention on Biological Diversity establish that "By 2020 the extinction of known threatened species has been prevented and their conservation status, particularly of those most in decline, has been improved and sustained", whereas target 17 requires that "by 2015 each Party has developed, adopted as a policy instrument, and has commenced implementing an effective, participatory and updated national biodiversity strategy and action plan." It then follows that basic species knowledge and assessment are the first steps towards conservation actions. We thus analyze the gaps in generating a comprehensive assessment of the Mexican biota, and then assess how effective the National Red List has been as policy instrument to achieve the Aichi Targets. In so doing, we analyze a number of case studies from animals and plants in the List for which their risk status have granted them a positive impact

towards their conservation, or on the contrary those that although enlisted have not receive any effective protection.

MANAGEMENT PLANS FOR THE CONSERVATION OF FIVE INDIGENOUS PROTECTED AREAS OF THE ETHNICITY NONAN IN THE PACIFIC COAST OF COLOMBIA

Andrés Quintero Angel

Pontificia Universidad Javeriana

Miyela RIASCOS, ACIVA-RP Association of Indigenous councils ; Luis TANDIOY CHASOY, ACIVA-RP Association of Indigenous councils ; Carolina GAITÁN-NARANJO, ACIVA-RP Association of Indigenous councils

The Chocó biogeographic is recognized as one of the most biodiversity areas in the world; however anthropogenic pressures on these habitats represent major threats to this region. In this sense as a response to this problem two indigenous communities of the ethnicity Nonan located on the banks of the river San Juan and on the River Calima in the municipality of Buenaventura in the pacific coast of Colombia, stated autonomously in 2008 five areas of environmental interest (indigenous protected areas), with the aim of conserving natural and cultural resources, closely related to their customs and their stay in these ancestral territories. In 2013 using the methodology of research - action and Participation we gather the biological information and the Traditional knowledge associated to the five indigenous protected areas. The natural resources used and recognized by the community of these territories a long list of species that are related to different levels of community life, a relationship that leads to an ancestral knowledge of use and customs. Also identifying key issues such as: Conservation Actors, Co-management of Natural Resources and Agricultural Production in the region. As a result we establish eight biological and cultural conservation objectives for each area in the management plans for conservation, which were subsequently validated and agreed with communities in the two Indian Reservations. Although it is not yet possible to assess the impact of these management plans for conservation is important to emphasize that it is the first experience that involves biological and cultural values objects for conservation in the country and that the five "indigenous protected areas" area about 1850 hectares of continues forest.

COMMUNITY-BASED APPROACHES FOR THE CONSERVATION OF INDIGENOUS PROTECTED AREAS IN THE CHOCHO REGION OF COLOMBIA

Andrés Quintero Angel

ACIVA-RP Association of Indigenous councils

Miyela RIASCOS, ACIVA-RP Association of Indigenous councils ; Luis Hernando TANDIOY CHASOY, ACIVA-RP Association of Indigenous councils ; Carolina GAITÁN-NARANJO, ACIVA-RP Association of Indigenous councils

The loss of cultural identity, poverty, lack of environmental education, the population growth and the low level of development of indigenous communities are among the causes of environmental problems plaguing the Chocó biogeographical region. In response to this problem, we used a community based approaches to design and implement an educational tool that incorporate the traditional knowledge for the conservation of indigenous protected areas defined by two communities of the ethnicity Nonan located on the banks of the river San Juan and on the River Calima in the municipality of Buenaventura in the pacific coast of Colombia. With the aim to develop in the communities environmental competencies and recovery of the Traditional knowledge that help in the conservation of natural resources in the ancestral territories, we made an participant observation exercise and knowledge dialogue to identify the species of fauna and Flora related to different levels of the community life. Resulting in the recovery of traditional knowledge of 266 species of fauna-flora and 40 cultural elements associated with indigenous protected areas. This knowledge was incorporated into the education material that recognized equality of scientific and traditional knowledge. The material was presented in mother language (Mach meu), Spanish and Latin (scientific names). Additionally, it was accepted and agreed with each Indian reservation communities improving their design and facilitating its implementation. Being widely appealing to all community members, fulfilling some of the pedagogical principles that make relative to the stimulus in learning so we recommend for future conservation initiatives in indigenous territories recovering knowledge and use of educational tool as a means of interaction between members of the indigenous communities; facilitate the transmission of traditional knowledge related to biodiversity and improving attitudes of responsibility and respect for nature.

ASSESING THE CULTURAL AND SOCIO-ECONOMIC IMPORTANCE OF THE HAIRY ARMADILLO (CHAETOPHRACTUS NATIONI) IN ORURO, BOLIVIA

Carmen Julia Quiroga Pacheco

University of Kent

Douglas MCMILLAN, Durrell Institute of Conservation and Ecology

The high Andes hairy armadillo (*Chaetophractus nationi*) has been traditionally used in Bolivia to manufacture charms, souvenirs and musical instruments such as the charango, a small traditional guitar, and especially a music box named "matraca" used during Carnaval processions. The species is

vulnerable to extinction according to IUCN and over-harvesting seems to be one of the main threats. Although the trade of the hairy armadillo is illegal according to national laws and local bylaws in some Bolivian towns, and on the fact that the species is listed in CITES Appendix II, the trade of the animal is open across the country, mostly on the west side, with additional evidence that dead individuals are also taken inside and outside the country without export permits. In the first stage of the research, we interviewed dancers and artisans, as well as visited local markets to assess the use of the species during Carnival celebration, particularly in Oruro, where the biggest procession is held. At least 160 animals are harvested every year only for the festivity, despite the availability of alternative non-animal products with a lower price in the market, so we believe that the reason for dancers to still prefer buying and using the real animal goes beyond the economic drivers and has a deep socio-cultural root, as interviewees stated they love the animal and feel identify by this particular species. Therefore, to have deeper knowledge about the value of the species in Oruro, further information was gathered using a mixed method approach, and was then processed using qualitative and quantitative analysis. The results of this research will help not only to generate knowledge about people's perceptions on this matter, but also to pursue cultural-friendly conservation solutions for the hairy armadillo, suitable with the needs and beliefs of the actors involved in the trade chain

SMALL SCALE SEAGRASS FISHERIES IN THE PHILIPPINES, A CASE STUDY OF TWO COASTAL BARANGAYS

T E Angela Quiros

University of California Santa Cruz

Alexis ARAW, University of California Santa Cruz ; Josephine DE LOS REYES, Barangay Gulod ; Corianna HUME-FLANNERY, University of California Santa Cruz ; Leah May LLONTES, Barangay Bulata

In developing countries, seagrass fisheries provide essential resources for coastal communities. While there is a bias towards management and conservation of coral reef fisheries, seagrass fisheries are important to rural communities, especially when there are declining artisanal fisheries catches. Between March 2013 and February 2014, we conducted semi-structured interviews of fishers, quantitative household surveys, observed fishing practices, and measured fish catch in landing sites in two coastal villages in the Philippines: one in a rural province and the other near a metropolitan area. In one site, seagrass fishers made up 85% of nearshore fishers, while coral reef fishers made up 15%. Compared to coral reef fishers, seagrass fishers had easier access to fishing grounds and only 85% used boats. The majority either gleaned at night or used boats and seine nets. The second most popular gear was crab and eel traps, and fish corrals. The majority of the

catch was juvenile fish, dominated by the Families Siganidae, Labridae, Muraenidae, Gerreidae and adult invertebrates in the Families Holothuroidea, Strombidae and Portunidae. Local food preferences aligned with the most abundant catches in both barangays. Household interviews assessed overall income and reliance on seagrass resources for income and protein. In the rural province, seagrass fisheries provided essential protein for daily consumption to the majority of households, while in the province near a metropolitan area which had access to non-fishing jobs, seagrass fisheries provided supplemental protein to a portion of the households. Regardless, proper management of seagrass resources under both scenarios is critical.

CONSERVATION OF THE FRAGMENTED FOREST SURROUNDING RANOMAFANA NATIONAL PARK, MADAGASCAR USING PARTICIPATORY ECOLOGICAL MONITORING AND GIS AS A TOOL FOR BIODIVERSITY AND ITS HABITAT MONITORING

Pascal Nalimanana Rabeson

Centre ValBio

Eileen LARNEY, Centre ValBio ; Patricia WRIGHT, Centre ValBio

Local people are not considered as stakeholders of their environment, biodiversity, and its forest habitat worldwide. Many countries use Participatory Ecological Monitoring to involve local people to be responsible of their environment. This project aim to engage local people surrounding Ranomafana National Park, Madagascar in conservation and management of their natural resources. 10 villages surrounding the Park will be targeted to monitor the fauna and flora biodiversity, and the pressures in the forest. Three transects will be used for observations using the existing trails in the forest. Observations will be conducted once a month for four days for each village. Villagers will be trained on survey methods, data collection, use of GPS and camera for the observation. All the forest transects of each village will be mapped using Mapsource and Arcgis 10.2.2 software. Data recorded from biodiversity and pressures observations will be analysed based on indicators for biodiversity and pressures. Baseline information from the sites will be taken including delimitation of the villagers' forest habitat characteristics, the forest fragments around Ranomafana National Park with the observation trails, number of encountered species of animals and targeted plants during observations, and potential disturbances (e.g., slash and burn agriculture, gold mining, etc.). I expect the local community to be responsible in site and trained in GPS, confident in conducting transect observations. Analyzed data from the surveys will be used as management tools and at the end as a standardized biological monitoring that will be elaborated for future use in other regions in Madagascar. In conclusion, this project can motivate locale

population to be responsible for conserving locale biodiversity and extending the protected areas with these new monitored sites.

MUSHROOMS AND MACAQUES: USING ANTHROPOLOGY FOR CONSERVATION IN NORTH MOROCCO

Lucy Radford

Barbary Macaque Awareness and Conservation
Kenza EL HARRAD, Barbary Macaque Awareness and Conservation ; Sian WATERS, Barbary Macaque Awareness and Conservation

Around the oak forest of Bouhachem, north Morocco, Endangered Barbary macaques and people coexist in close proximity. With Barbary macaque populations in decline across their range due to human activity, using sociocultural and anthropological methods to approach their conservation is vital. Many agropastoralists from villages around Bouhachem collect wild mushrooms from the forest to sell as an additional source of income. We conducted research on mushroom collectors' perceptions of Barbary macaques. We used semi-structured interviews, allowing for open discussion of all the wild and domestic species the collectors encounter in the forest, and avoiding bias towards discussion of the macaques. We discovered that some mushroom collectors find the macaques helpful because they uncover mushrooms in the leaf litter as they forage. The species the macaques eat are different from the species people collect to sell, so there is no competition. With a history of macaques being persecuted by other forest users, the mushroom collectors' perceptions are an important facet to our understanding of the greater picture of macaque-human relationships in the area. Predation by dogs is another major threat to macaque populations in Bouhachem, and some mushroom collectors take dogs with them to the forest which harass the macaques. By ascertaining that mushroom collectors who go without dogs - and are therefore able to follow macaques - have greater success, we are able to tacitly communicate the message that it is better for people to keep dogs out of the forest unless they are being used for livestock guarding. We conclude that encouraging open discourse with forest users about the species they encounter can be a valuable conservation tool for Barbary macaques, as it allows us to gain deeper understanding which aids the design of our initiatives and our communications with local people.

HOW OXFAM AND SCARES DOLLARS CREATED TNC AND WCS

Stéphane Radureau

AgroParisTech[INSTITUTE]Centre of Excellence for Environmental Decision

Shaun COUTTS, Centre of Excellence for Environmental Decision[INSTITUTE]School of Natural Sciences, Trinity College ; Michael BODE, Centre of Excellence for Environmental Decision[INSTITUTE]University of Melbourne ; Jonathan RHODES, Centre of Excellence for Environmental Decision[INSTITUTE]University of Queensland ; Edward GAME, The Nature Conservancy ; Eve MCDONALD-MADDEN, Centre of Excellence for Environmental Decision[INSTITUTE]University of Queensland

While the ultimate aim of conservation non-government organizations (NGOs) is the preservation of biodiversity, two divergent strategies are used to achieve these aims. The first strategy is to implement projects that focus solely on biodiversity. The second strategy emphasizes the social benefits derived from biodiversity so as to enhance community engagement with biodiversity protection (an ecosystem services strategy). The last decade has seen an increased and contentious focus on the second of these strategies by some NGOs. The reason for this shift is not clear. One explanation is that it is the outcome of competition among NGOs for fund-raising from a limited donor pool. To test this we construct a game theoretical model of strategic interaction within the NGO sector. We demonstrate that competition for donations and the availability of funds for ecosystem services could explain recent changes in the structure of the conservation NGO sector, and that such changes could undermine biodiversity conservation outcomes. Within our model fund-raising competition leads to both NGO's converging on an ES orientated strategy. However, the presence of a human development NGO and the possibility of NGO's attaining funds from non-donor sources changes the game - now the NGO receiving non-donor funds focuses solely on biodiversity protection while the other focuses on providing ecosystem services. Knowing how such games play out allows insight into why conservation NGOs may have shifted focus in recent times but also provides understanding that could help funding bodies and governments influence conservation NGO strategies through targeted project funding. However, caution must be taken, even in our relatively simple model we find counterintuitive results suggesting that such interventions could not be the most efficient in terms of investment in biodiversity protection.

FINDING ALTERNATIVES TO SWIDDEN AGRICULTURE: DOES AGROFORESTRY PROVIDE SUPERIOR LIVELIHOOD OPTIONS AND REDUCE PRESSURE ON EXISTING FOREST?

Syed Rahman

Center for International Forestry Research (CIFOR)

Healey JOHN, *Bangor University*; Sunderland TERRY, *Center for International Forestry Research (CIFOR)*

Swidden cultivation causes deforestation and land degradation, which result in a number of serious environmental problems. This paper examines the financial and social potential of agroforestry systems and their barriers of widespread adoption, as a land use alternative to swidden cultivation, which may potentially help protecting local forest. The Gunung Salak valley in West Java, Indonesia is presented as a case study. Empirical data collected from the study site found that, agroforestry systems have higher net present value (NPV) and benefit-cost ratio (B/C) than swidden cultivation. Tree ownership creates more permanent right on farm land and is prestigious in the community. Agroforestry products have high monetary value and help strengthen social cohesion when shared (fruits, vegetables, etc) with neighbors. Yet farmers are reluctant to implement agroforestry. Stated reasons are both cultural and capacity oriented. Agroforestry farmers are less involved in forest clearing and forest products collection than swidden farmers indicating that it may better preserve local forests. Support is needed to overcome capacity constraints and facilitate agroforestry adoption in the study site if conversion to agroforestry is wanted.

DO ROADS INFLUENCE PREDATOR ACTIVITY IN INTACT LANDSCAPES?

Keren Raiter

University of Western Australia

Richard HOBBS, University of Western Australia; Suzanne PROBER, CSIRO Land and Water Flagship; Leonie VALENTINE, University of Western Australia; Hugh POSSINGHAM, School of Biological Sciences, University of Queensland

Extensive developments such as mining, and oil and gas extraction in relatively intact landscapes have numerous ecological impacts that affect ecosystems beyond their immediate footprints. Many of these impacts are poorly understood, particularly for linear infrastructure. We quantified linear infrastructure development in Western Australia's Great Western Woodlands, a region with significant mineral values supporting extensive and diverse woodlands and shrublands. Linear infrastructure in this region represents a large source of direct physical alteration that is likely to have an array of other consequences, such as hydrological change and altered connectivity for fauna. We then surveyed predator activity in woodland and shrubland habitats for evidence of changed native and introduced predator activity associated with unsealed roads. We established motion sensor cameras and searched for spoor (scats, prints and other evidence of predator activity) along 16, 3-kilometer transects situated perpendicular to roads. We discovered a strong association between predator activity and roads, although the effect of

the road did not extend far into the surrounding vegetation matrix, and trends varied between species. In particular, dingo preferences for tracks were stronger than cat preferences, and this may indicate some spatial interactions between the apex and mesopredators. These results have implications for the consideration of ecological impacts of developments in impact evaluations and land-use plans, and can inform predator control strategies.

THE RESPONSE OF NAIVE BUMBLEBEE (B. TERRESTRIS) FORAGERS TO CONSPECIFIC AND HETEROSPECIFIC SOCIAL CUES

Sara Raj Pant

UCL

Elli LEADBEATER, Royal Holloway University of London

Across the animal kingdom, animals rely on social information to make adaptive decisions. Recent work has highlighted that animals respond not only to cues provided by their conspecifics, but also to those provided by other species that share the same habitat. Yet, we know little about whether selection might specifically have favoured responding to heterospecific cues, or whether animals simply learn through experience that heterospecifics provide useful information. Here, we test the responses of naïve bumblebee (*Bombus terrestris*) foragers to the presence of conspecifics, heterospecific *Bombus* species, and the honeybee *Apis mellifera* at forage sites. We find that foragers respond only to their conspecifics and to a heterospecific species displaying most similar tongue length, niche overlap and close relatedness. We also compare the responses of naïve bumblebees to nestmate and non-nestmate cues. Our results suggest that bees show naïve responses to conspecific and not heterospecific cues, with the exception of *B. hypnorum*, and that these responses are unlikely to simply be the by-product of an attraction to the scent of nestmates.

INTERVIEW SURVEYS VS. MONITORING PROGRAMMES: EVALUATING ALTERNATIVE METHODS OF MONITORING MARINE MAMMAL POPULATIONS IN DEVELOPING COUNTRIES, A CASE STUDY FROM MALAYSIA

Leela Rajamani

Universiti Sains Malaysia

Luz Helena RODRIGUEZ-VARGAS, Universiti Sains Malaysia

The interview survey is a cost-effective method to learn of the distribution, crude abundance, and threats of marine mammals, especially in data-deficient developing countries. These surveys can also provide information on conservation issues and community perceptions regarding these mammals. Monitoring programmes are interview surveys conducted at regular intervals to obtain a temporal evaluation of trends

in population status, seasonal occurrence and movement patterns. Interview surveys and monitoring programmes were conducted at two locations namely, Sabah (dugong) and Penang (cetaceans) in Malaysia, in 2002 and 2013, respectively. This paper aims to evaluate and compare interview surveys and monitoring programmes used in these two study sites. The topics discussed will include: questionnaire design and the importance of pilot studies, biases involved in conducting these surveys, the measures recommended to decrease them in terms of validation of interview answers, repeat sightings, and respondent daily routine. The feasibility of using interview surveys as a onetime survey, or continuing with a monitoring programme, which could be short term (e.g. one year) or long term (e.g. several years) will also be discussed. The importance of developing a relationship with the local community, interviewer skills and experience, and recommendations on how to approach community will be highlighted.

LOCAL WELFARE IMPACTS OF FOREST CONSERVATION: EXAMINING THE RELIABILITY AND VALIDITY OF ESTIMATES USING THE CHOICE EXPERIMENT METHOD

Sarobidy Rakotonarivo

Bangor University

Neal HOCKLEY, Bangor University

Understanding the impacts of conservation on local people's welfare remains very difficult in least-developed countries where markets for land and labour are weak and analysts often lack good understanding of people's livelihoods. This study tests whether choice experiment surveys can provide reliable and valid estimates. I used choice experiments to investigate trade-offs between swidden agriculture and attributes such as cash payments and agricultural support. I surveyed matched households in an open and closed forest frontier where people have different experiences of restrictions. I also conducted qualitative debriefing interviews with a sub-sample of respondents to explore respondents' motivations and strategies. Past experiences of restrictions significantly affect how people answer choice experiment surveys. Where restrictions have been enforced for a relatively longer period (closed frontier), swidden agriculture is almost incommensurable. Whereas in the open forest frontier, respondents are willing to make trade-offs although important discrepancies exist between migrants and indigenes. Findings also show that respondents anchored their responses in a variety of ways which are rooted in their perceptions and beliefs. These results call into question the reliability and validity of choice experiments conducted prior to conservation actions or other policy interventions. My research has implications for how we design choice experiment (and other) surveys. I identify circumstances when we can expect them to provide reliable and valid estimates of welfare

impacts. Findings also suggest that conservationists may need to rethink their approaches and inform the design of more effective compensation measures since forest dwellers have the greatest impact on resources.

EFFECTS OF FRAGMENTATION AND DEGRADATION ON THE DISPERSAL ABILITY OF THE WOODY PLANT COMMUNITIES IN THE ATTAPPADY HILLS, WESTERN GHATS (INDIA): IMPLICATIONS FOR FOREST LANDSCAPE RESTORATION

Ravi Ramalingam

Ashoka Trust for Research in Ecology and the Environment

Priyadarsanan DHARMA RAJAN, Ashoka Trust for Research in Ecology and the Environment

Seed dispersal plays a key role in structuring the plant communities across a range of spatial scales resulting in different patterns of species diversity across landscapes. Spatial patterns occur due to the movement of seeds based on different dispersal vectors (whether abiotic or biotic), which operates at various spatial scales and consequently determine the community structure. When forest landscapes are altered due to fragmentation and habitat loss, the mechanisms of various dispersal vectors are affected and subsequently hinder species dispersal resulting in altered community structure. Although it is the only factor that accounts for the movement of species among fragmented habitats, local processes such as disturbance and biotic interactions may determine their persistence within the habitat. Therefore, studying the distribution of woody plants (based on seed dispersal) among the habitat fragments provides insights into how vegetation communities were shaped by factors related to environmental disturbances. In the Attappady hills, Western Ghats, efforts to restore several hundred hectares of degraded forests have been organized under an eco-restoration project. We studied the spatial distribution of the woody plant communities based on the seed dispersal modes to understand the mechanisms of recolonization of the woody plants into the fragmented habitats, and thereby help restorationists to adopt better restoration management. We found that the larger habitat fragments positively affected the diversity of passive and animal dispersed species. Secondly, passively dispersed species that are short-distance dispersal mechanisms were more dispersal-limited than species with adaptations for long-distance dispersal such as animal and wind dispersed species. This indicated that dispersal indeed constrains species' recolonization into degraded fragments, and facilitating natural regeneration may not be sufficient in restoring these fragmented forests.

IDENTIFYING CRYPTIC LINEAGES WITHIN AN ENDEMIC FROG GENUS (INDIRANA) IN THE WESTERN GHATS

Vijay Ramesh

Columbia University

Vijayakumar SP, National Centre for Biological Sciences ; Kartik SHANKER, Centre for Ecological Sciences, Indian Institute of Science

A large number of extant species in the tropics are awaiting discovery, many due to their crypticity ie. lack of morphological difference. We tested for crypticity in a frog genus, *Indirana*, endemic to the Western Ghats of peninsular India. We updated a published phylogeny using increased taxon and spatial sampling, and by examining the relationship between genetic and morphological divergence among close relatives. Initially, we delimited potential lineages using a 16S rRNA haplotype tree and then, a multigene tree using multiple criteria including haplotype clusters, genetic distances and geographical range separation. Our results suggest that there are 19 – 21 potential lineages in *Indirana*, which is an increase of between 70 – 90 % from earlier estimates. Pairs of potential lineages that differed in their levels of genetic divergence were examined in multivariate morphological space. Several lineages within *Indirana* were cryptic and could not be distinguished on the basis of morphology, and the potential lineages identified await formal description as species.

TRACKING THE MOVEMENTS OF A SMALL AND THREATENED NEW ZEALAND NATIVE FROG

Patricia Ramirez

Victoria University of Wellington

Ben D BELL, Victoria University of Wellington ; Nicola J NELSON, Victoria University of Wellington

New Zealand native frogs belong to the genus *Leiopelma* and are classified as threatened, both internationally and nationally. All four extant species have suffered major range reductions and are now restricted to a few islands in the Marlborough Sounds and parts of the North Island mainland. The study of amphibian movement is a critical component of their ecology, relating to interaction between species and their environment. Small-scale movements are important as they enable identification of habitat features essential for species persistence, which relates to conservation management. Despite this, little is known about small-scale movements in *Leiopelma* species. Their small size and cryptic nature presents a challenge, and therefore commonly used techniques (e.g. radio-tracking) are not adequate. This study aims to investigate small-scale movements of a nocturnal terrestrial species, *Leiopelma pakeka*, in its natural environment. Non-toxic fluorescent powders were applied to randomly selected frogs

during their putative breeding and non-breeding seasons to track their movements throughout the night. Irrespective of season, males and females moved similar distances during the night. Females grow larger than males, but there was no correlation between movement behaviour and size (SVL) of frogs. However, there was a marked variation in movement behaviour between individuals. Total distance moved was significantly higher during the breeding season, independent of sex. Microhabitat selection differed between seasons, reflecting different substrate preferences during movement. The use of fluorescent powders proved effective for short-term tracking of this species. This research improves our understanding of *L. pakeka* habitat requirements, and should allow more effective conservation management, such as translocation and captive husbandry.

WHERE TO GO NEXT? PREDICTING HABITAT SUITABILITY OF AN EXPANDING MESOCARNIVORE - THE GOLDEN JACKAL (CANIS AUREUS) IN EUROPE

Nathan Ranc

Harvard University

Francesca CAGNACCI, Fondazione Edmund Mach ; Ovidiu BANEA, Crispus NGO ; Tomaz BERCE, Slovenia Forest Service ; Dusko CIROVIC, University of Belgrade ; Sandor CSANYI, Szent István University ; Georgios GIANNATOS, University of Athens ; Miklos HELTAI, Szent István University ; Jozsef LANSZKI, University of Kaposvar ; Luca LAPINI, Friulian Natural History Museum ; Luigi MAIORANO, La Sapienza University of Rome ; Danijela MALESEVIC, University of Banja Luka ; Despina MIGLI, Aristotle University of Thessaloniki ; Jasna MLADENOVIC, University of Ljubljana ; Aleksandra PENEZIC, University of Belgrade ; Martin SALEK, Academy of Sciences of the Czech Republic ; Ivana SELANEC, Association BIOM ; Stoyan STOYANOV, University of Forestry ; Laszlo SZABO, Szent István University ; Igor TRBOJEVIC, University of Banja Luka ; Miha KROFEL, University of Ljubljana

The golden jackal's *Canis aureus* range in Europe is expanding rapidly. Historically restricted to the Mediterranean and Black sea coastal regions, golden jackals are now reproducing in most of Southeastern European and some Central European countries. In addition, vagrant animals have been detected further to the north and west (Estonia, Germany, Switzerland). The presence of this new carnivore could have impact on existing animal communities and is already receiving high interest among wildlife managers. There is thus an urgent need to forecast species colonization at the European scale. In this analysis, we used species distribution models (SDMs) to map the species habitat suitability across the continent. SDMs were calibrated within the core range of the species using data of territorial jackal groups (>1000 locations, mostly from howling surveys) as presence. By contrast, absences

were drawn from hunting-statistics and refined with both expert-based distribution models and opportunistic jackal records. We used environmental variables relevant to the species ecology: altitude, snow cover, land-cover and grey wolf *Canis lupus* presence. We controlled for sampling selection bias by manipulating presence weights and absence spatial selection. We calibrated 10 different algorithms; all internally and externally validated. The final model projection was achieved through an ensemble procedure and we investigated the robustness of our predictions to extrapolation using a multivariate environmental surface analysis. Our analysis indicates that mountain areas characterized by unfragmented forest cover, high snow prevalence and wolf presence are particularly unsuitable. Besides these areas, large parts of Western and Central Europe appear suitable, so we can expect further expansion of this species in the future. These results provide managers with the opportunity to prepare for the future colonization by the jackals in areas, where expansion is most likely.

DEAD WOOD CREATION TO COMPENSATE FOR HABITAT LOSS FROM INTENSIVE FORESTRY

Thomas Ranius

Swedish University of Agricultural Sciences
Alexandro CARUSO, Swedish University of Agricultural Sciences ; Mats JONSELL, Swedish University of Agricultural Sciences ; Artti JUUTINEN, University of Oulu ; Jörgen Rudolphi, Swedish University of Agricultural Sciences

Negative consequences of human activities for biodiversity may be mitigated by compensation measures. Although the interest in applying compensation measures is generally increasing, such measures have rarely been applied in forestry. Many boreal forests are managed by clear felling and used for timber and pulp production. There is an increasing interest in intensifying forestry by also harvesting slash and stumps for biofuel at felling. We evaluated the efficiency of combining intensified forestry production with compensation measures, by estimating the net revenue from slash and stump harvest, the cost of high stump creation, and simulating habitat amount for 680 bark- and wood-living species (fungi, beetles, lichens, and bryophytes) in Norway spruce forests in Sweden under different scenarios of biofuel harvest and compensation. We show that the harvest of slash and stumps has a clear negative effect on the habitat amount available for many species, especially for many fungi and beetles. Combining slash harvesting with the creation of high stumps results in an economic surplus and at the same time provides significantly more habitat in comparison with no slash harvesting and no high stump creation. When undertaking stump harvesting it is currently impossible to achieve such positive effects. Thus, our analyses show that compensation can sometimes be a useful tool when both economic and biodiversity goals must be

achieved in forestry, but in other cases it is a better alternative to avoid the activity that causes the negative effects.

TO SET ASIDE YOUNG FORESTS MAY BE A COST-EFFICIENT STRATEGY FOR CONSERVING DEAD WOOD-DEPENDENT SPECIES

Thomas Ranius

Swedish University of Agricultural Sciences
Anu KOROSUO, Swedish University of Agricultural Sciences ; Jean-Michel ROBERGE, Swedish University of Agricultural Sciences ; Mikko MÖNKKÖNEN, University of Jyväskylä ; Artti JUUTINEN, University of Oulu ; Martin SCHROEDER, Swedish University of Agricultural Sciences

In managed forest landscapes, a common practice to mitigate negative consequences on biodiversity is to set aside old forest stands. However, alternatives to this have been suggested: young stands can be set aside and the rotation period can be extended in forests managed by clearfelling. Using simulation models, we have analysed the consequences of applying these strategies in a managed boreal forest landscape in Sweden. Then we applied a constant conservation budget and predicted forest development and harvesting over the following 250 years and the colonisation-extinction dynamics of a redlisted beetle species dependent on dead wood. In the short term, setting aside young stands leads to a higher extinction risk, as it takes longer time before the amount of dead wood increases. However, since young forests are cheaper, the total area set aside becomes much larger with that strategy, which in the long term generates a lower extinction risk and a decreased volume harvested in the forest. Prolonging the rotation period was not a cost-efficient strategy, given a 3% interest rate, which is commonly assumed. In our case, the most cost-efficient strategy to preserve the beetle species in the study landscape over 250 years was to spend about half of the budget on young set-asides and spend the other half on old set-asides, which is significantly different in comparison to the current strategy that almost only involves old set-asides. However, to set aside young stands instead of old means that both the cost (decreased harvest) and benefit (decreased extinction risk) is delayed, and it is a question of values whether this is desirable or not.

ROB PETER TO ROB PAUL. TRIAGE OR THE LIMITS OF CONSERVATION APPROACHES THAT IGNORE STRATEGY

Aleksandar Rankovic

IDDR-Sciences Po
Raphaël BILLÉ, Associate researcher at IDDR-Sciences Po

In recent years, "triage" has received a growing interest in the conservation community. It is increasingly present in the

scientific literature, in expert discussions and even echoes in the general media. Following its advocates, triage is the undesirable but necessary path through which conservation has to go through in order to stay “realistic” in a context where the resources allocated to conservation seem scarce in regard to its needs. What seems at stake is the capacity of the conservation community to remain credible in the eyes of decision-makers and to have transparent, scientifically-informed debates as to “what to let go”. This approach has spurred many debates, that for the most part focus on its moral implications and feasibility. However, we argue that triage must at first be critically assessed through strategic analysis. Indeed, current debates remain in an intellectual space where the premisses underlying triage and its supposed fit to real world constraints are very seldomly discussed. Yet, the efficacy of any given strategy strongly depends on first making an accurate framing of the issue it is supposed to tackle. Here, we will first propose an overview of the triage rationale and the debates surrounding its morality and implementability. Then, we will show that most hypotheses behind the triage rationale are actually highly disputable on strategic grounds. We will particularly address three misconceptions that are at the core of the triage rationale: (i) The lack of pertinence of its displayed tactical dimension; (ii) How it underestimates the complexity of conservation action contexts; and (iii) The numerous uncertainties pertaining the actual resources allocated to conservation and their pathways. Based on these elements, we will argue that instead of helping conservationists better achieve their goals by moving away from the zero extinction goal, triage might unnecessarily weaken their position in real world negotiations.

RESPONSE COMPOSITION OF EPIPHYTIC LICHENS DIFFERS AMONG TREE TAXA

Åsa Ranlund

Swedish University of Agricultural Sciences
Victor JOHANSSON, *Swedish University of Agricultural Sciences*; Kristoffer HYLANDER, *Stockholm University*; Lena GUSTAFSSON, *Swedish University of Agricultural Sciences*

Organisms vary in their responses to environmental change. Characterizing these response differences is important in order to understand how anthropogenic changes to the environment affect communities and how adverse effects might be mitigated. We propose the term “response composition” to capture variation in the distribution of responses by the species in a community. As an example we used lichens in Sweden to compare the response composition among epiphytic communities, in relation to the forest disturbance of clearcutting. We found a distinction between lichen species that were mainly associated with the late successional Norway spruce and the early successional European aspen, birches, and Scots pine. The spruce-associated species had on average a

negative response to the exposure of logging, while the species associated with early successional tree taxa had on average a positive response to exposure. Consequently, epiphytic lichens response to exposure correlates with the conditions of where their host tree taxa have commonly occurred in the landscape. Our results are in line with theory on how historic environmental conditions have affected species pools. We introduce the term “response composition”, which has the potential to complement studies on response diversity by adding dimensions such as response direction, magnitude, and variation over time. Such additions can help define community-specific conservation actions.

MONITORING SUITABLE HABITATS FOR FOREST BIRDS IN MADAGASCAR USING TIME-EXPLICIT SPECIES DISTRIBUTION MODELS AND TIME-SERIES OF SATELLITE DATA

Andrianarivelosoa Solohery Rasamison

Université d'Antananarivo

Madagascar is home five endemic bird families and 37 endemic bird genera, more than any other country in the African region. Among 286 bird species that can be found in the island, many species are threatened by habitat loss. In this study I used GBIF and other sources of spatial-temporal records of birds, time-series of environmental variables derived from satellite data at moderate spatial resolution, and species distribution models to estimate trends in the extent of suitable habitat for birds in Madagascar from 1990-2010. This method allows area of habitat for bird species, a proxy for population size, to be monitored retrospectively and into the future. It complements the studies of population trends at a very limited number of sites.

THE DEVELOPING WORLD BIAS IN STUDIES OF HUMAN DIMENSIONS OF INVASIVE SPECIES: RESULTS OF A SYSTEMATIC REVIEW

Archi Rastogi

University of Waterloo
Brendon LARSON, *University of Waterloo*

The focus of invasion biology are invasive species, which are often defined in terms of their non-native origin, their tendency to spread, and their social-ecological impacts. To date invasion biology has largely been developed from an ecological perspective. It is critical to understand human dimensions of invasive species, since this knowledge can help conservationists to determine when to intervene and how to design effective interventions. We conducted a systematic review of social scientific research on the human dimensions of invasive species. Adapting the method from prior studies, we aimed to explore how humans relate to invasive species

by characterizing the current state of the literature, and identifying lacunae for future research. Our review revealed that the funding agencies, lead authors, and respondents were primarily based in the developed countries for the majority of studies. As a result, there is dearth of relevant knowledge from developing country contexts. This disparity in scientific knowledge can create serious challenges for global policy discussions on invasion biology. Further, we found that the majority of studies tended to subscribe to the philosophical viewpoint of “stewardship” or “participation with nature”, which relate to management challenges created by invasive species, and the loss of ecological integrity. We found a small minority of studies allying with the viewpoint on “mastery over nature”, discernible by their emphasis on the monetary functions of nature. Since invasion biology is a relatively new discipline, this review provides the opportunity to assess the direction of the discipline and take corrective measures. In this paper, we outline other trajectories of the literature on human dimensions of invasive species and identify implications for conservation and management.

WHO KILLED THE TIGER? UNDERSTANDING THE SOCIAL DIMENSIONS OF TIGER CONSERVATION IN INDIA.

Archi Rastogi

University of Waterloo [INSTITUTE] McGill University
Gordon HICKEY, McGill University ; Sneha THAPLIYAL, Indian Institute of Management Bangalore ; Ruchi BADOLA, Wildlife Institute of India ; Syed Ainul HUSSAIN, Wildlife Institute of India ; Anupam ANAND, University of Maryland

Tiger conservation represents some of the most intense challenges facing Protected Areas management. It involves the protection of a potentially-dangerous predator in some of the world’s most densely populated landscapes shared by the animal with human populations. This is known to create a serious dilemma: successful tiger conservation requires the establishment of ‘exclusively-managed’ Protected Areas, which can antagonize local communities and render tiger conservation unsuccessful. What, then, are the lessons to be learnt from successful governance of tiger conservation? We present the results of a five-year research project that considered the case of tiger conservation in India. The research utilized diverse academic approaches to understand the social dimensions and governance of Protected Areas in India at several levels of governance (policy, national, Protected Area, community and village-level). We utilized diverse methods ranging from psychometrics to institutional analysis, and economics to analysis of geographic information system (GIS). This research was designed to fulfil an important gap by using science to devise pragmatic and practical inputs for conservation. The key outcomes of the research include: a) outlining ‘the dilemma of tiger conservation’, b) understanding

the psychological make-up that affects policy networks, c) examining the processes through which local-level politics can affect and undermine Protected Area management, d) identifying local-level social capital as a potential resource, rather than a challenge, for Protected Areas, e) exploring the implications of tourism for institutions and ecology of Protected Areas, and f) analysis of popular media on tiger conservation. Overall, the research makes pragmatic inputs for tiger conservation, with implications for Protected Areas globally. The pragmatic results inform long-term and short-term policy and management of Protected Areas worldwide.

COMMUNITY-BASED INTEGRATED MONITORING FOR LONG TERM BIODIVERSITY CONSERVATION IN SOUTHERN MADAGASCAR

Joelisoa Ratsirarson

University of Antananarivo

Jeannin RANAIVONASY, University of Antananarivo ; Alison F. RICHARD, University of Yale

For nearly 30 years, a monitoring and conservation program in partnership with local community is implemented at the Bezà Mahafaly Reserve (southern Madagascar). The study documents the vulnerability and resilience of local ecology, landscapes and communities and combines ecological and socioeconomic data at Bezà Mahafaly. Land cover changes show fragmentation of vegetation cover, mainly outside the protected Reserve. The role of the protection of the Reserve is very important as the study demonstrated the stability of some indicator vertebrate species populations of habitat health). The impact of local climate variability has been noted on phenology of flora as well as reproductive success of lemurs. Thus, years of good rain are associated with available vital resources for lemurs and thus higher fertility and a higher survival rate of newborn lemurs. Community livelihoods and food security, which are based on agriculture and forests products, are strongly influenced by climate variability and its ecological implications. The integrated community-based monitoring system has an important role as an early warning system, and has helped to make relevant decisions for adaptive sustainable management of the Reserve, including protected area extension and protection, ecological restoration and promotion of local development. Local partnership at Bezà Mahafaly, with by mutual trust between stakeholders can be considered as a unique model for sustainable conservation.

ECOLOGY AND CONSERVATION OF BIRDS AND CARNIVORE SPECIES OF RANOMAFANA NATIONAL PARK RAINFOREST: MONITORING ENVIRONMENTAL AND CLIMATIC CHANGE THROUGH CAMERA TRAPPING

A. Jean Claude R. Razafimahaimodison

Centre ValBio Ranomafana

Ranomafana national park has been well known worldwide for its high level of biodiversity endemism and diversity, following the 1986 discovery of the golden bamboo lemur. Birds and carnivores represent among the most unique and diverse species of the rainforest biodiversity. Within the 416001ha protected area, bird diversity of Ranomafana represents a relatively low number of species, but a high number of endemics. 115 bird species are found and more than 60% of them are endemics. The three endemic civet-like carnivore species and two out of the five endemic mongoose species are also well represented in Ranomafana national park. However, environmental deterioration, through human pressures, such as intrusion, illegal mining, forest exploitation; and natural catastrophic damage, like cyclone, erosion, and land slide lead to the vulnerability of these species. Little is known on the impact of environmental and climatic changes on the distribution of bird and carnivore species within the forest area. Ecology and conservation of these species are also poorly understood. From 2010 to 2014, large-scale camera trap monitoring of terrestrial vertebrates within the protected rainforest has revealed that bird and carnivore species distribution has impacted greatly by human induced habitat and environmental climatic changes. Rare and cryptic species are the most vulnerable, as they tend to skip human induced habitat disturbance by moving towards the more pristine habitats. The degree of human frequentation, the presence of invasive species, and the variation of temperature are the most determinant for their distribution and movement within the area. However, no decrease in diversity or abundance of these species was recorded at Ranomafana national park. Conservation management policy of this world heritage rainforest can be greatly influenced by the outcomes from the camera trapping research, especially from studies on the most threatened endemic cryptic species.

USING MULTISCALE PRIORITIZATION CRITERIA TO OPTIMIZE ELECTROCUTION MITIGATION: AN EXAMPLE FOR THE ENDANGERED BONELLI'S EAGLE *AQUILA FASCIATA*

Joan Real

UNIVERSITAT DE BARCELONA

Antonio HERNANDEZ-MATIAS, UNIVERSITAT DE BARCELONA ; Rafel BOSCH, UNIVERSITAT DE BARCELONA ; Alex ROLLAN, UNIVERSITAT DE BARCELONA ; Albert TINTO, UNIVERSITAT DE BARCELONA

Electrocution on power lines is a serious threat to a wide range of birds, including several endangered species. Currently, the main factors that increase the risk of electrocution are known. However, power lines are ubiquitous and approaches

useful to optimize mitigation actions are urgently required. In this regard, we developed a procedure based on multiscale prioritization criteria. It follows four main steps to identify: (i) sink populations over large areas; (ii) sink territories within target populations; (iii) intensively used areas by individuals within target territories; and (iv) dangerous pylons within used areas. We applied this procedure in the endangered Bonelli's Eagle (*Aquila fasciata*) populations in western Europe, where electrocution is a major cause of mortality. We used demographic models to identify sink populations. Then, we focused in the local population of NE Iberia, which acts as a sink, and identified those territories acting as sinks within this population. After that, we delimited the home range of 12 territorial pairs in this area, most of them acting as sinks, which allowed us to identify the power lines candidate to be corrected. In three of these territories, we assessed the dangerousness of all power line pylons. In collaboration with electric companies, we proceed to correct the dangerous pylons. We also monitored the main vital rates of these three territories, both before and after mitigation measures were carried out. Our results suggest that the risk of electrocution would be reduced by 65% by correcting 2.5% of pylons in the 12 territories analyzed. Accordingly, we found a significant increase of survival in those territories where corrections were done, meaning that population viability would be guaranteed. Overall, our study establishes a framework for performing electrocution mitigation actions in a concerted and rigorous fashion and for optimizing resources to address this conservation concern.

LISTENING IN AND NOT LOOKING OUT: CONSIDERING THE DIFFERENCES IN THE ACOUSTICAL ECOLOGY OF BALEEN WHALES TO IMPROVE OPTIMAL MONITORING USING PASSIVE ACOUSTICS.

Angela Paola Recalde Salas

Curtin University

Chandra Patricia SALGADO KENT, Curtin University ; Christine ERBE, Curtin University ; Robert D. MCCAULEY, Curtin University ; Hugh P. POSSINGHAM, The University of Queensland

Passive acoustics monitoring is one of the most common techniques for assessing the effects of underwater noise on baleen whale populations. However, for it to be successfully implemented some basic gaps in acoustical ecology of baleen whale species need to be understood. Blue and humpback whales are two of the most commonly studied species in Western Australia (WA) waters, an area under pressure from coastal development and industrial activities. Here, we compare acoustical detection rates of blue and humpback whales using a combination of acoustic and land based surveys. Surveys were conducted between November-

December of 2010-2014 in Geographe Bay, WA. Land based observations were run using theodolite tracking methods from a 50m hill. An acoustic logger was placed on the seabed at 2.5km from the land station in 30m of water. The recording schedule was either 800 or 1300 seconds every 900 seconds, depending upon the unit deployed. Data presented here only includes the daylight hours between 7am and 6pm. Transmission loss methods were used to identify vocalising groups. A total of 1228 humpback and 87 blue whale groups were visually tracked. Of those less than 30% were vocalising. Differences in the dominant vocalisations were also observed. While humpback whales produced song and non-song sounds with no apparent preference, blue whales mostly produced non-song sounds and only sang in a few occasions. For both species, mother and calf, or mother, calf and escort groups did not sing and were less vocal in terms of non-song sounds. Groups with two individuals and lone singers were the most vocal for blue and humpback whales, respectively. While song is the most widely used vocalisation for monitoring, our results suggest that song may not be the best option for all species at all locations. We suggest the inclusion of non-song sounds to increase the likelihood of species detection and increase the scope of monitoring to other groups such as females with calves.

COEXISTENCE WITH AQUATIC PREDATORS IN THE PERUVIAN AMAZON

Maribel Recharte

University of Stirling

Mathew ANDERSON, Institute of Conservation Research, San Diego Zoo Global ; Phyllis C. LEE, University of Stirling

Human-wildlife interactions are increasing as human populations expand, and some wildlife species cause damage or losses to humans. In Amazonian Peru, communities are principally riparian, and fish provide an important source of protein. We interviewed community members close to the Pucacuro National Reserve (PNR), to see if large aquatic predators are considered problematic. Between September and December 2014, we interviewed men and women in three communities in the PNR buffer zone to determine opinions, attitudes and perceptions towards wildlife. For 58 interviewees, the main activities listed were farming (n=41), hunting (n=35) and fishing (n=20). Despite the dominance of farming and hunting, when asked to rank the top 3 most damaging species from 22 photos of terrestrial (n=8), arboreal (n=7) and aquatic (n=7) animals, the most listed were giant otters (37.9%), pink dolphins (37.9%) and black caiman (36.2%). When asked to choose the worst fishing net damager from 7 aquatic predators: the most commonly ranked first were giant otter (34%), pink dolphin (33%), black caiman (16%), and Neotropical otter (10%). Retaliatory actions occurred against some species. Of 30 respondents, 43% interviewees said they had previously

hunted giant otter (23% because of damage to nets, 20% to sell the skin), although 93% knew that hunting giant otters is currently illegal. 87% thought that there were more otters than 10 years ago, 70% of people agreed that there are enough fish for people and giant otters (n=21) and 73% of interviewees agreed that not all animals that break nets should be killed. However, 73% of people did not like to live close to the otters, 27% felt scared of otters, and 57% of people thought that it would be better if the giant otters disappeared from the area. In Pucacuro, negative attitudes to aquatic predators exist, due to concerns of damage to nets. This may be causing hostility and retaliation towards giant otters in particular, despite legal protection.

RETHINKING THE USE OF PPGIS IN EXPLORING PERCEPTION OF ECOSYSTEM SERVICES - HOW TO ASSURE DATA VALIDITY?

Marcin Rechcinski

Institute of Geography and Spatial Management,
Jagiellonian University

Agnieszka OLSZANSKA, Institute of Nature Conservation, Polish Academy of Sciences ; Agata PIETRZYK-KASZYNSKA, Institute of Nature Conservation, Polish Academy of Sciences [INSTITUTE] Institute of Environmental Sciences, Jagiellonian University ; Barbara PEEK, Institute of Nature Conservation, Polish Academy of Sciences ; Joanna CENT, Institute of Environmental Sciences, Jagiellonian University ; Malgorzata GRODZINSKA-JURCZAK, Institute of Nature Conservation, Polish Academy of Sciences [INSTITUTE] Institute of Environmental Sciences, Jagiellonian University

Although the concept of ecosystem services (ES) has become influential in environmental sciences, relatively less effort is put on improving the ways public perception of ES is investigated. In case of irreplaceable ES, the ES concept has any explanatory power only with the assumption of sustainable use of the services, otherwise – attempts of their valuation would always end up with acquiring infinite figures. Since social perception of ES is crucial for assuring sustainability, we find proper methodology for gathering the data a critical issue. ES without their spatial references would remain abstract constructs, thus examining patterns of their perception should also reflect their geographical attributes. However, despite variety of available PPGIS methods, their limitations seem to be even exacerbated in aforementioned research context. Within the presentation we discuss applicability of both Internet-based and workshop mapping for collecting data on perceived ES distribution. We analyzed the use of both points and polygon as basic units of spatial representation of responses. We comment the issue of perceptual inconsistency of ES categories in the light of its consequences for methods' validity. We review and comment examples of ES operationalization in PPGIS studies

i.e. from Australia, USA and rare examples from Europe. We also provide reflections from empirical studies led in Poland where the basemap with pre-demarcated polygons was used for ES mapping. We describe criteria for establishing the polygons and the role of bottom-up knowledge in defining their borders. Finally, we confront applicability of using regular-grid and habitat-based basemap layer in similar studies. We believe that our recommendations will help to deal with utmost uncertainty: are some ES (e.g. regulating ones) actually poorly recognized by the public or are these only imperfect operationalization techniques, which hinder the process and bias validity of results?

(SYMPOSIUM ID: 33) UNDERSTANDING HUMAN BEHAVIOR AND NATURE TO UNCOVER NEW CONSERVATION STRATEGIES

Sheila Reddy

The Nature Conservancy

Jensen MONTAMBAULT, The Nature Conservancy; Yuta MASUDA, The Nature Conservancy; Jon FISHER, The Nature Conservancy

Human behavior influences virtually all aspects of nature conservation. Yet, to date, conservation science has rarely studied human behavior. The dominant theory of change in conservation about human behavior assumes that there is a deficit of information on environmental conditions or ecosystem services and that decision makers are rational. This theory of change has seldom incorporated other models of or influences on human behavior, such as those that consider psychological, social, or institutional processes. We examine five classes of decision-makers that have a large impact on nature conservation by reviewing the literature to identify models of human behavior that best explain these decisions. Using case examples, we show how human behavior interacts with the ecological, economic, psychological, social, and institutional conditions and constraints in each case and how the strength of the interactions depend on the model of human behavior. Our analysis shows that interactions between humans and nature are often more multi-faceted and less driven by information and rational decision-making than is currently understood by mainstream conservation science and practice. We then identify new conservation strategies that could be used in each case to create systemic change in human's relationship with nature. We discuss how the strategies would complement or contrast with current conservation strategies. The results of this research should provide a new way of thinking about human behavior and nature, as well as specific hypotheses to be tried out and tested.

#165 TOO BUSY SAVING THE WORLD TO BE ACCOUNTABLE

Kent Redford

Archipelago Consulting

Andrew KNIGHT, Imperial College; Matthew KEANE, Environmental Protection Agency

Conservation is a value-based enterprise that was founded as a crisis discipline. Despite its base in science, much of the practice of conservation has been driven by values, funding availability and donor requirements. As such, learning, and the evaluation that is part of it, has received little attention. Though acknowledged as important there are a variety of reasons for this that we will explore in this talk. This lack of work has hampered the ability of conservation practitioners to be accountable, which may be limiting our success.

106-CONSERVATION CONFLICTS: APPROACHES, OPPORTUNITIES AND CHALLENGES

Steve Redpath

Institute of Biological and Environmental Sciences

Conservation conflicts are widespread and typically damaging to biodiversity and human livelihoods. They arise from situations where conservation objectives clash with other objectives, such as those of farmers, or foresters or hunters or business. There is an urgent need to understand how we can most effectively deal with these difficult problems. In this talk I will first reflect on how we frame and understand conservation conflicts and why this is important in developing effective management strategies. I will then move on to consider some of the opportunities and challenges in this field, focusing on i) the role of models in helping us understand conflict, ii) why and how we might link science and stakeholder knowledge, and iii) how we evaluate the effectiveness of alternative conflict resolution strategies. Throughout I will draw on a range of conflict case studies to illustrate the approaches, opportunities and challenges.

BIODIVERSITY SURVEYS GUIDE URBAN DEVELOPMENT STRATEGIES TO CONSERVE NATURE IN THE CITY

Sarah Reed

Wildlife Conservation Society[INSTITUTE]Colorado State University

Jessica SUSHINSKY, Wildlife Conservation Society; Lindsay EX, City of Fort Collins; Liba PEJCHAR, Colorado State University; Kate RENTSCHLAR, City of Fort Collins

More than half of the world's population now lives in urban areas, and preserving natural areas in urban ecosystems is

critical for conserving biodiversity, maintaining ecosystem function, and sustaining human well-being. The population of Fort Collins, Colorado (USA) is projected to grow from 155,000 today to 240,000 by 2045. The Nature in the City initiative aims to minimize negative effects of increasing urbanization by creating a connected open space network that provides a variety of experiences for people and functional habitat for plant and animal species. To support this goal, we formed an interdisciplinary team to assess the current status of biodiversity throughout the City and guide future development patterns. We selected 166 points stratified among nine land uses ranging from formal City Parks and Natural Areas to informal neighborhood open spaces and urban farms across the City's 201 km² growth management area. We conducted repeat point-count and Pollard-walk surveys from May-August 2014, detecting 88 species of birds and 33 species of butterflies. Land use had the greatest influence on species richness and community composition. The greatest numbers of bird species and proportions of urban avoiders were detected in public and private lands managed specifically for their natural resource values, whereas the greatest numbers of butterfly species and proportions of native species were detected in parks and urban farms. Representation of some bird guilds (e.g., grassland specialists, ground nesters, urban avoiders) was positively correlated with site area ($r=0.34-0.47$) and proportion of remnant natural area ($r=0.55-0.60$). Together with concurrent social and economic assessments, occupancy analyses and connectivity models resulting from our study are being used to guide implementation of a strategic plan, which includes design guidelines, policies, and actions to ensure that high-quality natural areas are preserved in a rapidly growing urban environment.

SPATIAL DISTRIBUTION ESTIMATES OF ASSAMESE MACAQUE (*MACACA ASSAMENSIS*) IN SOUTH AND SOUTH-EAST ASIA BASED ON A FIRST OPEN ACCESS ENSEMBLE MODEL-PREDICTION

Ganga Ram Regmi

Global Primate Network-Nepal
Falk HUETTMANN, -EWHALE lab-, University of Alaska Fairbanks (UAF); Madan Krishna SUWAL, Global Primate Network-Nepal; Vincent NIJMAN, Oxford Brookes University; K. A. I. NEKARIS, Oxford Brookes University; Kamal KANDEL, Global Primate Network-Nepal; Narayan SHARMA, National Institute of Advanced Studies, IISC Campus; Camille COUDRAT, Oxford Brookes University

We developed the first quantitative and climatically potential niche distribution models for the Assamese macaque (*Macaca assamensis*) for 12 countries in South and South-east Asia. We used species occurrence records from our own field work as well as extracted species occurrence records from published

sources. We applied Random Forests, Classification and Regression Trees, TreeNet, MaxEnt and Multivariate Adaptive Regression Splines machine learning algorithms in concert. Then we averaged all of these model outputs as an ensemble model prediction. Elevation and 19 environmental layers related to precipitation and temperature from WorldClim were utilized to develop these models. The predicted distribution of Assamese macaque was strongly associated with Precipitation of Warmest Quarter, Temperature Annual Range and Temperature Seasonality. The predicted map shows that there is a continuous and potential niche of Assamese macaque from east of the Kaligandaki river in Nepal up to the Brahmaputra river in northeast India. Other predicted areas seem to be either fragmented or confined to small pockets except in Lao PDR where some continuous potential habitat can be seen in the predicted map. Here we provide the first robust rules and resource selection functions for such predictions using partial dependence plots. Our predictions also confirm that there are no ecologically suitable areas for this species in Pakistan, Afghanistan and Cambodia. Our most significant contribution is the identification of the areas with a high probability of the presence of Assamese macaque, which is the information that can be applied to identify new populations of this species and for planning future surveys in previously un-surveyed areas of the large geographical extent. The model outputs obtained here are also helpful for understanding biogeography and historical ecological niche evolution of the species, as well as for taxonomy, genetics and conservation management.

193 REWILDING AS A LAND-USE OPTION FOR BIODIVERSITY CONSERVATION IN A CONTEXT OF LAND ABANDONMENT AND FIRE DISTURBANCES: WINNERS AND LOSERS

Adrián Regos

Forestry Science Center of Catalonia
Jesús DOMÍNGUEZ, University of Santiago de Compostela; Asunción GIL-TENA, Forestry Science Center of Catalonia; Manuela D'AMÉN, University of Lausanne; Antoine GUIBAN, University of Lausanne; Lluís BROTONS, Forestry Science Center of Catalonia

Land-use change is a large component of global change and the effects on biodiversity and ecosystem services currently represent a major challenge for ecologists and conservationists. Rewilding has been proposed as a potential alternative approach to conservation in abandoned landscapes where rural communities have been depleted because the low-intensity farming that supported them is no longer economically viable. Fire is a major disturbance in Mediterranean ecosystems. For millennia, fire has been a key self-regulating process influenced by natural factors such as climate and vegetation characteristics. Nevertheless,

the ongoing trend towards landscape homogenization that has taken place over recent decades has led to an increase in fire impact. Despite all of this, knowledge about positive and negative effects of rewilding as a land-use option on biodiversity in fire-prone, abandoned landscapes and how fire management policies could alter these causal relationships is astonishingly poor. Here we present one of the first assessments of rewilding as an opportunity for biodiversity conservation in a context of land abandonment and fire disturbance in Spain. Two fire-prone, abandoned landscapes and their past and potential future pathways were evaluated combining medium-term data on avifauna distribution with information on temporal changes in land-use/land-cover from remote sensing data and landscape dynamic simulations. Our results showed that rewilding in these landscapes provides habitat for high-priority, shrub-forest-dwelling bird species at the cost of modest reductions in numbers of open-habitat birds. In addition, fire suppression strategies based on 'letting fires burn' could counterbalance the negative effects of land abandonment on fire risk and biodiversity conservation. We conclude that biodiversity conservation via rewilding could be a cost-effective land-use option in abandoned landscapes wherein fire management programs should be also integrated.

ADVANCING PUBLIC LANDS MANAGEMENT: A MODEL FOR FILLING THE IMPLEMENTATION VOID

Evan Reimondo

Western Sense

Spencer PLUMB, University of Idaho

Two US federal agencies, the US Forest Service and the Bureau of Land Management, are jointly responsible for managing approximately 1,781,000 km² of public lands. Managers are facing threats to public resources of unprecedented scale and severity with dwindling budgets and fewer personnel, and their ability to innovate is often constrained by policies and institutional barriers. Worsening budget shortfalls are resulting from national funding cutbacks and emergency internal borrowing to respond to natural disasters like catastrophic wildfires. This has created an "implementation void" due to the loss of technicians who perform on-the-ground implementation of policies, plans, and rules related to conservation and restoration. We propose a model of integrating a nonprofit internship program with existing federal volunteer programs to leverage funds and human power to fill this void. Nonprofits can leverage diverse funding sources over multiple years, bypassing current shortfalls of agency budget cycles, and are mission-driven to achieve these objectives. The existing federal volunteer programs are an affordable way to put "boots on the ground," but are traditionally limited to those who are willing and able to volunteer, and be without compensation, for extended periods. Our model would select interns through a competitive process

and award recipients with a supplemental stipend. The intern would function as full-time agency staff, but be required to devote a percentage of their time to a pre-determined conservation or restoration project. These projects, defined in consultation with regional community leaders, NGOs, and agency staff, would have high potential value and otherwise lack the necessary funding or staff. The local or regional focus of these projects allows communities to have a meaningful impact in protecting and restoring their public lands through tax-deductible donations to support the internship program's project.

SEMINATURAL FORESTRY CAN SUSTAIN LAND SNAIL ASSEMBLAGES: A CASE STUDY ACROSS FOREST TYPES IN ESTONIA

Liina Remm

University of Tartu

Asko LÕHMUS, University of Tartu

Snails are an integral part of many forest ecosystems. Their sensitivity to timber harvesting seems to depend on multiple and sometimes counteractive factors. Some snail species have been proposed to indicate natural forest conditions, and old-growth forests with abundant dead wood have been reported to be most species rich. Other studies, in contrast, have demonstrated richer snail fauna in young managed forests, and clearcutting has been hypothesized to be less detrimental on wet soils. We examined forest management impacts in 100 stands, which represented a balanced design of five site types and four management types (old and mature forests, retention cuts and clearcuts, harvested 5-11 years ago). We collected ca. 20,000 individuals of 70 species and found that snail assemblages differ between site types. Dry pine forests with sparse vegetation and little woody debris were most distinct having only scant snail assemblages. Stand scale analyses showed that snail assemblages are tolerant of seminatural timber harvesting in all studied site types. We found neither strongly negative nor positive responses to timber harvesting for any species, no influence of the amount of woody debris or any species preferring old growth. In fact, several species that have been claimed to indicate natural forest tolerated timber harvesting well, and they were rather more abundant on clearcuts than in closed stands. The single retention trees on cut sites did not have remarkable impact on snail assemblages. Thus, seminatural forestry in such humid temperate climate and on calcium poor to moderately rich sites seems to sustain comparatively intact snail assemblages. The tolerance might be explained by lack of soil scarification on clearcuts and allowing natural regeneration instead of planting pure coniferous stands. However, snail assemblages are prone to combined effects of various intensive techniques, as can be demonstrated for cutting activities in artificially drained swamps.

WHAT HAPPENS WHEN 100 KM² OF SAND DUNES ARE SPRAYED WITH PESTICIDES?

Ittai Renan

Tel Aviv University

Yael LESHNO, Tel Aviv University

Swarms of locusts (*Locusta migratoria*) invaded the western Negev sand dunes in Israel during March 2013. Four weeks later, tens of millions of locust larvae hatched and marched across the dunes. In order to reduce swarm numbers, pesticides were sprayed by the Israel Ministry of Agriculture over the course of six weeks, covering more than 100 km². Arthropod-specific pesticides were used and no secondary poisoning was detected. Arthropods constitute the majority of fauna in most terrestrial habitats, forming a significant functional component due to their diverse feeding habits and lifestyles. Changes to the arthropod community may significantly impact the ecological functions of the habitat and lead to a cascade of negative processes. This study examined the impact of the intensive pesticide application on the terrestrial arthropod community. Arthropod sampling was undertaken in the spring of 2013, 50 days after the first spraying event, and in the following spring of 2014. Eight sprayed and eight control plots were sampled. Arthropods were collected from each plot via 25 pitfall traps, left open for 48 hours in each of the two years. A total of 4,736 specimens were collected from 400 pitfall traps. No significant differences in the arthropod community between the sprayed and unsprayed plots were found in spring 2013. However, in 2014 uni- and multivariate analyses revealed a significant decrease in diversity indices in the sprayed plots. The arthropod community in the sprayed area was highly dominated by ants, mainly *Cataglyphis savignyi*, a large scavenger that accounted for 66% of all individuals. A significant decrease in functional diversity index was found in the sprayed plots also when omitting the ants from the analysis. Ongoing monitoring of the area in 2015 (to be presented) will provide a better understanding of the system's response to the severe spraying event and its consequent impact on biodiversity.

FROM BEHAVIORAL PATTERNS TO POPULATION GENETICS: THE REINTRODUCED ASIATIC WILD ASS IN THE NEGEV DESERT

Sharon Renan

Ben-Gurion University of the Negev

Gili GREENBAUM, Ben-Gurion University of the Negev ; Alon ZIV, Ben-Gurion University of the Negev ; Naama SHAHAR, Ben-Gurion University of the Negev ; Alan R. TEMPLETON, Washington University ; Amos BOUSKILA, Ben-Gurion

University of the Negev ; Shirli BAR-DAVID, Ben-Gurion University of the Negev

Long-term viability of populations is highly dependent on genetic diversity. One factor that can strongly influence genetic diversity of small populations is the social structure, affecting both gene flow and genetic drift. Therefore, in threatened species, studying the social behavior and its effect on population genetics is of high importance. The endangered Asiatic wild ass (*Equus hemionus*) was reintroduced to the Negev Desert, Israel, and population's activity centers were naturally established around water sources. This species lives in a resource-defense polygyny in which dominant territorial males obtain most of the mating opportunities. We hypothesized that if territorial males constitute only a small portion of all males and their dominance tenure is relatively long, the strong site fidelity of these genetically important males may result in limited gene flow among activity centers, accelerating the development of population structuring. We combined behavioral observations, non-invasive genetic study and simulation modeling to examine the level of polygyny and male dominance stability of the wild ass, and to evaluate the spatial genetic structure of the Negev population. From five years of behavioral observations, we found that only a quarter of all males were dominant and that males remained dominant for several years. This was supported by a simulation model, based on genetic data, revealing a strongly polygynous mating system in which less than 25% of all males participate in the mating process. Additionally, a population genetic structure among activity centers was detected. This structure could be a result of limited gene flow, possibly due to strong site fidelity of dominant males, coupled with potential founder effects during the population's establishment. The information gained in this study can be applied for assessing the Asiatic wild ass long term viability and as a basis for conservation and management regimes.

1.01 INTEGRATING GENETIC AND STABLE ISOTOPE ANALYSES TO INFER THE POPULATION STRUCTURE OF THE SNOWFINCH (*MONTIFRINGILLA NIVALIS*) IN WESTERN EUROPE

Alpine ecosystems count among the most threatened by climate change. Species occurring in high mountains now face high risk of habitat loss, range contractions and local extinction. The Snowfinch (*Montifringilla nivalis*) is a characteristic passerine of alpine habitats in Europe. Despite its breeding nuclei are relatively well-defined, we still know little about the connectivity between breeding and wintering grounds. Based on a 10 year banding program conducted in the Eastern Pyrenees during winter, we know there is connectivity between breeding grounds in the Alps and overwintering areas in the Pyrenees. Return rates of banded birds are however too low to address how often such movements occur. By analysing intrinsic biomarkers (i.e. sequences of the mitochondrial gene *cyt b* and stable isotopes $\delta^2\text{H}$), here we assess to which extent breeding populations of Snowfinches in the Cantabrian Mountains, Pyrenees and Alps and the wintering population in the Eastern Pyrenees function as a metapopulation. Two out of three main haplotypes (A and B) characterized for *cyt b* were present in all breeding populations, but haplotype C is only found in the Cantabrian Mountains and predominant there. Most wintering individuals either have A or B but none show C. Two more haplotypes (D and E) are present in a few wintering individuals. Thus initial genetic analyses suggest connectivity between all breeding populations, although the one at the Cantabrian Mountains seem to be more isolated. Wintering individuals in the Eastern Pyrenees may have their breeding grounds either in the Pyrenees or the Alps but less likely in the Cantabrian Mountains. No differences in $\delta^2\text{H}$ from the most inner primary were found between breeding populations so we could not assign the breeding grounds of wintering individuals by isotopic analysis. Further analyses are required for a better understanding of the species' population structure in Western Europe.

LIVE CAPTURE AND OWNERSHIP OF LEMURS IN MADAGASCAR: EXTENT AND CONSERVATION IMPLICATIONS

Kim Reuter

Temple University

Haley Gilles, Temple University; Abigail Wills, Mpingo Conservation & Development Initiative; Brent Sewall, Temple University

Overexploitation represents a severe threat to biodiversity, with live capture affecting millions of animals yearly. The

impacts of live capture could be extensive as 4 million living birds, 640,000 reptiles, and 40,000 primates are captured and traded globally each year; the live capture of animals could be widespread and increasing. Little is known about the live capture of Madagascar's mammals, 97% of which are endemic. This is especially true for Madagascar's lemurs, which are the world's most threatened group of large vertebrates. Therefore, this study aimed to increase an understanding of the captive ownership of lemurs. Our objectives were to provide the first quantitative estimates of (1) the prevalence, spatial extent, correlates, and timing of lemur ownership; and (2) procurement methods, within-country movements, and numbers and durations of ownership. Using semi-structured interviews of 1093 households and 61 transporters across 17 towns, we found that lemur ownership was common, widespread, and affected a variety of taxa. Lemur ownership is ongoing, impacting an estimated 28,253 animals since 2010. Most lemurs were caught by owners, and kept for short (≤ 1 week) or long (≥ 3 years) periods. The live capture of lemurs within Madagascar is not highly organized, but may threaten several already-endangered species. Our work is an important first step towards quantifying the live capture of lemurs, informing efforts to conserve lemur populations, and clarifying means to effectively regulate lemur ownership. These findings illustrate how common and widespread lemur ownership is, and further indicate that a large number of threatened or otherwise susceptible taxa may be affected. In addition, these findings underscore the importance of quantifying ownership of endemic primates in other tropical countries, especially where they are facing additional anthropogenic threats like hunting and habitat change.

THE CONSUMPTION OF WILD MEAT IN MADAGASCAR: FOOD SECURITY, DRIVERS OF CONSUMPTION, AND POPULARITY AS A FOOD ITEM

Kim Reuter

Temple University

Brent SEWALL, Temple University

The role of wild meat consumption in developing countries is debated; some communities rely heavily on wild meat, yet others treat it as a luxury good. We investigated the role of wild meat in food security in Madagascar, a country with high levels of malnutrition, but where wild meat consumption is poorly understood in urban areas and at regional scales. Specifically, we aimed to: 1) quantify the amount and purpose of; 2) understand the macro-level drivers behind; and, 3) examine recent changes in wild meat consumption in Madagascar. Using semi-structured interviews with 1339 heads-of-household in 12 urban and nine rural towns, we found that few respondents preferred wild meat ($8 \pm 3\%$) but most had eaten it at least once ($78 \pm 7\%$), and consumption occurred across ethnic groups and in urban and rural settings. More food

insecure areas reported higher rates of recent consumption of wild meat. However, patterns of wild meat consumption were best explained by individual preferences and taboos. Despite reports of increasing wild meat consumption in Madagascar, few respondents ($<1 \pm <1\%$) had increased rates of wild meat consumption during their lifetimes, and wild meat prices showed no change from 2005-2013. Most consumption involved wild pigs, or small-bodied animals such as bats and tenrecs, though these animal groups and lemurs were consumed less in recent years. Given the low preference for wild meat, the focus of wild meat consumption on mostly small-bodied animals, and evidence that ongoing hunting is unsustainable, wild meat is unlikely to enhance food security for most Malagasy people in urban and well-connected rural areas.

SYMPOSIUM ID 88: POTENTIAL LIMITING FACTORS OF REINTRODUCTION SUCCESS ACROSS MULTIPLE SPATIAL SCALES: AN EXAMPLE WITH THE IBERIAN LYNX

Eloy Revilla

Estacion Biologica de Doñana CSIC

Carlos RODRÍGUEZ, Estacion Biologica de Doñana CSIC; José Antonio GODOY, Estacion Biologica de Doñana CSIC; Mireia CASAS-MARCÉ, University of Canterbury

Apart from a poor design and implementation and the wrong environmental conditions, many things can lead a reintroduction to failure. In many cases failures associate with non-evident combinations of environmental conditions precluding the long term establishment of new populations. Here we investigate thresholds in combinations of demographic scenarios that may allow for the successful reintroduction of Iberian lynx (*Lynx pardinus*), from local populations to the distribution range of the species. Isolated areas should have a carrying capacity of at least 20 female territories with a normal breeding rate and high resident's survival rates (equivalent to good quality habitat in protected areas). The spatial distribution of breeding habitat should be continuous as fragmentation seriously limits success (the threshold in carrying capacity goes up to 30 when distributed in two patches). In order to be sure that the number of animals released is non-limiting, we should release above 4 animals of each sex per year during 5 years. These recommendations can be relaxed with larger spatially structured populations connected by dispersers. Using a set of areas preselected by informed managers, we determined that for many scenarios we can have a few isolated areas (including the existing Doñana population) and a large system in central Spain, including Sierra Morena-Montes de Toledo historical range in which the current Andújar population has a central location (in general areas more than 50 km apart will be isolated). The good news is that the large central population (Andújar plus 6 reintroduced

small local populations) can have a low long term extinction risk even with moderately high mortality rates. The bad news is that a normal breeding rate is required. The outbreak of a new disease affecting lynx prey (European rabbits) precludes normal breeding, as already happened during the collapse of lynx populations due to the appearance of rabbit hemorrhagic disease.

95 LINEAR INFRASTRUCTURE PLANNING AT LANDSCAPE SCALES: IMPACTS, COSTS AND COLLABORATION

Jonathan Rhodes

The University of Queensland

Sharna BOURKE, The University of Queensland; Ascelin GORDON, RMIT University; Claire RUNGE, The University of Queensland; Ayesha TULLOCH, Australian National University

Linear infrastructure such as roads, railway lines, and pipe lines present significant threats to biodiversity through both direct and indirect impacts. Linear infrastructure commonly has strong local impacts on biodiversity, but cumulative impacts across infrastructure networks can also lead to substantial impacts on biodiversity at broader scales. Dealing with these cumulative impacts requires an assessment of environmental impacts at the scale of whole landscapes, rather than only at the site scale. Using landscape scale models it can be shown that the impact of linear infrastructure networks depends on the spatial patterns of linear infrastructure and particularly in relation to the spatial pattern of biodiversity. However, the choice of linear infrastructure placement also drives the economic costs of construction and maintenance; a critical factor driving the feasibility of alternative locations. We therefore extended the assessment of landscape scale linear infrastructure impacts to also consider the trade-offs between costs and biodiversity impacts. We show that the trade-off between construction costs and biodiversity impacts depends critically on the distribution of biodiversity in the landscape. However, we also show that costs can be reduced substantially through collaboration among infrastructure providers, although the economic benefits of collaboration can be highly asymmetric. This provides general insights into the economic feasibility of minimising linear infrastructure impacts on biodiversity and has important implications for how we design linear infrastructure networks that are biodiversity friendly.

PREDICTING ANURAN VULNERABILITY IN A BIODIVERSITY HOTSPOT: AN INTEGRATED TRAIT-BASED ANALYSIS

Joana Ribeiro

University of Aveiro

Guarino COLLI, University of Brasilia, Department of Biology; Janalee CALDWELL, Sam Noble Museum & Department of

Biology, University of Oklahoma ; Amadeu SOARES, University of Aveiro

Determining species extinction risk and its drivers is one of the major goals of conservation biology. Species traits are often associated with extinction risk and perceived as determinant for species resiliency to disturbances. Trait-based analyses may identify potentially vulnerable species, even when data are scarce (e.g. Data Deficient species). Standing as Brazil's agricultural frontier, the Cerrado is one of the world's most imperiled biomes. Despite its high endemism, the Cerrado herpetofauna remains largely disregarded and generally perceived as resilient to disturbances. We provide a predictive spatially explicit assessment of anuran vulnerability in the Cerrado, based on intrinsic species traits and extrinsic environmental variables for 195 species extant in the biome. We applied machine-learning techniques to built decision-tree models using IUCN population trend and expert-perceived vulnerability as proxies for anuran vulnerability. About 23% of Least Concern species are sensitive and 13% are decreasing. Furthermore, 65% of Data Deficient species are predicted as sensitive, 11% as decreasing and 17% as sensitive and decreasing. Breeding site, clutch size, range size and body size are important predictors of anuran vulnerability to habitat alteration. Family is the main predictor of decreasing population trends, although stream-associated breeding habits are also important, especially if in synergy with forest/rupestrian habitats. The center of the Cerrado is the main hotspot for sensitive/decreasing anuran species, but effective protection is very low in this region because protected areas are scarce, small and disconnected, while crops and pastures are ubiquitous. This study is the first to predict and represent anuran vulnerability using several intrinsic traits and extrinsic variables to direct conservation practice in the Cerrado, while also identifying important patterns for anuran conservation worldwide.

REAPING THE LAST HARVEST: POST-DEPLETION TIMBER VALUE OF AMAZONIAN FOREST STANDS

Vanessa Richardson

University of East Anglia

Carlos PERES, University of East Anglia

Slow-renewal biological resource populations have been predictably overexploited over the course of human history, often to economic extinction. Industrial scale logging in old-growth tropical forests occurs along variable-aged logging frontiers. Initially highly selective operations target slow-growing, shade-tolerant hardwood species, but subsequent harvests may shift towards fast-growing light-wooded pioneer trees. Brazil accounts for 85% of the roundlog production in the Latin America/Caribbean region, Pará state for almost 50% of all offtakes from Brazilian Amazonia. Yet the degree to

which subsequent timber harvests can be financially profitable or demographically sustainable remains poorly understood. We report data on the legally planned logging of ~9.6 million m³ of timber across 314 species extracted from 446 private and community-based logging concessions between 2009 and 2012. Using data from government-approved logging concession management plans, we document patterns of timber offtake by volume, species and value along aging logging frontiers of eastern Amazonia, which are then explained on the basis of historical and environmental variables. Generalized linear models indicate that logging operations farthest from heavy-traffic roads can afford to be most selective, concentrating their gross timber revenues on fewer high-value species. We find no evidence that the post-depletion timber species composition and total value of forest stands recovers, suggesting that high value timber species become predictably rare or economically extinct in old logging frontiers. Predicting the sustained financial yields of selectively-logged forests is crucial for the long-term integrity of both forest biodiversity and the financial viability of local extractive industries. The history of logging in primary forests in Pará likely mirrors broad patterns of sequential timber exploitation over time elsewhere in Brazil, and arguably throughout the humid tropics.

208 THE CITIZEN SCIENCE STRATEGY 2020 FOR GERMANY

Anett Richter

Helmholtz- Centre for Environmental Research (UFZ)/ Centre for Integrated Biodiversity Research (iDiv)

Lisa PETTIBONE, Museum für Naturkunde

Citizen science at an international level is currently experiencing an increasing attention among scientists, politicians, members of the society and policymakers. Germany is no exception to this trend, which has increased the need to develop a strategy to promote and support citizen science in Germany. "Citizens create knowledge" (in German, "Bürger schaffen WISSEN" or GEWISS) is a capacity-building program and online platform for citizen science in Germany, led by a consortium of 10 scientific institutions and partners. GEWISS aims to develop citizen science in Germany in several ways: networking and exchange for engaged or interested actors; analysis of current citizen science activities and needs; development of a citizen science toolkit for practitioners; and the development of the Citizen Science Strategy 2020 for Germany through a moderated consultation process. Here, we focus on development of a citizen science strategy 2020 for Germany. Specifically, we report on the initial results of the consultation process, and discuss the possibilities and challenges of using online consultations as a practical tool to allow equitable participation of all actors in the diverse citizen science community. We discuss the two-stage online

consultation conducted in parallel to a series of dialogue events in 2015. The GEWISS consultation was based on a draft strategy document developed during a think tank event and kick-off conference in 2014. We discuss the challenges surrounding the consultation process and link them to concepts of e-Democracy and Government 2.0.

CHANGING OCEANS - CHANGING FISH CONSUMPTION. A PSYCHOLOGICAL APPROACH TOWARDS SUSTAINABLE FISH CONSUMPTION AS A WAY OF COMBATTING OVERFISHING

Isabel Richter

NTNU

Christian KLOECKNER, NTNU ; Mehmet MEHMETOGLU, NTNU

The thoughtless mass-consumption of seafood drives the oceans to complete exploitation. Besides changes on industrial and governmental levels, it is also the consumer's responsibility to shift consumption patterns. This presentation shows how seafood consumption can be shifted into a sustainable direction by merging the knowledge of marine biology with theories and methods of environmental psychology. A challenge in addressing seafood consumption is the fuzziness of its concepts. Therefore, a definition for sustainable fish consumption (SFC) from a consumer perspective is introduced. Subsequently, potential predictors of SFC are selected and analyzed, including variables covering the three subcategories proposed in Thøgersen's (1995) Motivation-Opportunity-Ability Model. The opportunity part comprises socioeconomic characteristics, living conditions and product qualities like availability, visibility, price and labelling that hinder or facilitate the behavioral performance of SFC. The motivational part includes common psychological variables like intentions, attitudes and norms and the availability part finally incorporates habits and knowledge about the target behavior. The predictive value of each variable is discussed and inter-variable relationships are suggested in orientation to widely applied models from environmental and social psychology. The best variable fit is verified with Structural Equation Modelling ending up in a comprehensive model for SFC. The psychological analysis of SFC as the target behavior provides an ideal starting point for effective intervention design because interventions can be individually adapted to target groups (i.e. from different countries) in consideration to the pattern the predicting variables show. The SFC model will be used to create and later evaluate effective interventions for a national campaign fostering SFC together with the World Wildlife Fund Norway.

IMPROVING COMPLEMENTARITY WITHIN A PORTFOLIO OF CONSERVATION FENCES

Jeremy Ringma

The University of Queensland

Wintle BRENDAN, The University of Melbourne ; Richard FULLER, The University of Queensland ; Diana FISHER, The University of Queensland ; Michael BODE, The University of Melbourne [INSTITUTE] The University of Melbourne

Invasive predators are a major cause of wildlife decline globally. In Australia, 30 % of native mammals are at risk of extinction, primarily as a result of predation by introduced feral cats and foxes. Feral predators have contributed to the extinction of at least 20 species of Australian mammals and are listed nationally as a major threatening process for further 58. Translocations within predator exclusion fences are the more favourable option over baited areas because for many of these species only fences can provide sufficient predator protection.. A gap analysis of Australia's fenced conservation areas (30 in total), targeted the 58 threatened mammal species that would most benefit from predator exclusion fences. Only one third of the species were represented within fenced areas, but many of the species that were protected were represented many times, often disproportionately to their extinction risk. It appears that fence conservation areas in Australia are emerging from largely from ad hoc decision making. Without a systematic approach to determining suitable fence locations, cost inefficiency and compromised conservation of important threatened species is likely. We developed a decision support tool for systematically identifying and assessing priority sites for future fencing projects, to create more representative fence network. The method considers biogeographic and population viability factors to measure the complementary benefits offered by a new fence at any point in a landscape. A greedy algorithm chooses the optimal combination of new fenced sites that lead to the greatest reduction in risk of extinction for threatened species included in the study. Although we analyzed fencing options in the state of New South Wales; the generality of our approach means that it can be applied to any spatially localised management action that benefits a suite of species, such as the location of a baiting program, or the choice of islands for translocations.

EFFECT OF LANDSCAPE FRAGMENTATION ON GENETIC DIVERSITY OF A GENERALIST SPECIES IN CHIAPAS, MEXICO

Tamara Rioja-Paradela

Oikos: Conservacion y Desarrollo Sustentable A.C.

Arturo Carrillo-Reyes, Universidad de Ciencias y Artes de Chiapas ; Andrea ROJAS, Universidad de Ciencias y Artes de Chiapas ; Eduardo ESPINOZA-MEDINILLA, Universidad de Ciencias y Artes de Chiapas

One of the main consequences of landscape fragmentation is the reduction of species diversity in the remaining landscape patches. Fragmentation are also reflected at the genetic level,

particularly in the genetic diversity of populations isolated by landscape degradation. However, certain generalists species characterized by high population density and short dispersion ranges seem to thrive in fragmented landscapes. This study aimed to estimate the effect of landscape fragmentation on a generalist species, *Peromyscus mexicanus*, in tropical forest sites with varying degrees of fragmentation, in Chiapas, Mexico. During 2012, five sampling sites were established in a highly fragmented area, and five in an area with average-low fragmentation rates. Each site was established with a minimum distance of 500 meters between each other. At each site were captured 5-8 individuals, which were measured and weighed. In addition, a tissue sample was taken. All individuals were eventually released on the same site of capture. Nine landscape fragmentation variables for each of the capture sites was measured. Genetic diversity was calculated for each site. Finally, F_{st} values were contrasted against landscape variables by GESTE, and confirmed by the method implemented by Passage. Results showed that the degree of fragmentation had no significant effect on the genetic diversity despite the landscape fragmentation level. Prevalence of these generalist species despite high fragmentation level becomes relevant because the fragmentation not only adversely affects certain species, but also can benefit to potentially harmful species, which can displace species of restricted distribution. Also, can become a public health risk to humans, since they can be reservoirs of diseases.

SECONDARY HABITATS: A VALUABLE OPPORTUNITY FOR THE CONSERVATION OF VERTEBRATES IN THE CENTRAL MEXICAN PLATEAU

Mónica E. Riojas-López

CUCBA-University of Guadalajara

Eric MELLINK, Centro de Investigación Científica y de Educación Superior de Ensenada

During the last 100 years, human activities have modified natural landscapes at considerable scale and speed, generating, in many cases, complex secondary landscapes. Some of these retain some characteristics of the original landscapes, in which more or less random assemblages of native plants and animals survive successfully. In the central part of Mexico's Central Plateau, agriculture and animal husbandry have caused a drastic transformation of the original landscape, and the area is now covered mostly by secondary habitat patches. The ecological consequences of this transformation have not been recorded, but are likely to include negative impacts to many species of the native flora and fauna. However, the establishment of natural protected areas in the area to alleviate these impacts is highly unlikely, due to the scale of landscape transformation. Hence, biological conservation must rest on the tapestry of man-modified, or created, habitats. For the past decade we have studied some of the ecological characteristics

of the communities of terrestrial vertebrates in different secondary habitats. Our findings indicate that just three of the most emblematic secondary habitats in the Llanos de Ojuelos (grasslands, nopal orchards, water reservoirs) support at least about 40% of all potential bird species and 80% of rodent species of the area, in addition to many amphibians and reptiles, including 17 or more species of conservation concern. Our data provide evidence that secondary habitats can indeed be the basis for a regional biodiversity conservation program. However, in addition to management decisions to benefit certain species and promote other ecosystem services, to be effective, it is imperative that such conservation projects be compatible with resource appropriation by humans, especially those many farmers that survive under precarious conditions.

DOES THE MATRIX TYPE MODIFY THE RODENT COMMUNITY COMPOSITION IN PRICKLY PEAR ORCHARDS IN THE CENTRAL HIGH PLATEAU OF MEXICO?

Mónica E. Riojas-López

CUCBA-University of Guadalajara

Eric MELLINK, Centro de Investigación Científica y de Educación Superior de Ensenada ; Patrick GIRAUDOUX, Département de Chronoenvironnement, Université de Franche-Comté- CNRS, Usc INRA and Institut Universitaire de France

Some perennial agroecosystems retain a considerable number of wildlife species. In the Central high Plateau of Mexico fruit-oriented prickly pear orchards, based on 30 different varieties, offer suitable conditions for native rodent species that occupy natural habitats that are currently highly modified and/or fragmented. The orchards are patches distributed in different matrix types, and it was not known whether the matrix affected the composition of their rodent assemblages. To assess this, during each of the three climatic regional seasons we performed a rodent survey in 12 orchards in three different matrix types: secondary shrubland, grassland and rain-fed annual agriculture. Species richness, diversity value (Shannon exponential index), and same-matrix inter-orchards similarity were not different between orchards in different matrix type. The orchards were as diverse and as rich as the adjacent shrubland matrix (16 out of 25 potential species for the region), and significantly richer than the grassland and rain-fed agriculture habitats. The rodent assemblages in orchards in shrubland matrix were significantly more similar to those of the matrix ($40 \pm 8\%$), than the ones in grassland ($3\% \pm 1$) or in rain-fed agriculture ($8 \pm 4\%$) were to their matrix. The orchards have a similar habitat structure to some of the secondary shrublands in the region. In all the orchards studied we captured rodent species commonly present in both, the region's shrublands and grasslands. Based on the data we concluded that: 1) prickly pear orchards retain 64% of the known native rodent species

regardless of the surrounding matrix, (2) they can contribute importantly to biodiversity conservation in the region, and (3) their structural attributes can be managed (without negatively affect fruit production) to reach specific conservation objectives.

LAND USE AND DEFORESTATION IN THE PERUVIAN AMAZON: IMPACTS OF DIFFERENT LAND USE STRATEGIES OVER CLIMATE CHANGE

Sandra Rios

Instituto del Bien Comun

Percy SUMMERS, Conservation International

Amazonia has recently received wide attention for its role in climate change regulation. Substantial efforts have been placed to measure the role of forests and land use change over the carbon cycle, especially greenhouse gas emissions from deforestation. However, the relationship between different land management regimes and their impacts over land use change processes and how this can impact climate change have not been analyzed thoroughly. We present a comprehensive analysis of the impact of different land use types over carbon stocks and its potential impacts over climate change processes using Peru as a case study. We especially review different land cover configurations depending on tenure arrangements, the management regime and management potential to impact the role of forests in climate change processes. Forests managed as commons will be compared with other land cover types like public and private management, as well as open access, for climate change implications. Close to 20% of the land in the Peruvian Amazon is titled as indigenous communities and an even larger percentage is under their management and control. Also, riverine people control another similar percentage of land but without any official land tenure recognition. Recent studies of deforestation have highlighted the reduced rates in indigenous community lands in comparison with the national average, suggesting an important role of indigenous peoples in managing their territories as commons. As we have been compiling additional geographical information on other land cover type and management regimes such as protected areas and forest concessions we will expand the analysis to include the range of land cover management regimes existing in the Amazon. Analysis will focus on how deforestation varies between different tenure regimes, land management regimes and competing land use.

AGRI-ENVIRONMENT SCHEMES IN AGRICULTURAL LANDSCAPES: THE IMPORTANCE OF AREA, QUALITY AND CONNECTIVITY FOR BIRD AND BUTTERFLY BIODIVERSITY

Eva Ritschard

University of Bern

Silvia ZINGG, University of Bern ; Raphaël ARLETTAZ, University of Bern ; Jean-Yves HUMBERT, University of Bern

European farmland biodiversity is facing serious declines due to agricultural intensification since the second half of the 20th century. Since decades European governments subsidize agri-environment schemes (AES), aiming to counteract the loss of biodiversity. Thereby, semi-natural habitats, such as extensively managed meadows, wildflower-strips, hedgerows or traditional orchards, are managed as wildlife-friendly areas in agricultural landscapes. However, evaluation studies showed that their effects on biodiversity are only modest and that we still observe a persisting decline in biodiversity. Missing connectivity between AES or too poor quality of individual AES, are often used as arguments to explain the lack of effectiveness of these schemes. In our project we studied the influence of AES on bird and butterfly species richness and abundance in over 40 agricultural landscapes (1 km²) in Switzerland. We found a positive effect of total AES area (% of utilized agricultural area) on overall bird species richness and a particularly strong effect on farmland species abundance and richness. However, there was no evidence that connectivity (distance between AES) has an effect on bird species richness or abundance (when total AES area was taken into account). Butterfly data are currently analysed. There is an urgent need to define and implement effective conservation measures if we want to stop the loss of biodiversity in agricultural landscapes. The results of our study will help decision makers to allocate AES financial resources in the most effective way, by defining if they should be invested in increasing the total amount of area under AES, the connectivity or the quality of them.

FLYING OFF RAILS: HABITAT LOSS DUE TO CLIMATE CHANGE MAY ENDANGER MARSH-DWELLING BIRDS

Nicolette Roach

Clemson University

Kyle BARRETT, Clemson University ; Elizabeth HUNTER, University of Georgia ; Nathan NIBBELINK, University of Georgia

Species distribution models have been applied across a wide range of spatial scales to generate information for conservation planning. However, the generality of these models has rarely been tested. Understanding how well models transfer through space and time is important to promote effective species-habitat conservation. When transferability of models is evaluated it is typically done using occurrence data. Here we assess model transferability in coastal tidal marshes of the Southeastern United States using point counts of a widespread marsh bird: the clapper rail (*Rallus crepitans*). We first derived the top species-habitat models at a state-level in both South Carolina and Georgia, and then assessed how well top models from each state predicted abundances across the region. Internally (locally) validated models performed well

with reasonable fit, and high significance; however, during the independent model validation process (between states) both models performed poorly. Even if model transfer across regions poorly predicts absolute abundance, it is possible that transferred models still have utility for identifying the best relative habitat. To address this possibility, we applied the South Carolina- and Georgia-derived parameters to habitat features in South Carolina and then identified the top 25% of tidal marsh habitat each model predicted within the state. Our results address the predictive power and uncertainties that arise from using habitat associations and climate models to predict species distributions or abundances through space. We discuss potential reasons model transferability was not successful and address the need for better regional datasets and further studies addressing issues associated with transferability.

RELATIVE CONTRIBUTIONS OF SET-ASIDES AND TREE RETENTION TO THE LONG-TERM AVAILABILITY OF KEY FOREST BIODIVERSITY STRUCTURES AT THE LANDSCAPE SCALE

Jean-Michel Roberge

Swedish University of Agricultural Sciences (SLU)
Tomas LÄMÅS, Swedish University of Agricultural Sciences (SLU); Tomas LUNDMARK, Swedish University of Agricultural Sciences (SLU); Thomas RANIUS, Swedish University of Agricultural Sciences (SLU); Adam FELTON, Swedish University of Agricultural Sciences (SLU); Annika NORDIN, Swedish University of Agricultural Sciences (SLU)

During recent decades new environmental measures have been implemented in forestry. In Fennoscandia, forest management practices were modified to set aside conservation areas and to retain trees at final felling. In this study we simulated the long-term effects of set-aside establishment and tree retention practices on the future availability of large trees and dead wood, two forest structures of documented importance to biodiversity conservation. Using the Heureka forest decision support system, we projected the amounts of these structures over two centuries in two managed boreal landscapes, under management scenarios with and without set-asides and tree retention. In line with common best practice, we simulated set-asides covering 5% of the productive area with priority to older stands, as well as ~5% green-tree retention (solitary trees and forest patches) including high-stump creation at final felling. We found that only tree retention contributed to sizeable increases in the future density of large (DBH ≥ 35 cm) deciduous trees, while both measures made substantial contributions to the availability of large conifers. It took more than half a century to observe stronger increases in the densities of large deciduous trees as an effect of tree retention. The mean landscape-scale volumes of hard dead

wood fluctuated widely, but the conservation measures yielded values which were, on average over the entire simulation period, about 2.5 times as high as for scenarios without these measures. While the density of large conifers increased with time in the landscape initially dominated by younger forest, best practice conservation measures did not avert a long-term decrease in large conifer availability in the landscape initially containing more old forest. Our results highlight the needs to adopt a long temporal perspective and to consider initial landscape conditions when evaluating the large-scale effects of current conservation measures on forest biodiversity.

76-AN EVALUATION OF THE CONTRIBUTION OF CITES TO THE CONSERVATION OF INTERNATIONALLY TRADED SPECIES

Rachel L. Roberts

IUCN

Daniel CHALLENGER, IUCN; Stuart BUTCHART, BirdLife International; Michael Hoffmann, IUCN

Illegal, international trade in wildlife products is a major threat to biodiversity conservation and a surge in this trade in recent years has led to unprecedented levels of poaching affecting many species. This trade occurs despite near universal political commitment to regulate international wildlife trade through CITES, the Convention on International Trade in Endangered Species of Wild Fauna and Flora, which entered into force in 1975, and seeks to ensure international trade in c.35, 000 species is sustainable as well as legal and traceable. However, there has been little evaluation of the effectiveness of CITES beyond single species, taxonomic groups and the impact of trade controls generally, and in particular quantitative assessment of the impact of CITES on the status of listed-species. This is partly due to the complexity of causally attributing interventions within the Convention to species' status. Here, we present analyses on how well CITES reflects species currently known to be threatened by international trade, whether CITES listings have impacted on species listed as threatened by international trade, and whether there are differences between species subject to different levels of regulation within CITES, in order to quantitatively evaluate the contribution of CITES to the conservation of trade-threatened species.

141 - WHEN INTEGRATION FAILS: WISHES VERSUS REALITY IN THE EU AGRICULTURAL POLICY AND BIODIVERSITY

Trees Robijns

Stichting BirdLife Europe

Guy PE'ER, Helmholtz Centre for Environmental Research

The facts are plain and simple: Farmland biodiversity in Europe is in decline, and compared to birds in all other

ecosystems, farmland birds are suffering the most. The causes are well-known, and include agricultural intensification; growing monocultures; ongoing loss of natural and semi-natural landscape features; land abandonment; and, in the EU's new Member States, an increase in agrochemical use. The EU's Common Agricultural Policy (CAP) supports farmers by ~50 billion Euros/ year. Originally, the CAP aimed to boost production and sustain farmers' income. However, the public increasingly criticized the subsidies for harming the environment while failing to stop the decline in farmers' employment. Reflecting on this criticism, new "greening measures" were introduced into the CAP in its recent reform. However, pressures in favour of increasing agricultural production, seemingly to address concerns about food security, resulted in the watering down of the green components of the CAP. This failure should serve as a warning signal, questioning the entire integrative approach which seeks to bring environmental criteria into existing policies whose main aims inherently contrasts with environmental protection. Alternative approaches are urgently needed. For instance, one may wish to "rethink integration", and instead develop an opposite approach where environmentally-friendly policies and practices are designed for their own purpose and judged on their own merit. Alternatively, or additionally, one may ask how policies could support the common wellbeing of farmers and nature. Thereby, we could potentially achieve greater success in addressing the two parallel, but related, processes: the loss of traditional, often small-scale, agricultural practices and traditions (and employment) – and the loss of biodiversity, ecosystem functions and services. We offer the audience to judge on these two approaches, and come up with own ideas.

117. ENGAGEMENTS BETWEEN CONSERVATION NGOS AND CORPORATIONS: LESSONS FROM THE FRONT LINES

John Robinson

Wildlife Conservation Society

The conservation community increasingly is engaging with corporations so as (1) to mitigate the negative effects of corporate activities, (2) to encourage corporations to generate positive effects on biodiversity conservation, and (3) to benefit from financial support for conservation programs. The interests and goals of conservationists and corporations can sometimes be aligned but they are not identical, and they can be in conflict. For conservationists, therefore, there are ethical and reputational risks and vulnerabilities of these engagements. These risks depend especially on the financial and contractual nature of the specific relationship. I consider a variety of relationships between conservation organizations and corporations: philanthropic support; sponsorship/ marketing engagements: conservation-driven business

collaborations; and operational/business collaborations to mitigate environmental impacts. Drawing on the portfolio of engagements that the Wildlife Conservation Society (WCS) has with corporations, I outline how WCS has sought to mitigate those risks and promote the conservation outcomes.

208 TEN PRINCIPLES OF CITIZEN SCIENCE: SHARING BEST PRACTICE AMONGST THE CITIZEN SCIENCE COMMUNITY

Lucy Danielle Robinson

Natural History Museum London

Jade Lauren CAWTHRAY, Natural History Museum London

The European Citizen Science Association (ECSA) is a network of scientists, researchers, informal education practitioners and others who are working together to encourage the growth of the citizen science movement in Europe. Key goals of the Association are to identify, develop and promote best practice and excellence in citizen science, and to share knowledge and skills on citizen science approaches across Europe and globally. In such a diverse and rapidly expanding field as citizen science, developing a shared understanding of what characteristics and principles underpin good quality citizen science is key. Sharing knowledge, experiences and expertise gathered through running or participating in citizen science projects is a vital part of advancing the field and ensuring that new projects are as engaging, exciting, valuable and impactful as possible. The European Citizen Science Association, through its working group on 'sharing best practice and building capacity in citizen science' has developed a document setting out Ten Principles of Citizen Science. The Principles represent a shared understanding of the core attributes and attitudes that are common to successful citizen science programmes. The Principles have been developed collaboratively within ECSA with input from many of its members. Here we present the Ten Principles, and discuss their relevance and application in the field of citizen science. We also present a range of other materials that support citizen science practitioners to develop or enhance their own projects, including guidelines for ensuring citizen science is the right approach to meet the research aims, setting up new projects, running BioBlitz events, and evaluating the outcomes and impacts of a citizen science programme.

THE MICROVERSE CITIZEN SCIENCE PROJECT: COLLABORATIVE MICROBIOLOGY RESEARCH WITH UK SECONDARY SCHOOLS

Lucy Danielle Robinson

Natural History Museum London

Jade Lauren CAWTHRAY, Natural History Museum London ; Anne JUNGBLUT, Natural History Museum London ; John C TWEDDLE, Natural History Museum London

The Microverse is a UK-based citizen science project that actively involves school students and community groups in microbial research using cutting edge DNA sequencing technologies. The Natural History Museum in London is collaborating with over 150 schools on this research, engaging over 1000 students aged 16-18 from across the country. By collecting samples of microorganisms from buildings and other man-made structures across the UK and using next generation DNA sequencing techniques, this research will reveal new insights into the microbial communities present and the role they are playing in the urban ecosystem. Students collect samples of microorganisms from a building local to them, submit them to the Natural History Museum for DNA sequencing, analyse the data, write blog posts to share their experiences, and suggest future directions for the research. Samples collected by the students are stored indefinitely within the Museum's Molecular Collections Facility, creating a lasting legacy for the project and an ongoing resource for researchers both at the Museum and internationally. This poster will introduce The Microverse project, share initial research findings, and analyse the challenges, benefits and impacts of involving school students in citizen science projects.

ECOGEOMORPHOLOGICAL ASSESSMENT OF AGRICULTURAL ABANDONMENT IN SEMIARID MEDITERRANEAN AREAS: A BASIS FOR NATURAL RECONSTRUCTION

Francisco Robledano

University of Murcia

Asunción ROMERO-DÍAZ, University of Murcia ; Francisco BELMONTE, University of Murcia ; Víctor Manuel ZAPATA, University of Murcia ; Carlos MARTÍNEZ-HERNÁNDEZ, University of Murcia ; Vicente MARTÍNEZ-LÓPEZ, University of Murcia

Agricultural policies and socioeconomic drivers, reinforced by climate change, promote the spontaneous abandonment of large areas critical for soil, water and biodiversity conservation. Natural reconstruction can be a cost-effective management option, alternative to reforestation policies. We present a framework for assessing the potential for ecosystem recovery in semiarid agricultural areas of the Mediterranean, based on the results of SENECA Research Foundation's Project 15233/PI/10, focused at the evaluation of ecogeomorphological responses to land abandonment in Southeastern Spain. To delimit the feasibility of applying passive restoration methods, we have made an integrated assessment of biodiversity and physical conservation indicators, with substrate lithology as key factor controlling physical vulnerability, and colonization dynamics (sources, agents and filters) as main driver of recovery. The

assessment has been applied at different scales covering lithological-climatic gradients and space-for-time substitution scenarios of post-agricultural succession. Compositional, structural and functional indicators were built on field surveys of woody flora, vegetation and animal communities, including multispecies indexes of conservation value and functional contribution to recovery. Physical and biological indicators often followed divergent or contrasting trajectories, particularly in less coherent substrates where soil degradation and erosion processes concur with high biodiversity value. Abandonment per se is not widely applicable but in many instances can naturally improve soil and vegetation conditions. Although not generalizable, the results can help decisions about management measures and the scale and intensity of their application. The assessment of new areas, the search for ecogeographical patterns, and the reformulation of the rewilding paradigm within traditional agricultural landscapes, are the next steps forward.

LIFE+ RIPISILVANATURA: AN ECOLOGICAL ENGINEERING, ADAPTIVE APPROACH TO THE RECOVERY OF SOUTHERN MEDITERRANEAN RIPARIAN HABITATS OF EUROPEAN COMMUNITY IMPORTANCE THROUGH THE CONTROL OF EXOTIC INVASIVE SPECIES

Francisco Robledano

University of Murcia

Josefa VELASCO, University of Murcia ; Daniel BRUNO, University of Murcia ; Víctor Manuel ZAPATA, University of Murcia ; José Francisco CALVO, University of Murcia ; Andrés MILLÁN, University of Murcia

In Southeastern Spain, the control of Exotic Invasive Species (EIS) invading riparian habitats is based mostly on short-lived, intensive eradication campaigns. Project LIFE 13 BIO/ES/001407 RIPISILVANATURA (2014-2019), co-funded by the European Commission, adopts a new approach which combines low-intensity restoration and ecological engineering techniques, taking advantage of the native species' capacity to recover and outcompete EIS. Its main objective is to recover the riparian forest along 57 km of the Segura River, through the protection of key habitats and the control of EIS. The Project Leader is the Basin Authority, Confederación Hidrográfica del Segura (CHS), and partners two municipalities, the Autonomous Government of Murcia Region, a NGO, and the University of Murcia, responsible for preparatory habitat assessments and ecological monitoring. Target formations are priority habitats 92A0 and 92D0 (Directive 92/43 EEC). Drafting restoration projects requires selecting sections with higher expectations of success, on the basis of: a) closeness to natural habitats; b) presence of native remnants, and c) vegetation dynamics capable of reinforcing repeated controls of EIS (mostly Giant

Reed *Arundo donax*). Coordinated work involving project drafters and researchers, seeks to optimize the choice of protection and restoration units, and the type and intensity of actions. Methodological steps are: 1) Database and literature search on native and exotic biodiversity, and ecological quality indexes; 2) Surveys to complete species inventories, habitat maps and quality assessments; 3) Definition of reference, good quality riparian stretches; 4) Selection of nearby sections of intermediate quality, on which to focus actions; 5) Selection of methods for the control of EIS, depending on their dominance and the presence of native vegetation remnants; and 6) Definition of riparian structural design (trees and shrubs) and accompanying species to be used in restorations.

RAT ERADICATION AND ECOSYSTEM RECOVERY IN SEYCHELLES

Gerard Rocamora

University of Seychelles

André LABICHE, Island Conservation Society; Elvina HENRIETTE, University of Seychelles; Gaëtan GALMAN, Island Conservation Society

The outcome of rat eradications on ecosystems is poorly documented, especially in the tropics. Between 1996 and 2010, invasive rats were eradicated in the Seychelles from 12 islands of up to 219 ha. Monitoring comprised 13 formal protocols combined with empirical wildlife observations. A minimum of 24 native vertebrates and several large invertebrates (snails, millipedes, crabs) benefited from these operations. Reptiles and landbirds normally showed increasing or stable trends, although some strongly declined first but later recovered beyond initial abundances. Seabirds already present increased in numbers, and 4 species established a total of 8 new breeding populations across 6 islands. Post-eradication invertebrate abundance appears unpredictable and difficult to interpret within complex ecosystem interactions such as trophic webs, habitat modifications, and species reintroductions. In high islands, overall invertebrate abundance and diversity decreased, contrary to flat islands where it increased on the ground. Invertebrate groups declining were possibly preferentially preyed upon by increasing lizards, birds, and/or large invertebrates. Vegetation changes include the increase of endemic palm seedlings and the rapid development of native *Pisonia grandis* trees. On coralline islands, the spread of several invasive grasses was inconclusive. Negative effects included the spread of two invasive animals on one island. Seven island translocations of 5 globally threatened endemic birds and one reptile were conducted on 3 islands, contributing to IUCN status downgrading for 4 of them. Pre-eradication baseline surveys were often absent or insufficient and long-term monitoring protocols not regularly implemented. Documenting ecosystem recovery should be given higher

priority in future. Overall rat eradication consistently benefited island ecosystems in all cases.

SPATIO-TEMPORAL DYNAMICS OF THE IMPACTS OF FOREST FRAGMENTATION ON NEOTROPICAL BAT ASSEMBLAGES

Ricardo Rocha

Centre for Ecology, Evolution and Environmental Changes, University of Lisbon[INSTITUTE]Biological Dynamics of Forest Fragments Project, National Institute for Amazonian Research and Smithsonian Tropical Research Institute[INSTITUTE]Metapopulation Research Centre, Faculty of Biosciences, University of Helsinki

The consequences of forest fragmentation for tropical vertebrate assemblages have garnered much attention over the last few years. However, many fragmentation studies conducted to date are hampered by the fact that they typically only provide a brief snapshot in time as most research is carried out in the form of short-term projects. This study aimed to investigate the temporal variation in tropical bat responses to forest fragmentation within the experimentally fragmented landscape of the Biological Dynamics of Forest Fragments Project, Manaus, Brazil, specifically focusing on how changes in matrix quality and composition over time mediate species responses to landscape modification. We surveyed bat assemblages in 6 forest fragments (3 of 1-ha and 3 of 10-ha) and in 6 sites in continuous forest in 1996-99 and resurveyed the same sites in 2011-13, using the same methodology. Although there were no pronounced differences in terms of species richness between sampling periods, we

found high between-period species turnover, especially in the smaller fragments. Moreover, between-period differences in species composition were more pronounced for the fragment assemblages indicating that when compared with continuous habitat, fragment assemblages tend to be hyperdynamic. Several species that were commonly captured in 1996-99 were not captured during our resurvey or are now uncommon in the fragments. Conversely, certain forest-dependent species are now among those commonly captured in fragments. These findings demonstrate the mitigating effects of the relatively tall secondary forest vegetation that nowadays dominates the matrix surrounding the fragments. Our study also highlights that responses of bats to habitat fragmentation are strongly influenced by temporal changes in the composition of the landscape matrix surrounding forest fragments.

151 - ON THE THEORETICAL GENERALITY OF DILUTION EFFECT

Benjamin Roche
IRD

Zoonotic pathogens exist within a complex environment that involves many host species. The diversity of host species with low competence for transmitting a given pathogen can reduce the intensity of pathogen transmission, leading to a prophylactic "dilution effect". However, the generality of this effect in wildlife disease systems is unclear. Here, we use a theoretical framework to examine the expected generality of the dilution effect for vector-borne zoonoses by removing all the assumptions generally involved in dilution effect theory. We found that either a dilution effect or an amplification effect was each found in about 50% of simulations; however, the magnitude of the decrease in reservoir species richness was not associated with either effect. We then explore the condition for observing a dilution effect and we compare these conditions with the current knowledge about a large range of vector-borne diseases. We found that dilution is significantly more likely to occur than an amplification, opening the way to use conservation biology as a potential public health tool.

PLASTIC IN MY SEAFOOD!: PLASTIC IN FISH AND BIVALVES SOLD FOR HUMAN CONSUMPTION

Chelsea Rochman
UC Davis

Akbar TAHIR, University of Hasanuddin ; Dolores BAXA, UC Davis ; Rosalyn LAM, UC Davis ; Jeffrey MILLER, UC Davis ; Foo-Ching TEH, UC Davis ; Shinta WERORILANGI, University of Hasanuddin ; Swee TEH, UC Davis

Plastic debris is now recognized globally as one of the several persistent contaminants that have become ubiquitous on our planet. Its presence has been discovered across multiple

habitats worldwide, but most strikingly is its occurrence in wildlife. Plastic debris has been recovered from the gut content of hundreds of species, including several that are part of the human food chain. As such, people have begun to raise concern regarding marine plastic debris and its effects on human health. To help address these concerns, and as part of a collaborative study between the University of California, Davis, USA and the University of Hasanuddin, Makassar, Indonesia, we looked for the presence of plastic debris in seafood sold at local fish markets. From the local fish market in Makassar, Indonesia, we purchased 5-10 fish from across 10 species, encompassing 76 samples in total. From local fisherman and fish markets in Half Moon Bay and Princeton, CA we purchased whole fish/shellfish or collected the gut of 1-12 fish from across 11 species, encompassing 76 samples in total. Overall, our work shows that plastic debris is ingested by marine animals sold for human consumption, including some that we consume whole (i.e., including the gut—anchovies, bivalves). Results to date show plastic debris in a total of 21 fish across 5 species in Indonesia and in a total of 22 fish and 6 oysters across 10 species in California. This presentation will provide details of results including patterns among species and location, the type and size of the debris found and how the waste management strategies in each location relate to our findings. Because our past research has shown that plastic debris can act as a vector for organic pollutants to bioaccumulate in fish tissue, this work warrants further research to examine if our seafood is contaminated with harmful chemicals associated with ingested plastic.

73-MULTI-DISCIPLINARY APPROACHES TO THE STUDY OF MARINE CONNECTIVITY: RECENT EXPERIENCES IN THE WESTERN MEDITERRANEAN BASIN

Delphine Rocklin

University of Murcia

Manuel MUNTONI, University of Cagliari ; Irene MUNOZ, University of Murcia ; Carlos VERGARA CHEN, University of Murcia ; Jessica GARCIA, University of Murcia ; Olga RENONES, IEO ; Alicia DALONGEVILLE, CEFE - Centre d'Ecologie Fonctionnelle - UMR 5175 ; Romain CREC'HRIOU, University of Perpignan - CEFREM ; Frida BEN RAIS LASRAM, INAT ; Cheoma FRONGIA, University of Cagliari ; Maximiliano GIACALONE, CNR-IAMC ; Amalia CUADROS CASADO, IEO ; Raquel TORRES CARDENAL, University of Murcia ; Nora CHAHBAR, University M'hamed Bougara Boumerdes ; Jonathan BEUVIER, Mercator Ocean ; David MOUILLOT, University Montpellier II ; Giovanni D'ANNA, CNR-IAMC ; Philippe LENFANT, University of Perpignan

- CEFREM ; Matteo MURENU, University of Cagliari ; Jose Antonio GARCÍA CHARTON, University of Murcia

Increasing population connectivity knowledge is essential for proposing a coherent management of the resources. In the Mediterranean Sea, marine connectivity studies are still scarce. Here, we present the results of a large-scale study combining various approaches, gathering genetic, modelling and otoliths techniques, for studying the striped red mullet *Mullus surmuletus* and the red mullet *Mullus barbatus* populations connectivity. These species are highly targeted by Mediterranean fisheries, being among the most important demersal fishing resources of the Western Mediterranean Sea. First, we performed genetic analyses using microsatellites markers on adults and juveniles collected in numerous areas spread in the Western Mediterranean basin. Second, since larval dispersal, during the early life-history of many fish species, is a major process influencing populations connectivity, the dispersal patterns of *M. surmuletus* and *M. barbatus* larvae were assessed using a Lagrangian tool coupled with a general oceanic circulation model, to underline the spatio-temporal dynamic and variability of this crucial stage. Finally, to highlight the population structure of these species and to discriminate among possible different stocks, we evaluated the differences in otolith shape. This multi-disciplinary approach was helpful for understanding and assessing the connectivity patterns of *Mullus* sp. in the Western Mediterranean Sea and to shed new light on the resource management of these highly targeted species.

POPULATION SIZE AND HABITAT PREFERENCES OF THE BAWEAN WARTY PIG *SUS BLOUCHI*, ONE OF THE RAREST PIG SPECIES IN THE WORLD, AND APPLICATIONS FOR CONSERVATION

E. Johanna Rode-Margono

Oxford Brookes University

Mark A. RADEMAKER, University Van Hall Larenstein ; Gono SEMIADI, Indonesian Institute of Sciences

The Bawean warty pig (*Sus blouchi*) was believed to be extinct, but got rediscovered on Bawean island, located in the Java Sea near East Java, Indonesia, in 2013. No study has been done on this species and its conservation status is not yet assessed. The legally unprotected pig is heavily hunted by local people to protect crops. In November 2014, we started the first ecological study on Bawean warty pigs with the aim to assess the total population size, habitat preferences, and behaviour. This information is crucial for species conservation planning and future Red-Listing of the taxa. We installed camera traps at 105 random points in the island's five isolated protected areas (46 km²), the only forested areas on the island. We calculated pig density using the Random Encounter Model (REM) that does not require the recognition of individuals.

Furthermore, we used a Generalised Linear Model to assess the influence of habitat parameters on the trapping rate at the trapping locations. Finally, we assessed the pigs' behaviour on the videos, such as activity profile and social group patterns. We collected 92 independent videos showing in total 162 individuals, including 67 adult females, 35 adult males and 30 immatures. The REM revealed that a total of 292 to 598 pigs live on the island. Based on the number of mature animals between 225 and 460 and an area of occurrence below 100km², the Bawean warty pig should be assessed as Critically Endangered. Mean group size was 2.18 animals. Animals are active mainly during the night, at dusk and dawn. Trapping rates were significantly higher in community forest as compared to natural mature forest, nearer to the forest boarder and in areas with higher tree density. Habitat preference for community forest stresses the problem of human-wildlife conflict, which should be addressed in future conservation projects.

POPULATION GENETIC STRUCTURE OF ACACIA TORTILIS TREES IN ISRAEL AND IMPLICATIONS FOR THEIR CONSERVATION

Yael Rodger

Ben-Gurion University of the Negev

Gidon WINTERS, The Dead Sea and Arava Science Center ; Shirli BAR-DAVID, Ben-Gurion University of the Negev

Genetic diversity and population structure are of great importance for potential adaptation to environmental changes, and consequently for the long-term survival of species. Therefore, species conservation should account for the potential negative effects of climate change and anthropogenic disturbance on its genetic diversity. *Acacia tortilis* is a thermophilic desert tree that has a range of distribution along the hyper-arid Arava valley in Israel. Acacias are a keystone species in this ecosystem, under threat from water depletion due to agriculture, road-building and changing climate. The aim of this study is to evaluate the genetic diversity, structure, and connectivity in the *Acacia tortilis* population and to correlate these findings to natural and anthropogenic factors occurring across their range. Using eight polymorphic microsatellite loci to conduct the population genetic study, we sampled and analyzed eight subpopulations of *A. tortilis* along their distribution in Israel. High levels of expected heterozygosity were found, with an average of 0.77 ± 0.01 across the population. An AMOVA test showed that a significant amount of variation occurs between subpopulations ($F_{st}=0.04$; $p<0.01$) and Pairwise F_{st} calculations showed high genetic differentiation between all subpopulations, particularly between the extreme northern (Ein Gedi) and southern (Shlomo) subpopulations ($F_{st}(L)=0.071$; $p<0.001$). A Mantel test indicated that some of the genetic differentiation between subpopulations could be explained by geographic distance ($R^2=0.13$; $p<0.01$). A "gap" in distribution of the trees occurring

along an elevated region with lower temperatures could act as a barrier to gene flow. These results suggest that the *A. tortilis* population is genetically structured and significant differentiation between subpopulations exists, which should be taken into account in the development of management strategies aimed at maintaining the genetic diversity of this keystone species.

LOCAL KNOWLEDGE AND ADAPTATIVE MANAGEMENT IN BRAZIL NUTS HARVEST IN WESTERN AMAZON

Raquel Rodrigues Dos Santos

Núcleo de Apoio a População Ribeirinha da Amazônia

The approaches of socio-ecological systems, resilience, and adaptive management suggest new forest governance arrangements that include the participation of marginalized rural people in territorial management. These approaches require efforts of scientists and managers to deal with these people local knowledge and social institutions that govern resources access and use. Moreover, Non-timber Forest Products are recognized as one of the most important products for rural communities livelihood. This research characterizes the Brazil nut *Bertholletia excelsa* (Humb. & Bonpl.) harvest based on harvest practices and local knowledge in Brazilian Western Amazon protected areas and their surroundings. Then, these practices and knowledge are discussed based on human ecology and adaptative management approaches. For this, qualitative and ethnographic methods were applied (i.e. semi-structured and open-ended questionnaires, participant observation). The obtained information was classified in: Brazil Nuts stands zoning, technical and social organization for the work, pre-harvest management and management practices, and the local knowledge about biological and ecological aspects of the species. The results suggest that the existing local knowledge in the region is extensive and constantly driven by environmental feedbacks. This knowledge therefore should be considered for adaptive co-management. This research reiterates local people's capacities to work toward effective resource management if they are given the opportunity.

PROPERTY RIGHTS COMPLEXITY OF BRAZIL-NUT HARVEST AND THEIR IMPLICATIONS FOR AMAZON FOREST CONSERVATION

Raquel Rodrigues Dos Santos

Núcleo de Apoio a População Ribeirinha da Amazônia
Danilo MUNIZ DA SILVA, Universidade Federal de São Carlos

Non-timber Forest Products are among the most important livelihoods for rural communities. The study of Non-timber Forest Products based on the property rights approach can

explain community's equity, livelihoods and sustainable forestry management. Here, we examine Brazil nuts harvest *Bertholletia excelsa* (Humb. & Bonpl.) in Brazilian Western Amazon protected areas and their surroundings. We searched for property rights arrangements in Brazil nuts stands and management practices. Then we tested relationship between property rights and management practices, and their implications for tropical forests conservation, particularly for the managed species. At first, a socioeconomic household survey was conducted, followed by ethnographic and participant observation interviews. Finally, the Brazil nuts stands were cooperatively mapped by the authors and the harvesters. A three-digit code system categorization was used to describe the property rights arrangements. Our findings show that (i) Brazil Nuts harvest operates in a complexity of tenure situations where *de jure* (legitimated by law) and *de facto* (legitimated by practice) rights are not in perfect alignment; (ii) secure rights are related to conservation and effective management; (iii) secure rights to resources and conservation can occur within different property rights or combinations, except for open access regimes. This study reinforces that local people are capable of working toward effective resource management even under complex property rights, if they are given the opportunity.

GPS TRACKING FOR MAPPING SEABIRD MORTALITY INDUCED BY LIGHT POLLUTION

Airam Rodriguez

Phillip Island Nature Parks

Beneharo RODRIGUEZ, Canary Islands' Ornithology and Natural History Group (GOHNIC); Juan Jose NEGRO, Estacion Biologica de Doñana CSIC

Light pollution and their consequences on ecosystems are increasing worldwide. Knowledge on the threshold levels of light pollution at which significant ecological impacts emerge and the size of dark refuges to maintain natural nocturnal processes is crucial to mitigate its negative consequences. In seabirds, fledglings are attracted by artificial lights when they leave their nests at night, causing high mortality. We used GPS data-loggers to track the flights of Cory's shearwater *Calonectris diomedea* fledglings from their nest-burrows to grounding lit locations, and to evaluate the light pollution levels overflow using nocturnal high resolution satellite imagery. Birds were grounded at locations closer than 16 km from colonies, 50% of individuals being rescued in a 4-km radius from the nest-site, and rescue locations showed radiance values greater than 18nW/sr*cm². Breeding habitat alteration by light pollution is more severe for inland colonies, and point to its extinction if artificial lights continue with current regulation. Furthermore, we provide scientific-based information to create dark corridors facilitating that fledglings from inland colonies reach the sea successfully. Given the

similarities in seabird attraction to lights elsewhere, our results could help in the management of other critically threatened or rare species grounded by light pollution across the world.

A NOVEL AND LOW COST METHOD TO CALCULATE POPULATION SURVIVAL USING INVERSE MODELLING

Roberto C Rodriguez-Caro

Universidad Miguel Hernandez

Easton R WHITE, University of California ; Thorsten WIEGAND, Helmholtz Centre for Environmental Research - UFZ ; Eva GRACIA, Universidad Miguel Hernandez ; Andres GIMENEZ, Universidad Miguel Hernandez ; Jose Daniel ANADON, City University of New York

Estimating survival is paramount population ecology and conservation, since they are at the core of population models and population viability analyses. However state-of-the-art methods to estimate survival, such as capture-recapture analysis, are highly costly since they are based in long-term monitoring and require large number of individuals captured. In this sense, developing new approaches that provides accurate, but affordable, estimates of survival is a priority in population ecology. In the present work, we present a novel method to estimate population survival starting from short-term census data. Our method merges two well-known approaches in the ecological and modeling literature (matrix population models and inverse modelling), however we advocate that their joint potential has not been explored and exploited for parameter estimation. Specifically, we search for those survival parameters that best reproduce the observed age structure of the population according to a likelihood function. This method also allows to test for changes in the survival through time (i.e. due a perturbation). Our method was evaluated against a long-term monitored population (10 years) of the tortoise *Testudo graeca* that experienced a fire during the monitoring period. Our estimates of survival were very similar both in their mean values and their error measures when compared to estimates obtained using capture-recapture methods. In addition, in agreement with capture-recapture results, our approach indicated that fire strongly impacted survival the years after the fire and that this parameter recovered pre-perturbation values few years after the event. Survival estimates with our method were consistent with a sample size as low as 50 individuals sampled in one single year. Our results should encourage of alternative methods, such as those based in inverse modelling, as one more of the possible standard tools for estimating demographic parameters in ecology and conservation.

ID38: UNDERSTANDING THE COMPLEX RELATIONSHIP BETWEEN POVERTY AND WILDLIFE CRIME

Dilys Roe

International Institute for Environment and Development (IIED)

Mariel HARRISON, Imperial College

There is a common assumption in the conservation literature that wildlife poaching is driven by poverty. The evidence base for this assumption is, however, patchy. Duffy and St John (2013) highlight that "poaching and trafficking of ivory and rhino horn are ultimately driven by wealth and not by poverty per se" but concede that poverty is an important factor. The relationship between poverty and wildlife crime is complex - and indeed there is no one relationship. It is clear that in some cases poverty is a major motivation for engaging in wildlife crime. But equally wildlife crime can exacerbate poverty by depleting the natural resource base on which many poor people depend - and which in many cases makes a significant contribution to the GDP of poor countries. In addition, responses to wildlife crime can affect poor people negatively. Recent calls to address wildlife crime have emphasised the need to increase law enforcement. However this can be a blunt instrument which can result in disproportionate persecution of minor actors and alienation of poor people from critical livelihood resources. This paper explores these different relationships assessing the state of the evidence base for each. Uganda is used as a case study country to illustrate some of the complexity involved.

ARE ALTERNATIVE LIVELIHOODS PROJECTS EFFECTIVE AT DELIVERING CONSERVATION RESULTS?

Dilys Roe

International Institute for Environment & Development

Francesca BOOKER, IIED & CIFOR ; Mike DAY, IIED & CIFOR ; Wen ZHOU, Centre for International Forestry Research ; Noëlle KÜMPEL, Zoological Society of London ; Terry SUNDERLAND, Centre for International Forestry Research

Alternative livelihood projects are used by a variety of organisations as a tool for achieving conservation results. Yet these interventions, including their objectives, vary a great deal, and there is no single accepted definition of what constitutes an alternative livelihood project. In addition, very little is known about what impacts, if any, alternative livelihoods projects have had on biodiversity conservation, as well as what determines the success or failure of these interventions. Reflecting this concern, a resolution was passed at the IUCN World Conservation Congress in 2012 calling for a critical review of the benefits to biodiversity of alternative

livelihood projects and we report here on a systematic review undertaken for that purpose. We define alternative livelihoods projects as interventions that seek to alleviate a human threat to biodiversity through providing, or encouraging the use of an alternative resource; an alternative occupation; or an alternative method (lower impact) of exploitation. Our review identified approximately 100 studies of alternative livelihood interventions of which 50 include detailed assessments of their effectiveness. We explore the types of interventions that have been deployed, the nature and scale of their impacts and the types of contexts in which they have been found to be effective or not.

MULTIPLE EVIDENCE FOR THE PHYLOPATRIC BEHAVIOR OF THE CRITICALLY ENDANGERED HOODED GREBE: IMPLICATIONS FOR ITS CONSERVATION

Carlos Ignacio Roesler

Universidad de Buenos Aires

Marcel VAN TUINEN, Center of Ecological and Evolutionary Studies ; Julio Lucio LANCELOTTI, Centro Nacional Patagónico ; Laura FASOLA, Centro Austral de Investigaciones Científicas ; Bettina MAHLER, Universidad de Buenos Aires

The Hooded Grebe (*Podiceps gallardoi*) belongs to one of the most endangered groups of birds, the Podicipediformes. It was discovered in 1974 at Santa Cruz province, Argentina. Its numbers have dropped over 80% in less than 25 years, with a current population of less than 400 pairs. It inhabits highland basaltic plateaus, spotted in an area of 120.000 km² through out arid Patagonia. In 2009, census program was started in 400 lakes at 7 plateaus monitored regularly. Numbers across seasons in each single plateau did not change ($\chi^2 < 0,001$). Additionally, we collected tissue samples to assess its population structure. We sequenced a 353 bp fragment of mtDNA control region for 51 individuals obtained at Buenos Aires (n=31) and Siberia (n=20) plateaus. We analyzed population structure between plateaus with AMOVA, for testing the fidelity to breeding sites. The genetic variability between them explained 11% of the variation, and the haplotype frequency distribution was significantly different between plateaus ($F_{ST} = 0.1$, $p = 0.009$). Finally, we tagged 20 individuals from two plateaus (wing tags n=8; color bands n=12). A juvenile banded at Buenos Aires plateau was detected nesting on the same lake one year after. These results showed that the distribution between breeding sites is not random, which suggests this species shows a phylopatric behavior. Although the series of surveys showed similar numbers in every plateau each year, the observed variation among lakes suggest that grebes have fidelity at the scale of plateau, instead of to specific lakes. From a conservation perspective this information is fundamental to understand the population

dynamic of Hooded Grebe and the importance of each plateau as reproductive habitat. This represents primary information to conduct specific management plans, considering the population structure of Hooded Grebe and the geographic complexity of this region.

MODELLING EXTINCTION RISK OF GLOBAL REPTILES

Uri Roll

University of Oxford

Shai MEIRI, Tel-Aviv University ; David CHAPPLE, Monash University ; Richard GRENYER, University of Oxford

The IUCN's Red List of threatened species has grown in scope and importance for the prioritizing, planning and management of biodiversity, yet most global biodiversity remains unassessed. To-date only 4256 reptile species (45%) have been assessed by the IUCN. Here we make use of a unique and comprehensive database on traits and ranges of all living reptiles in order to explore patterns in their extinction risk. Initially we highlight geographic and taxonomic biases in assessed versus unassessed species and link threat category to various morphological, ecological, physiological and life-history traits of the species, as well as attributes derived from their geographic ranges. We use machine learning models to assign tentative threat categories, based on the range size of each species (criterion B) and the various attributes that were found to correlate with the different threat categories of assessed species. Our results indicate that assessed species are on average larger and have a larger range size than unassessed species. Furthermore, many more Nearctic and Madagascar reptiles have been assessed, and only few in the Australian, Afrotropic, Neotropic and oriental realms. Restricted range size species are on average more threatened as are iguanas, and Madagascan species. Geckos are less threatened, as are Afrotropic species and species living at higher elevations. Modelling threat categories to unassessed species highlights more than a thousand species that receive a provisional threat status. It also enables us to identify potentially miss-classified species and reveals general inconsistencies between classifiers and classifications. Our work highlights lacunas in the reptile assessment and identifies attributes most important for threat status prediction. We also give provisional threat categories to all unassessed reptile species, and provide a robust 'shortcut' mechanism for the classification of species from lesser known groups, yet to be assessed.

TEMPORAL AND SPATIAL DYNAMICS OF REEF FISH SPAWNING AGGREGATIONS IN NEW CALEDONIA

William Roman

IFREMER

Dominique PELLETIER, IFREMER ; Abigail POWELL, IFREMER ; Pierre LABOUE, Consultant

Reef fish spawning aggregations reflect the diversity of reproductive strategies of coral reef organisms. Groups of conspecific fishes are gathered for the purpose of spawning. These aggregations occur at a specific times and locations and are often the target of intensive fisheries. To protect and manage spawning aggregations, it is desirable to locate sites, identify the species that form aggregations and the periodicity with which species form them. We focused our study on a multi-species aggregation site that experiences low levels of exploitation, the Kouare channel, located in the New Caledonia's south lagoon. Conventional underwater visual census methods and diver operated stereo-video transects (Stereo DOV) were combined with four remote underwater video systems to provide very high replicated observations in low light conditions, up to 40m depth and strong current. Globally, 33 species of coral reef fishes have been identified forming spawning aggregations, including commercially important and emblematic species in New Caledonia (*P.leopardus*, *L.nebulosus*, *C.undulatus*). Seasonal and daily patterns in spawning activity and aggregations were analyzed with regard to topographic complexity, coral cover and temperature. Significant spatial differences between species were detected plotting the aggregations on a bathymetric 3D map. For example, *E.cyanopodus* only spawned on the outer slope between 25 and 40m deep whereas *S.globiceps* only spawned on promontories between 5 and 8m deep. Differences between temporal patterns were defined by the frequency with which the spawning aggregation occurs and the length of time the aggregation persists. The time of day varied between species from dawn to dusk. Among the species observed during the survey, 6 species were identified as priority species for conservation. Data collected during the survey will be used in a population dynamics model (ISIS Fish) that is designed to assess different management scenarios.

SYMPOSIUM 91. ISSUES FOR IMPACT EVALUATION DESIGN OF FSC CERTIFICATION OF NATURAL FOREST MANAGEMENT

Claudia Romero

CIFOR -University of Florida

Francis PUTZ, CIFOR -University of Florida ; Erin SILLS, CIFOR -North Carolina State University ; Manuel GUARIGUATA, CIFOR ; Paolo CERUTTI, CIFOR ; Guillaume LESCUYER, CIFOR-CIRAD

FSC natural forest management certification has been implemented for >20 years. FSC's goal is to provide a system through which responsible forest management is recognized by consumers and others. Our team works on the design of an empirical theory-based impact evaluation (IE) of the biophysical, social, economic, and policy impacts of this

intervention in Brazil, Peru and Indonesia. The range of expected outcomes, and the scales at which impacts ensue, forced us to use inter and trans-disciplinary approaches to define the IE scope and goals. While this research is still ongoing, our goal is to share lessons learned in tackling the complexity of the social-ecological systems where the FSC intervention occurs. We present ideas that see evaluation as a knowledge-generating process as well as a goal in itself. Thus, we introduce the rationale for a multi-stakeholder platform to assure the IE design would be built upon discussions with a range of social actors on the value of this knowledge-generation research to improve their conservation practice. We introduce a conceptual framework that lays out the foundation for the IE work, tightly linked to relevant concepts for conservation biologists such as adaptive management and systems thinking. We discuss results of preparatory studies that provide information used as a backbone for the IE design and that attempts, from the different angles where conservation trade-offs occur, to provide a roadmap for the IE. Studies include a descriptive analysis of auditing and accreditation activities aimed at providing transparency and accountability to the audit component behind certification. We developed country-based studies of political economy factors that underlie historical issues regarding forested lands use and analyze these issues across countries. We ground on these quantitative and qualitative studies hypotheses on how forest management decisions in general and FSC certification in particular, have occurred

INCORPORATING THE EFFECTS OF MULTIPLE FUTURE THREATS ON DECLINING MAMMALSTO IDENTIFY SPATIAL PRIORITIES FOR PRIVATE LAND CONSERVATION INCENTIVES

Cristina Romero

University of Queensland

Ayesha TULLOCH, Australian National University ; Hugh POSSINGHAM, University of Queensland ; Karen MUSTIN, Universidade Federal do Amapá

Climate change is predicted to alter the distributions of many species as their environments become unsuitable under future climatic conditions. Uncertainty in expected future climate scenarios plus the likely effects of additional threats complicate efforts to plan for the conservation of threatened species. It is therefore important to incorporate multiple threats when planning for species conservation under climate change to avoid costly errors in prioritising limited conservation funding. We explore future scenarios of climatic conditions, and incorporate the threat of urbanisation, to plan for the persistence of species of conservation interest in a case study located in south-western Australia, a global biodiversity hotspot. We use species distribution modelling to understand how climate change might affect the geographical ranges of

a suite of endemic mammals. We develop a 'threat map' that describes the relative threat of urbanisation and associated clearing, and use cost-effectiveness analysis to identify spatial priorities for conservation on private land that supplement existing conservation strategies of public protected areas. Our approach targets areas of low cost, high threat and high likelihood of containing the present and future distribution of each species. The results suggest the species selected will move towards the coast. Although the percentage of species' range inside statutory protected areas is predicted to increase, the total range will contract and shift closer to urban areas. The cost-effectiveness analysis indicates the best areas to target for future conservation action on private land for these species would be those on the edge of protected areas in the south and west of the region. Our analysis demonstrates how predictive modeling, threat mapping and cost-effectiveness analysis can be used by conservation planners and decision-makers for anticipatory policy adaptation and implementation in the face of future threats.

DESIGNING A NETWORK OF WILDLIFE CORRIDORS ACROSS HETEROGENEOUS MOUNTAIN LANDSCAPE - THE CARPATHIANS CASE STUDY

Dušan Romportl

Faculty of Science, Charles University
Miroslav KUTAL, *Friends of the Earth* ; Vladimir ZYKA, *Faculty of Science, Charles University*

The Carpathian Mountains forming an arc roughly 1.500 km across seven states provide the habitat for some of the largest European populations of brown bears, grey wolves and Eurasian lynx, with the highest concentration in Romania. However, Ukrainian, Romanian and even Slovakian parts of Carpathians suffer from the lack of the functional nature protection and the effective landscape management. Several protected areas including the large number of NATURA 2000 sites have been declared, but their spatial design recalls rather patchwork instead of coherent network. Populations of large carnivores with enormous spatial requirements and extensive dispersal and migratory needs are widely endangered by rapid development of roads and motorways creating long impermeable barriers across the Carpathians. As new traffic projects are planned on supra-national level, the same scale is needed for designing an extensive system of wildlife corridors. Habitat suitability models for brown bear, grey wolf and Eurasian lynx were used to delineate core habitat areas and stepping stones important for dispersal. The Circuit Theory was applied for assessment of landscape connectivity and finally a coherent network of wildlife corridors was designed. Proposal of such green infrastructure was presented to regional authorities and stakeholders, to provide them with relevant information for negotiations with road and motorways planners.

DECLINE OF EUROPEAN LARGE MAMMALS UNDER GLOBAL CHANGE SCENARIOS

Carlo Rondinini

Sapienza University of Rome
Piero VISCONTI, Microsoft Research

The distributions and populations of large mammals are declining globally, leading to an increase in their extinction risk. We forecast the distribution of extant European large mammals (17 carnivores and 10 ungulates) based on two Rio+20 scenarios of socio-economic development: business as usual and reduced impact by consumption change. These are linked to scenarios of land use change and climate change through the spatial allocation of land claim until 2050. We used a hierarchical framework to forecast mammal suitable habitat, based on their habitat preferences recorded in the IUCN Red List database, within their suitable climatic space, fitted to their current geographic range. We analyzed the geographic and taxonomic variation of habitat loss for large mammals, and the potential effect of the reduced impact policy on loss mitigation. Averaging across scenarios, European large mammals would lose 10% of their habitat by 2050 (25% in the worst-case scenario). The loss would be much higher for species in northwestern Europe, where habitat is expected to be lost due to climate and land use change. Change in human consumption patterns would mark a substantial improvement in the conservation of habitat for European large mammals, but this would still be insufficient if they are not capable to adapt locally or disperse.

130 - CHALLENGES FOR COMBINING INDICATORS, MODELS AND SCENARIOS OF HUMAN PRESSURE AND BIODIVERSITY RESPONSE INTO A COHERENT STORY

Carlo Rondinini

Sapienza University of Rome

A variety of indicators, models and scenarios have been developed in the last decades to represent, quantify, monitor, and forecast human pressure on natural systems and the resulting response of biodiversity. These indicators, models and scenarios usually tell a broadly coherent story of biodiversity loss, but are often discordant when the story is developed in further detail. This discordance translates into high uncertainty on the relationships between pressures and responses, which hampers decisions on actions to halt biodiversity loss. To reduce this uncertainty we need to understand the sources of the observed differences. While part of the uncertainty derives from random sampling of a statistical population, other relevant components lie in the behaviour of indicators, in the assumptions of the models and scenarios, and in the pathways

chosen to combine them all. Building on the frameworks of the IPBES report "Policy support tools and methodologies for scenario analysis and modelling of biodiversity and ecosystem services" and of the EU COST action Harmonizing Biodiversity Modelling, I discuss: 1. how similar biodiversity indicators respond to different processes or different stages of the same process; 2. how choices on combining models and scenarios produce outputs with different interpretations; 3. how, when and why models of pressure and response should or should not be harmonized.

RESTORATION ECOLOGY, REWILDING, PASTORALISM AND FOOD SECURITY: RENEWING OLD CONNECTIONS IN CENTRAL CHILE

Meredith Root-Bernstein

Aarhus University

Luis Plúa, Universidad de Chile ; Cristian BONACIC, Pontificia Universidad Católica de Chile ; Matías GUERRERO, Pontificia Universidad Católica de Chile ; Fabian JAKSIC, Pontificia Universidad Católica de Chile ; Anna TSING, Aarhus University ; Jens-Christian SVENNING, Aarhus University

Restoration of the semi-arid Chilean silvopastoral system called "espinal" is a longstanding challenge. Here we present and discuss the prospects for a restoration approach inspired by rewilding. We suggest an alternative model of rewilding with the potential to contribute to food production and food security. We argue that the reconciliation of rewilding and food security approaches is appropriate to the central Chilean context. Pastoral systems are adaptations to environmental heterogeneity and variability, and may involve both domestic and semi-wild species. With sedentarization, the capacity for dynamic responses to the environment is lost, and with factory farming may be decoupled from local variability while strongly coupled to regional or inter-regional fodder production. Extensive pastoral systems have a large water footprint, which has been used as an argument against extensive meat production as a component of food security. However, the water input (precipitation) to pastoral systems produces a large number of supporting, provisioning and cultural ecosystem services, which intensive meat and vegetable production do not. Furthermore, the grazing of large herbivores can contribute to landscape management for ecosystem services. The rewilding movement has provided lessons on passive and dynamic approaches to megaherbivores as management tools. We discuss this model of rewilding with reference to our experiments on the potential to reintroduce semi-wild guanacos (*Lama guanicoe*), the "missing herbivore" in the espinal habitat, as a restoration tool. We provide preliminary evidence from our ongoing experiment and GIS analysis that the ecological restoration of a dynamic rewilding-inspired silvo-pastoral system can broadly contribute to food security as well as biodiversity and sustainability in central Chile.

GENETIC CHARACTERIZATION OF THE RELICT POPULATION OF THE EUROPEAN STURGEON, ACIPENSER STURIO: INSIGHTS INTO BREEDING AND CONSERVATION PROGRAMS

Séverine Roques

IRSTEA

Patrick BERREBI, Université Montpellier II, UMR 5554, "Institut des Sciences de l'Evolution", Equipe "Evolution des Poissons ; Patrick CHÈVRE, IRSTEA ; Eric ROCHARD, IRSTEA ; Marie-Laure ACOLAS, IRSTEA

Genetic evaluations in breeding programs of critically endangered species are essential not only to characterize and maintain genetic diversity, but also to improve both effectiveness and monitoring of repopulation. The European sturgeon was the most widespread sturgeon species all over Europe, but its abundance has been drastically reduced to be now on the brink of extinction. Only a single population is surviving in the Gironde-Garonne-Dordogne watersheds (France) where the last known natural spawning occurred in 1994. In the years that followed, a sturgeon restoration program has been launched to build up a broodstock and repopulate this watershed. In the present study, a microsatellite multiplex assay was developed to characterize genetically the relict population actually reduced to 70 captive-wild spawners and the seven generations (2007-2014) issued from the breeding program. Our genetic assay proved highly reliable and powerful in relatedness analysis and assignment approaches, and is thus promising to help the conservation-restoration actions of the species. Mains aims include assessing the genetic variability of broodstocks and F1 juveniles, estimating relatedness and effective population size within captive individuals, providing molecular tags for released individuals, and assisting in the evaluation of survival of stocked individuals according to the parents used and the stocking practice. Here, we will present the obtained data and their usefulness for discussing suitable strategies for the genetic management and conservation of this almost extinct species.

RECREATING THE SOUNDSCAPE: DISENTANGLING EFFECTS OF OIL WELL NOISE FROM INFRASTRUCTURE ON GRASSLAND SONGBIRDS

Patricia Rosa

University of Manitoba

Nicola KOPER, University of Manitoba

As anthropogenic noise becomes more prevalent across habitats, its impacts on wildlife remain difficult to assess. Noise from oil well development may contribute to grassland bird population declines, in western Canada. Thus far, noise playback studies have failed to accurately reproduce

anthropogenic sound sources, resulting in a limited understanding of its impact. To disentangle effects of noise from confounding factors of oil development (i.e. infrastructure presence, associated roads, traffic, human activities), we used a solar-powered broadcasting system that reproduces sound with a high degree of source fidelity, surveyed bird abundance on transects, and monitored nesting success at pumpjack playback sites, silent playback sites, and control sites without playback infrastructure. We found positive effects of noise for certain species (i.e. chestnut-collared longspurs and horned larks), but for other species, noise reduced abundance (i.e. vesper sparrows). Differences in noise sensitivity were also observed. Baird's sparrows were negatively impacted by the loudest sound stimulus and not the quieter on. The presence of infrastructure and not of the noise itself also had varying effects by species; for example, increased perch availability attracted Western meadowlarks and deterred Sprague's pipits. Decreased nesting success in Savannah sparrows was primarily driven by the presence of infrastructure. Thus, in our system, oil well noise does not have an overall negative or positive costs for residing songbird species. The management implications are not straightforward: simply reducing amplitude of noise without minimizing the footprint of above-ground infrastructure may not aid in conservation of grassland songbirds as a whole; species-specific mitigation must be considered.

COST-EFFECTIVE CONSERVATION OF AN ENDANGERED FROG UNDER UNCERTAINTY

Lucy Rose

University of Melbourne

Geoff HEARD, University of Melbourne ; Yung En CHEE, University of Melbourne ; Brendan WINTLE, University of Melbourne

How should managers and policy-makers choose between conservation actions when resources are scarce and there is uncertainty regarding the effectiveness of actions? Well-developed tools exist for prioritising areas for one-off and binary actions (e.g. reserve/don't-reserve), but methods for prioritising incremental or ongoing types of actions (e.g. habitat creation and maintenance) remain uncommon. We present an approach that combines population viability — a proximate measure of species benefit — with cost-effectiveness analysis to evaluate and identify alternative actions that are efficient and robust to uncertainty. We demonstrate our approach with a case study of the endangered growling grass frog, *Litoria raniformis*, which is threatened by urban development. We extended and customised a Bayesian metapopulation model to predict viability under ten urbanisation and management scenarios involving combinations of habitat removal, installation of stormwater management wetlands, and frog wetland

creation, enhancement and maintenance. The full probability distribution of possible outcomes produced for each scenario was incorporated in the cost-effectiveness analysis. This helped elucidate extinction risks and discriminate cost-effective alternatives robust to uncertainty from those with a high risk of failure. Extinction was predicted following urbanisation if the only conservation action was reservation of core habitat. Creation and maintenance of wetlands dedicated to *L. raniformis* was the only cost-effective action likely to result in sufficiently low risk of extinction. To our knowledge this is the first study to utilise a Bayesian population viability analysis to explicitly incorporate uncertainty in cost-effectiveness analysis of conservation actions. The approach offers guidance to decision-makers aiming to achieve cost-effective conservation under uncertainty.

CHANGES IN TWO DECADES IN THE BIRD AND PLANT COMMUNITIES IN TWO HIGHLAND ANDEAN LOCALITIES POTENTIALLY THREATENED BY CLIMATE CHANGE

Loreta Rosselli

Universidad de Ciencias Aplicadas y Ambientales

F. Gary STILES, Universidad Nacional de Colombia ; Alfonso ROMERO, Universidad de Ciencias Aplicadas y Ambientales

Tropical highland ecosystems have been identified as among the most threatened due to climate change. However, few studies exist with specific data assessing the effect on organisms, particularly in the Andes and in Colombia, a highly biodiverse country. Such data are needed to evaluate the theoretical models that are currently dominant in this field. We have detailed data from 23 years ago on the bird community and the phenology of fruits and flowers of two high Andean areas in a National Park in the Eastern Andes of Colombia, an Endemic Bird Area: paramo and highland tropical forest. Through bird, flower and fruit censuses, we are evaluating again these communities in order to document changes that could be related to climate change. We are also evaluating vegetation cover changes in the area through a multi-temporal analysis using satellite images to permit evaluation of changes in the bird community related to changes in vegetation. So far, we have found one hundred and two bird species, several of which are endemic and threatened or have restricted ranges. We tentatively have detected both increases and decreases in bird species, the former being more common. The species that are decreasing belong to different feeding guilds (insectivores, nectarivores), include migrants and do not belong to closely related taxonomic groups. Increasing species are mostly from lower elevations and also are diverse, including a guan, hummingbirds, and understory insectivores. With this ongoing study in its early stages, we expect to detect the number and type of species for which changes have occurred in their presence and abundance and relate these changes

to their ecology with predictive and conservation purposes. These data will contribute to the management of the park and the conservation of Colombian biodiversity as well as the corroboration of predictive theoretical models.

49-RESPONSES OF INSECT HERBIVORES AND HERBIVORY TO HABITAT FRAGMENTATION: A META-ANALYSIS

Maria Rosa Rossetti

Universidad Nacional de Córdoba, Argentina
Teja TSCHARNTKE, Agroecology, Georg-August-University ; Ramiro AGUILAR, Universidad Nacional de Córdoba, Argentina ; Péter BATÁRY, Agroecology, Georg-August-University

Habitat fragmentation is one of the main causes of species loss with consequences for ecological interactions and ecosystem functioning. Among ecosystem processes, insect herbivory has been widely studied because of its impact on plant growth and reproduction, affecting plant community structure and diversity. Evidence shows contrasting patterns of herbivory in fragmented habitats. On the one hand, reduction of herbivore populations and herbivory levels in small fragments may be due to direct loss of herbivore species and individuals, or through reduced number of plant species and their associated herbivore species. On the other hand, more herbivores and herbivory levels in small fragments may be a result of decreased density of herbivore natural enemies, which are often more vulnerable to fragmentation than herbivores, releasing them from potential biocontrol. Here we test in a meta-analysis, a powerful tool to combine results across studies, the effects of fragment area, isolation and fragmentation per se on herbivore abundance, species richness and herbivory levels. We performed subgroup analysis with fragmentation type (anthropogenic / experimental / natural), herbivore type (endophagous / ectophagous) and herbivore study level (community / species) as moderators. We identified 70 suitable studies evaluating habitat fragmentation effects. The overall habitat fragmentation effect across all studies was negative, but only significant for species richness and the abundance of endophagous insects, which were stronger affected than ectophagous herbivores. Habitat fragmentation effects seem to involve mainly direct loss of herbivore species with reduction of habitat area and these effects would be moderated by fragmentation and herbivore type.

DENSITY, DIET, AND PREY SELECTION OF THE INDOCHINESE LEOPARD IN EASTERN CAMBODIA

Susana Rostro-García

Wildlife Conservation Research Unit, University of Oxford
Jan KAMLER, Wildlife Conservation Research Unit, University of Oxford ; Visattha IN, WWF-Cambodia ; Rachel CROUTERS, WWF-Cambodia ; Sovanna PRUM, Forestry Administration,

Ministry of Agriculture, Forestry & Fisheries ; David MACDONALD, Wildlife Conservation Research Unit, University of Oxford

Leopards *Panthera pardus*, the most persecuted large cat in the world, have been eradicated from >50% of their range in Asia. The Monduliri Protected Forest (MPF) in eastern Cambodia contains one of the last viable populations of Indochinese leopards *P. p. delacouri* in the region, as well as a high diversity of potential prey, including several threatened species. Recent increases in illegal logging and poaching are believed to be impacting the faunal community, however little information has been gathered on this unique predator-prey community. Thus, the aims of this study were to determine the: 1) current density, and 2) diet and prey selection of leopards in MPF. In 2014, we conducted a camera-trapping study for leopards in MPF, and obtained density estimates using spatially explicit capture-recapture, calculated in program DENSITY. The resulting density estimate of 1.1 leopard/100 km² was 70% lower than that obtained in 2009 on the same site using the same methods. Analyses of scats (n = 83) revealed that leopards consumed at least 14 prey, ranging in size from insects and rodents to banteng *Bos javanicus*. Compared to availability, leopards selectively preyed most on muntjak *Muntiacus muntjak* followed by wild pig *Sus scrofa*, and these two species were the most important prey in terms of biomass consumed. We conclude that leopards are important apex predators in this unique ecosystem of eastern Cambodia. However, this high-priority population of Indochinese leopards is declining at an alarming rate, and will soon be eradicated unless effective protection is provided.

BIRD COMMUNITY RESPONSES TO WOODY BIOENERGY CROPS IN ARGENTINA AND THE U.S.

Amber Roth

Michigan Technological University
Colin PHIFER, Michigan Technological University ; Jessie KNOWLTON, Michigan Technological University ; Christopher WEBSTER, Michigan Technological University ; David Flaspohler, Michigan Technological University

As part of an interdisciplinary study of the effects of bioenergy development, we examined how changes in land use and management of forested landscapes influence bird communities in Wisconsin, USA and Entre Rios, Argentina. In Wisconsin, naturally occurring coppiced aspen trees (*Populus* spp.) are used as feedstock for a nearby biomass energy plant. Here, aspen is clearcut, though newer management includes hardwood and conifer legacy tree retention. In contrast, Argentina is manufacturing biomass pellets from non-native *Eucalyptus* spp. plantations, which are replacing annual crops and ranchlands, the dominant land use in the region for over a century. We compared bird communities in alternative

probable land uses in each country, censusing birds in 27 sites (9 replicates of clearcut, hardwood and conifer legacy tree retentions) in Wisconsin from 2007-10 and 12 sites in Argentina (4 replicates of large-scale eucalyptus, small-scale eucalyptus, and pastures/annual crops) in 2014. Breeding bird species richness in the Wisconsin averaged 25.2 species while conifer and hardwood retention sites contained an average of 27.6 and 30.9 species, respectively. In Argentina, eucalyptus stands greater than 100 ha contained on average 6.8 breeding bird species, compared with 23.2 species in smaller eucalyptus stands and 20.8 species in annual crops and ranchlands. In both countries, distinct bird communities were detected with little species overlap among treatments. Should bioenergy continue to increase in Wisconsin, the likely effect would be shorter rotation of aspen, resulting in more young and less structurally complex habitats that are more similar to large-scale eucalyptus monocultures that support fewer breeding bird species. Our results document consequences of current and potential future expansion of tree monocultures and shortening of stand rotation times in contrast with management for wood products using techniques that support greater bird species richness.

(117) ABORIGINAL ENGAGEMENTS WITH MARKET-BASED CONSERVATION

Robin Roth

York University

Ryan HACKETT, York University

Aboriginal and marginalized communities who have long resisted old 'fortress' style conservation are frequently finding that the new market-based trajectory offers a viable option for their territories. Critical analysis might assert that these communities have been duped by neoliberal capitalism but such critics fail to recognize 1) the agency of aboriginal people, 2) the history of their relationship to other conservation actors and 3) their constrained options for asserting their own conservation regimes in their territories. More favorable analysis might celebrate the benefits aboriginal communities can receive but express concern over the conservation outcomes of increased market-based actors in conservation. This paper starts to tease out the complexities and contradictions of Aboriginal engagements with Market-Based Conservation by drawing on case studies in Asia and North America.

DETECTING POPULATION TRENDS WITH LOCALLY-BASED TRANSECT DATA: CASE STUDY ON THREATENED PRIMATES IN THE UDZUNGWA MOUNTAINS OF TANZANIA

Francesco Rovero

MUSE-Museo delle Scienze

Simone TENAN, MUSE-Museo delle Scienze

Increasing threats to primates in the tropics make robust and long-term population assessments increasingly important for conservation. Concomitantly, monitoring becomes particularly relevant in countries with primate habitat. Yet monitoring schemes in these countries often suffer from logistic constraints and/or poor rigor in data collection, and a lack of consideration of sources of bias in analysis. We addressed the need for feasible monitoring schemes and flexible analytical tools by analyzing data collected by local technicians on abundance of three species of arboreal monkey in the Udzungwa Mountains of Tanzania (two *Colobus* species and one *Cercopithecus*), an area of international importance for biodiversity conservation. We counted primate social groups along eight line transects in two forests in the area, one protected and one unprotected, over a span of 11 years. We applied a recently proposed open metapopulation model to estimate abundance trends while controlling for confounding effects of observer, site, and season. Primate populations were stable in the protected forest, while the colobines, including the endemic Udzungwa red colobus, declined severely in the unprotected forest. Targeted hunting pressure at this second site is the most plausible explanation for the trend observed. The unexplained variability in detection probability among transects was greater than the variability due to observers, indicating consistency in data collection among observers. There were no significant differences in both primate abundance and detectability between wet and dry seasons, supporting the choice of sampling during the dry season only based on minimizing practical constraints. Simple monitoring routines implemented by trained local technicians can effectively detect changes in primate populations. The Bayesian model formulation provides a flexible tool to determine temporal trends with full account for data constraints and imperfect detection.

ENLACE VERDE: A COMMUNITY MANAGED TRAIL SYSTEM IN THE BELLBIRD BIOLOGICAL CORRIDOR, COSTA RICA

Clara Rowe

Yale University

Katherine Heller, Yale University ; Fiorella ORTIZ-ROSAS, Yale University ; Nathaniel SCRIMSHAW, Asociación de Desarrollo Integral de San Luis

In the 1980's Costa Rica had the highest rate of deforestation in the world, turning Costa Rica's Pacific Slope into a landscape of isolated forest fragments in a matrix of cattle pasture. The government has recognized the conservation value of this area by integrating it into the national system of biological corridors. However, the Bellbird Biological Corridor (BBC) is still not a protected area and lacks the on-the-ground influence to ensure sustained protection. One community in

the BBC, San Luis de Monteverde, has proposed an innovative approach to landscape connectivity: a network of community managed protected areas linked by a hiking trail stretching from the mountainous continental divide to the Pacific coast. This dispersed management structure would extend the economic and conservation benefits of lower-impact tourism along the the critically important Bellbird Biological Corridor. Our project supports San Luis de Monteverde's Community Development Association (ADISL) in establishing the first such co-management system. ADISL is in the process of negotiating a cooperative agreement with a conservation NGO to maintain trails within part of a 20,000ha forest, and would like to use this as the basis for negotiations with other communities and landowners to complete the trail. Using San Luis de Monteverde as a case study, we explore this framework for co-management and use participant observation and unstructured interviews to identify key community features that support such an initiative. Our findings and this program will serve as a pilot for a novel framework of co-management of protected areas, based on low-impact tourism that will support conservation priorities, promote rural tourism in the region, and protect the Bellbird Biological Corridor.

208 CELEBRATING 50 YEARS OF THE BIOLOGICAL RECORDS CENTRE

Helen Roy

Centre for Ecology & Hydrology

Michael POCOCK, Centre for Ecology & Hydrology ; David ROY, Centre for Ecology & Hydrology

The contribution of volunteers to our understanding of ecology is inspiring. Indeed people have been recording wildlife for centuries and the resulting datasets have underpinned important scientific research. The Biological Records Centre (BRC), established in 1964, is a national focus for terrestrial and freshwater species recording in the United Kingdom (UK). Together with more than 80 volunteer-led recording schemes and societies, BRC provides essential information which informs research, policy and the conservation of our heritage of wildlife. Biological recording is perhaps one of the oldest examples of citizen science with records spanning centuries. It represents a diverse range of activities, involving an estimated 70 000 people annually in the UK, from expert volunteers undertaking systematic monitoring to mass participation recording. Biological recording represents an invaluable monitoring tool because the datasets are long-term, large-scale and taxonomically diverse. There are many published outputs from biological including atlases showing national distributions (12,127 species from over 40 taxonomic groups), quantified trends (1,636 species) and peer-reviewed publications (more than 200 in the last ten years). BRC pioneers the use of technology for data capture (online portals and smartphone apps) and verification (including automated

verification) through customisable, inter-operable database systems to facilitate efficient data flow. Here we provide an overview of the activities of the BRC, highlighting lessons learnt with broad applicability to citizen science.

CAN THE NATURA 2000 NETWORK ADEQUATELY CONSERVE CROP WILD RELATIVES?

María Luisa Rubio

Universidad Rey Juan Carlos

Elena TORRES, Universidad Politécnica de Madrid ; Mauricio PARRA-QUIJANO, FAO ; José María IRIONDO, Universidad Rey Juan Carlos

Crop wild relatives (CWRs) are wild plant species that share a common ancestor with domesticated plants. In the context of the new challenges facing agriculture over the coming years, the conservation of these species and their genetic diversity is a matter of general interest as they may possess desirable characteristics that can be used to obtain new varieties adapted to climate change. To avoid the wasteful resource expenditure on establishing a parallel protected area system, the Natura 2000 network has been proposed as an available resource for the in situ conservation of these genetic resources, as it covers today almost a fifth of Europe's land area. As a part of the European project PGR Secure, the suitability of this approach has been evaluated in Spain. First, the coverage level offered by the Nature 2000 network to 508 species in the Spanish National Inventory of CWRs was calculated using gap analysis techniques. In 18 cases all known populations were inside the boundaries of a site of community importance (SCI), while 38 species were not represented in any protected area. The overall picture is that $42 \pm 24\%$ (mean \pm standard deviation) of the populations of the priority CWR species are located in SCIs. Next, an ecogeographical representativeness analysis for each species was performed to estimate the genetic diversity that would be preserved under this scenario. For 70 species, the ecogeographical representativeness in protected areas was maximum, as all environments in which the species is present would be represented by the populations inside SCIs. Finally, a complementarity analysis allowed to identify the SCIs that maximise the number of CWRs conserved by the Natura 2000 network and, more important, the genetic diversity of species. Advantages and limitations of this approach to conserve the Spanish CWRs are also discussed.

Implications of model and data uncertainty for conservation decision-making under the IUCN Red List."

Pamela Rueda-Cediel

University of California at Riverside

Kurt ANDERSON, *University of California at Riverside*; Tracey REGAN, *University of Melbourne*; Helen REGAN, *University of California at Riverside*

Threat rankings for endangered species often rely on assessments of extinction risk and population declines. The International Union for Conservation of Nature (IUCN) Red List Categories and Criteria has emerged as the global gold standard for quantitative assessment of extinction risk. Since data for many parameters used in IUCN Red List assessments are inherently uncertain, and in many cases absent, consideration of its reliability is fundamental in guiding priorities for conservation investment among species and populations. The adoption of population models has been recommended to minimize the uncertainty associated with subjective judgment in estimates of extinction risk or population decline but uncertainty remains in the choice of model that best represents population dynamics and in the parameters on which the model is based. In this study we investigate the effects of model choice, variability, measurement error and time series length on the reliability of risk classification decisions made with model outputs under the decision Rule A.3 of the IUCN Red List. We used an age-structured population model to simulate population trajectories subject to different controlled levels of variability and uncertainty and under a range of growth rates. We parameterize scalar and matrix models with these simulated time series to predict percent declines. These were then used to assess IUCN threat status and whether the estimated models' output accurately captured the underlying "true" threat status. We found that high levels of variability decrease model accuracy and high levels of measurement error generated biased risk assessments for both models. However, scalar models generate more reliable risk assessments than matrix models, which tended to be precautionary. Our study provides evidence that short time series and scalar models can be more useful than matrix models in conservation decision-making under particular conditions.

UNDERSTANDING THE ENVIRONMENTAL DRIVERS OF RECORDING BIAS IN CITIZEN SCIENCE DATA ACROSS SWEDEN

Alejandro Ruetz

Swedish University of Agricultural Sciences
Louise MAIR, *Swedish University of Agricultural Sciences*

The collation of citizen science data in open-access biodiversity databases makes temporally and spatially extensive species' observation data available to a wide range of users. Such data are an invaluable resource but contain inherent limitations, such as sampling bias in favour of recorder distribution, lack of survey effort assessment, and lack of coverage of the distribution of all organisms. Any technical assessment,

monitoring program or scientific research applying citizen science data should therefore include an evaluation of the uncertainty of its results. We consider that the open-access databases themselves can – and should – provide information about the quality of the data, and as such we present 'ignorance' scores using data accessed via the Swedish LifeWatch (SLW) biodiversity analysis portal. Ignorance scores are spatially explicit indices of the bias and lack of sampling effort across a study region, and are a feature soon to be implemented in the SLW portal. We analysed spatial patterns of ignorance scores for 13 reference taxonomic groups to further understand observer behaviour. The data is mainly based on voluntary observations between 2000 and 2014. Our aim was to compare the effect of six geographical variables (elevation, steepness, population density, log population density, road density and footpath density) on the ignorance scores among the reference taxonomic groups. We will show how the effect of geographic variables differs among taxonomic groups, and discuss how this information can be applied by the database users, allowing them to take account of the biases present in the citizen science data.

IS HYBRIDIZATION THREAT FOR CONSERVATION? CASE OF PRINCE RUSPOLI'S TURACO, ETHIOPIA

Alazar Ruffo

Addis Ababa University, Department of Biology
Afework BEKELE, *Addis Ababa University, Department of Biology*; Luca BORGHESIO, *University of Illinois, Department of Biology*; Jean-Mark LERNOULD, *CEPA-Conservation des Espèces et des Populations Animales*

Hybridization due to habitat loss is a concern due to genetic loss of material. This concern is more acute in species that are vulnerable and endemics. The Ethiopian highlands have two endemic species of turacos, the widespread White-cheeked Turaco (*Tauraco leucotis*) and the globally-threatened Ruspoli's Turaco (*Tauraco ruspolii*). The two turacos co-occur only in a small region of southern Ethiopia, where *T. leucotis* mainly lives in forest and *T. ruspolii* mainly in more open woodland vegetation. Natural hybrids of the two species were reported in 2002, which might pose a new threat to the survival of *T. ruspolii*. Field work was done between November 2007 and June 2011 to evaluate the abundance and distribution of the turaco hybrids as well as understand the impact of human-caused habitat change on Prince Ruspoli's turaco. The survey was conducted using the point count method within 200 m radius. Each locality was visited to record turacos and their hybrid in different habitats in the morning when the detectability is maximum (6:00-10:30) and playback method was used to detect the turacos. A total of 46 transects, which consisted 548 census points were surveyed. During the census 333 *T. ruspolii*, 251 *T. leucotis*, and nine hybrid individuals were recorded. Hybrids were observed in the overlap zone

between the ranges of the two parent species, suggesting that they are widespread in the region. Turaco hybrids are difficult to recognize and can only be safely distinguished from pure individuals if seen at close distance, therefore we believe that the abundance of hybrids might have been underestimated. All the hybrids were observed in anthropized habitats, suggesting that habitat change might be one of the causes of the hybridization. The distribution of the two turacos showed differences across habitat types and these differences were statistically significant at 1%.

DRIVERS AND MOTIVATIONS FOR COMMUNITY-BASED CONSERVATION: INSIGHTS FROM LATIN AMERICA

Isabel Ruiz-Mallén

Internet Interdisciplinary Institute (IN3), Universitat Oberta de Catalunya

Christoph SCHUNKO, University of Natural Resources and Life Sciences ; Esteve CORBERA, Universitat Autònoma de Barcelona

Indigenous and rural communities have worldwide developed strategies aimed at supporting their livelihoods and protecting biodiversity. Factors underlying these local conservation strategies, however, are still a largely neglected topic. We aim to enrich the conceptualization of community-based conservation by exploring trigger events and local people's motivations that result in functional institutional arrangements for successful natural resource management and biodiversity conservation. Examining the history and development of three community conservation initiatives in Brazil, Mexico and Bolivia, we illustrate and discuss two main ways of understanding community-based conservation from the interaction between external drivers and individuals' motivations. First, incentive-based conservation policies can stimulate people's economic motivations and mobilize individual and collective behavior toward the formalization of conservation-oriented actions. Second, environmental justice concerns, such as international and national movements for the recognition of indigenous peoples' rights, can support local people's sense of autonomy and result in their increased control over their territory and resources, and a renewed conservation commitment. The results are crucial from a policy perspective since they provide insight into the governance of conservation development by bridging the gap between communities' culturally-based motivations for conservation that are still embedded in customary institutions and broader political and socio-economic contexts.

DECISION TOOLS FROM EVIDENCE SYNTHESIS: SUPPORTING WOODLAND EUCALYPT RESTORATION

Libby Rumpff

University of Melbourne

Peter VESK, University of Melbourne ; David DUNCAN, University of Melbourne

The restoration of native vegetation and habitat is an inherently difficult and uncertain task. Calls to provide accessible evidence-based information to aid management decisions are well justified. Research syntheses can provide much needed information on the outcomes of interventions, the gaps in knowledge and future research needs. Yet more is needed; predictions of the outcomes of management, the relative effects of different actions and the uncertainties associated with these are needed so that managers can ask 'what-if' questions. Further, it is desirable that these can be updated with appropriate empirical data. Bayesian Networks can serve the role of a process model for an adaptive management approach. In this paper we present a process model that synthesizes knowledge from the scientific literature into a modelling framework that can be updated as new information emerges. Despite much research dedicated to determining the major factors that most influence tree recruitment, continued declines in the extent of woodland habitat challenge biodiversity conservation in Australia. Through development of a process model focused on eucalypt seedling establishment in woodlands in south-eastern Australia, this research aims to provide a crucial link between the scientific literature and management. We describe the development of the model, its evaluation, updating with new data, then demonstrate how the model can be used to determine the management options that maximise the probability of restoration success, given a set budget, under scenarios where land-use history or climatic conditions may vary.

27 PATTERNS AND PROCESSES OF BIODIVERSITY DEFINING CONSERVATION PRIORITIES IN MEDITERRANEAN-TYPE ECOSYSTEMS OF THE WORLD

Philip Rundel

University of California

Jeffrey CLARY, University of California ; Peggy FIEDLER, University of California Natural Reserve System ; Ben MILLER, Botanic Gardens and Parks Authority ; Pablo MARQUET, Pontificia Universidad Católica de Chile ; Pedro BEJA, InBIO/ CIBIO-Centro de Investigação em Biodiversidade e Recursos

Mediterranean-type ecosystems (MTEs) have been recognized as global hotspots of biodiversity since the "hotspot" concept was introduced (Myers 2003). Covering 2% of global land surface, the five MTEs are home to 16% of vascular plant species. All five regions show high species richness, diversification of many taxa, small population sizes, and comparatively high levels of endemism; both the species and their environments have proven to be appealing to human populations. Though the five regions share many climatic

characteristics, their floristic and faunal diversity have been generated and maintained by contrasting processes. The Cape Floristic Region and the Southwest Floristic Region of Western Australia are ancient landscapes, characterized by nutrient poor soils, long-term climatic stability (absence of glaciation), and accumulations of species over time from very old genetic lineages; these regions may have heightened vulnerability to human-associated extinction processes. The geologically and climatically more recent MTEs (central Chile, California Floristic Region, and the Mediterranean Basin) are heterogeneous landscapes with comparatively younger, more nutrient-rich soils, and a greater diversity of microhabitats; habitat diversity may explain more of the biodiversity in these regions. The distinctive attributes of each MTE region - including current biological and physical characteristics, past and present ecological and evolutionary processes, and the cultural norms of their human populations - must shape effective approaches to conservation of these resources.

SECURING MIGRATORY BIRDS IN PROTECTED AREAS

Claire Runge

University of Queensland

James WATSON, University of Queensland ; Stuart BUTCHART, BirdLife International ; Jeffrey HANSON, University of Queensland ; Hugh POSSINGHAM, University of Queensland ; Richard FULLER, University of Queensland

Migratory birds present the ultimate future challenge for conservation, as their protection relies heavily on international policy and cross-border collaboration. Over half of the world's migratory birds are declining and it is clear that key science-policy gaps remain despite a proliferation of international conservation agreements targeting their conservation over the past three decades. We discover that 91% of the world's migratory bird species are inadequately covered by protected areas across their whole annual migration cycle, compared to 55% of non-migratory birds. Moreover, we show that protection is highly inequitable among countries, so birds that are well protected in one nation might be exposed to threats as they traverse other nations. This first global assessment of migratory species conservation has sobering consequences, given the recently renewed efforts towards increasing both the size and representation of the global protected area estate since the development of the Convention on Biological Diversity Strategic Plan in 2010. Our results demonstrate that this expansion must specifically consider migratory species, and will require better-targeted investment and enhanced coordination among countries. The current 2020 CBD targets will drive the greatest expansion of protected areas in history and represent a key opportunity to conserve migrants into the future in a coordinated and equitable way.

COSTS AND OPPORTUNITIES FOR PRESERVING COASTAL WETLANDS UNDER SEA LEVEL RISE

Rebecca Kate Runting

University of Queensland

Catherine E LOVELOCK, University of Queensland ; Hawthorne L BEYER, University of Queensland ; Jonathan R RHODES, University of Queensland

Innovative strategies are needed to adapt to future impacts of climate change, such as sea level rise. Rises in sea level can alter the distribution of coastal wetlands, which may migrate landward or be lost as tolerance of inundation is exceeded. Coastal ecosystems are vital habitat for many species, such as migratory birds, and also provide essential ecosystem services. Whilst much attention has been given to the costs of human displacement and damage to property or infrastructure, the cost of preserving wetlands as their distribution changes under increasing rates of sea level rise has not previously been quantified. We illustrate that coastal land value increases with elevation and explore the implications of this for adapting the coastal reserve network to sea level rise using a local planning case study in Moreton Bay, Australia - a fast-growing urban region. Here we combined best practice in conservation planning with fine scale simulations of wetland change, revealing that the opportunity cost of preserving wetlands increases substantially with higher sea level rise projections. We quantified the value of carbon sequestration and nursery habitat for commercially important species and found that the additional costs could be attenuated by payments for ecosystem services, but only if these markets and payment mechanisms mature quickly. Until these markets mature, implementing climate change adaptation policy will require a greater investment in the conservation of coastal wetland communities.

USING CONTACT NETWORKS TO PREDICT INFECTIOUS DISEASE RISK IN SOCIAL MAMMALS

Julie Rushmore

University of Georgia

Damien CAILLAUD, Dian Fossey Gorilla Fund International ; Anna JOLLES, Oregon State University ; Brianna BEECHLER, Oregon State University ; Richard HALL, University of Georgia ; Rebecca STUMPF, University of Illinois at Urbana-Champaign ; Lauren MEYERS, University of Texas at Austin ; Sonia ALTIZER, University of Georgia

Disease prevention is a top conservation concern for many wildlife species. Traditional disease modeling approaches assume individual contact rates are constant within a population; however, this is not the case for many wildlife species, where individuals vary in frequency and duration of contact with conspecifics. Social interactions can be formalized

as contact networks, which have great potential to better interpret the spread of infectious disease within susceptible wildlife populations. Here we present case studies on how these networks can be used to predict pathogen transmission in two social wildlife species. In South Africa, we used proximity-logging collars to quantify contact rates in a herd of wild African buffalo, which are naturally exposed to pathogens that cause diseases like tuberculosis and foot-and-mouth disease. We found that pregnant buffalo had the highest contact rates, and may therefore act as “superspreaders” of outbreaks within the herd. By collecting biological samples during bi-monthly captures, we are currently examining how buffalo contact patterns scale with individual immunity and real-time pathogen transmission. In a separate study system, we evaluated the efficacy of targeted wildlife vaccinations. Endangered great apes live in large communities and have experienced major population declines from directly transmitted infectious diseases like measles and Ebola. We simulated pathogen transmission and control strategies on social networks informed by nine months of behavioral contact data from a wild chimpanzee community in Uganda. Our simulations indicate that targeting the most connected chimpanzees can prevent large outbreaks with up to 35% fewer vaccines than random vaccination. Together, these studies demonstrate the use and versatility of contact network models in wildlife epidemiology and underscore the value of incorporating behavioral data into wildlife disease control efforts, particularly for endangered species.

MARGINALIZATION OF AGRICULTURE AND CONSERVATION OF SEMI-NATURAL GRASSLAND HABITATS IN LATVIA

Solvita Rusina

University of Latvia

Pēteris LAKOVSKIS, Latvian State Institute of Agrarian Economics ; Lauma GUSTINA, University of Latvia ; Lauma KUPCA, University of Latvia

The important part of agrobiodiversity is semi-natural habitats. In Latvia, semi-natural grassland habitats cover approx. 47 500 ha (0.7 % of the total area of the country). Only 40 % of this area is located inside Natura 2000 sites. Overall conservation status of semi-natural grassland habitats was bad with the tendency to deteriorate according to the report on Article 17 of the Habitats Directive for 2007-2012 despite of ten year long support of management under agri-environment schemes of Rural Development Programme. One possible reason for this is marginalization of agriculture which leads to land abandonment and decline of biodiversity in agricultural landscapes. Our research aimed to evaluate the conservation status of grassland habitats in regions with different intensity of agriculture marginalization. We analyzed the area of grasslands and the number of households participating in the

agri-environment schemes. Analysis of grassland botanical quality was based on the results of Natura 2000 site monitoring (2007-2012), and inventory carried out in 2013 and 2014. In total, 4.5 % of the total area of semi-natural grasslands under agri-environment schemes were inventoried. The area and diversity of semi-natural habitats were not lower in marginal areas compared to non-marginal areas. Extent of abandonment of semi-natural grasslands was similar both in marginal areas with almost no agricultural activities, and in areas with the most intensive agriculture in Latvia. Biodiversity deterioration of abandoned grasslands was faster in areas with intensive agriculture. Semi-natural grasslands are located in river valleys in these regions, and flooding with nutrient-rich river water enhances eutrophication. The research was supported by the Latvian Council of Science (project No. 514/2012) and European Fund for Agriculture.

HOUSEHOLD LEVEL INFLUENCES ON FRAGMENTATION IN AN AFRICAN PARK LANDSCAPE

Sadie Ryan

University of Florida

Jane SOUTHWORTH, University of Florida ; Joel HARTTER, University of Colorado ; Rebecca FUDA, SUNY ESF ; Nicholas DOWHANIUK, University of New Hampshire ; Jeremy DIEM, Georgia State University

The process of landscape fragmentation outside park borders occurs through the actions of people living in the landscape. In the larger protected area landscape of Kibale National Park in western Uganda, human-landscape relationships are typified by small-scale subsistence agriculture, in which households rely on resources provided in forests and wetlands, whose use is in turn shaped by perceptions of resource availability. To understand and manage for fragmentation of resource pools, identifying the proximate drivers - perceived limitations, and thus enacted resource extraction and utilization - is of fundamental importance. We combine landscape analysis at the household scale, using remotely sensed data, with household surveys, to understand the potential human drivers of local scale landscape change. We found strong evidence for a local household zone (LHZ) effect on fragmentation patterns, with geographical and socioecological heterogeneities in LHZ impact. Differences were influenced by wealth, and in some cases, tribal identity. The perception of crop raiders - primarily baboons and small monkeys, but also elephants and other animals - may have largely shaped human-environment interactions, and were associated with fragmentation. Ninety-two percent of the best fit models included the attitude that the park should stay, but associated with increased fragmentation, suggesting that the uncharacteristic non-hostile attitude about Kibale does not directly translate into conservation-friendly local human-environment interactions. Thus, this study provides insight into park-neighbor

interactions, the influence of the LHZ on protected area landscapes, and points to important points in the system for collaborative opportunities to engage communities and conservation managers.

WHOLE GENOME SEQUENCING OF CALIFORNIA CONDORS IS NOW UTILIZED FOR GUIDING GENETIC MANAGEMENT

Oliver Ryder

San Diego Zoo Institute for Conservation Research
Webb MILLER, Pennsylvania State University ; Katherine RALLS, Smithsonian Institution National Zoological Park ; Jonathan BALLOU, Smithsonian Institution National Zoological Park ; Cynthia STEINER, San Diego Zoo Institute for Conservation Research ; Anna MITELBERG, San Diego Zoo Institute for Conservation Research ; Michael ROMANOV, University of Kent ; Leona CHEMNICK, San Diego Zoo Institute for Conservation Research ; Michael MACE, San Diego Zoo Global ; Stephan SCHUSTER, Pennsylvania State University

A surviving species from North American Pleistocene biodiversity, the California condor is a critically endangered avian species that, in 1982, was reduced to a population of 22 birds in 1982, became extinct in the wild, and has survived persevered through a captive breeding program. It is now back in multiple populations within its former range, through reintroduction efforts. As of October, 2014, 425 California condors, including 219 flying in the wild constituted the extant population. Concern regarding preservation of genetic diversity and other small population impacts such as inbreeding, have led to intensive population management supported by molecular genetics research. Following a 1993 study, estimation of kinship among founder birds was based on multi-locus probe DNA fingerprinting. More recently, genomic methodologies have been applied to better understand the evolutionary and population genetics of California condors. A genetic map has been produced, DNA microsatellites developed and utilized for parentage verification, and whole genome sequencing of 36 California condors has described the entire genomic variation of the species. This has allowed reassessment of kinship among the founder birds, which is now being applied to selecting breeding pairs for the ongoing captive propagation effort. The captive breeding program for the California condor has become the first to base genetic management recommendations on complete genomes of the founders. A genetic disease, chondrodystrophy, is inherited consistent with an autosomal recessive mode of transmission in condors. Utilizing whole genome sequencing of affected chicks and their carrier parents, a series of linked markers localized in a 1 Mb region of the condor genome have been employed to detect carrier condors heterozygous for the lethal mutation. This information can be incorporated into population

management and reduce risk of reproductive failure as reintroduced populations begin to expand.

GENETIC DIVERSITY OF GAZELLES (GAZELLA MARICA AND GAZELLA GAZELLA) IN SOUTHEAST TURKEY

Dilan Saatoglu

Middle East Technical University
Melis DENIZCI ONCU, The Scientific and Technological Research Council of Turkey, MAM, GENETIC ENGINEERING AND BIOTECHNOLOGY INSTITUTE ; Hasan EMIR, Ministry of Forest and Water Affairs, General Directorate of Nature Conservation and Natural Parks, Wildlife Department ; Taner HATIPOGLU, Ministry of Forest and Water Affairs, General Directorate of Nature Conservation and Natural Parks, Wildlife Department ; Sinan Can ACAN, Middle East Technical University ; Tolga KANKILIC, Aksaray University ; İnci TOGAN, Middle East Technical University ; Evren KOBAN BASTANLAR, The Scientific and Technological Research Council of Turkey, MAM, GENETIC ENGINEERING AND BIOTECHNOLOGY INSTITUTE

The present study was conducted to clarify and support the newly established taxonomic status of gazelles in Turkey and also to detect genetic differences between individuals (total n=77) based on 17 microsatellite loci, partial mtDNA cyt B sequence and restriction profiles for two restriction enzymes (Hinfl, HaeIII), and one Y-chromosome microsatellite locus (INRA126). We also investigated the variation between and within gazelle populations (n=3). First, we analyzed the effective population sizes and the recent past events which gazelles went through in the border of Turkey based on microsatellite data. Then, their taxonomic status was evaluated and confirmed by using mtDNA cyt B partial sequences and restriction enzyme profiles including the data from the literature. The results revealed no within population differentiation. However, observations on the basis of two restriction enzymes suggested that there is an easy and less time consuming method to differentiate the three gazelle species (*Gazella marica*, *Gazella gazella*, *Gazella subgutturosa*). Finally, the sequence of the INRA126 locus on the Y-chromosome differentiated between *Gazella marica* and *Gazella gazella* species. This preliminary Y-chromosome data may serve as a reference point for further studies on Y-chromosome diversity within and among gazelle species. The project was carried out in the name of Turkish Ministry of Forestry and Water Affairs and was supported by the Scientific and Technological Research Council of Turkey (TUBİTAK, project no: KAMAG 109G016).

THE CHANGING TRENDS IN BUSHMEAT EXPLOITATION IN GHANA

Hannah Naa Kai Sackey

University of Ghana, Department of Animal Biology and Conservation Science

Kofi AMPONSAH-MENSAH, University of Ghana, Department of Animal Biology and Conservation Science ; Erasmus Henaku OWUSU, University of Ghana, Department of Animal Biology and Conservation Science ; Yaa NTIAMOA-BAIDU, University of Ghana, Centre for African Wetlands

The high level of exploitation of wild animals as food has contributed to biodiversity loss and the depletion of several species of conservation concern. This study examined the dynamics of bushmeat exploitation and trade in the Mankessim area in the Central Region of Ghana, and implications for resource sustainability and wild animal species conservation. Direct observations and structured interviews were used to collect biological data on traded species and socio-economic data from key actors in the bushmeat exploitation and trade from January, 2013 to February, 2014. A total of 3,743 individuals of 19 species of wild animals were recorded at the Mankessim market; with rodents dominating (74%), and the grasscutter (*Thryonomys swinderianus*) accounting for 54.5% of the total number of carcasses recorded. Bushmeat was delivered to the market from a large catchment area including 129 towns and villages. A comparison of the results with surveys carried out in 1975 showed that there has been a change in the composition and relative abundance of bushmeat species delivered to the Mankessim market, with significant decreases in the average weight of the carcasses of two species (*GrasscutterThryonomys swinderianus*, $t=13.368$, $df=3465$, $P<0.05$; and Royal antelope *Neotragus pygmaeus*, $t=6.089$, $df=194$, $P<0.05$). Bushmeat, including protected species, was available on the market all-year-round. The level of exploitation was not sustainable and the level of wildlife protection in Ghana is inadequate for regulating bushmeat exploitation. There is an urgent need to increase wildlife law enforcement efforts and proactively engage the key actors in the bushmeat trade in the regulation of bushmeat exploitation, not only to support species protection, but also to ensure the sustainability of their livelihood sources.

MAPPING FRESHWATER SERVICES FOR ASSESSING CONSERVATION METRICS IN CAMBODIA UNDER CONDITIONS OF SPARSE DATA

Leonardo Saenz

Conservation International

Natalia ACERO, Conservation International

Mainstreaming ecosystem services into sustainable development policies is dependent on the scientifically sound demonstration of the role that ecosystems play in ensuring progress. This is of particular relevance to Cambodia, which is implementing the National strategic plan on green growth 2013 – 2030. Bearing in mind the importance of

freshwater systems to the country, assessing the role of conservation responses at safeguarding key provisioning and regulating services in Cambodia is likely to be essential for implementation of the strategy. This paper will provide context to current freshwater ecosystem mapping methods, will identify knowledge gaps in quantifying actual freshwater services and will propose and test a methodological framework to provide performance metrics for assessing the role that conservation has had in Cambodia in maintaining freshwater services. Many existing freshwater ecosystem mapping methods spatially represent the level of available services but very few use ecological production functions to elucidate the role that ecosystems play in delivering “actual” services. Moreover, many studies focus on quantifying the state of services but a knowledge gap still remains in integrating services to response dimensions such as conservation for appraising overall environmental sustainability. Here, we pilot the integration of an ecosystem services cascade framework with a pressure state response framework in order to create performance metrics of the role of conservation in ensuring provisioning and regulating freshwater services under conditions of sparse data. We demonstrate the method using the Tonle Sap Lake as a downstream reservoir of natural capital in Cambodia where a substantial amount of upstream provisioning and regulating freshwater services are realized.

AN ASSESSMENT OF ACADEMIC APPROACH ON A HOTSPOT REGION, TURKEY FOR BIRDS

Necmiye Sahin Arslan

Hitit University

Gönül ARSLAN, NEVSEHIR HACI BEKTAS VELI UNIVERSITY SCIENCE AND LETTERS FACULTY DEPARTMENT OF BIOLOGY

Turkey is a country that lies between Europe, Asia and Africa and has a total land area of more than 750.000 km². Millions of migratory birds passages across Turkey. A total of 464 species can be seen and there exist 16 globally endangered bird species in this region. There are 178 Important Bird Area with an area of 11,492,455 ha and four of them are in danger. Academic studies on birds are very important for conservation programs. We aimed to present the trend of the interest of birds in Turkish universities. The master and doctoral thesis which were done in Turkey on birds were searched between 1995 and 2014 years using the database of the Council of Higher Education and the thesis were grouped according to the topics and the study areas. Eventually, it was seen that 122 master and 27 doctoral thesis were issued throughout these 20 years. The thesis were related to avifauna (62), bio-ecology of one species (15), migration (12), breeding biology (8), bio-ecology of more than one species (6), anatomy (6), genetics (3), ecotoxicology, habitat, parasites, climatic changes, behavior, evolutionary biology, community ecology and conservation subtopics, respectively. These studies were carried out in

Biology, Zoology, Forestry and Forest Engineering, Veterinary Medicine, Genetics and Environmental Engineering departments. In conclusion, it was seen that the numbers of studies on birds have increased statistically significantly within years. Since Turkey is a critically important for birds, studies are still not enough. The awareness on the necessity of academic studies should be raised and the importance and necessity of studies in collaboration with different countries must be recognized in this important bird area where there are numerous endangered bird species.

POSTER: CO-INVASION BY ANTS: INHERENT BEHAVIOR FOR DISTINCT IMPACTS

Noémie Saint Germes

IRD

Eric VIDAL, IRD ; Hervé JOURDAN, IRD

With increased globalization, tourism and trade, more and more species are moved outside their native range. Some become invasives and then contribute to create multi-invaded ecosystems, but with unknown biotic interactions and other biotic consequences on communities (additive effects, facilitation, inhibition...). Among invasives, ants are considered prominently among the worst ones, according to their range of ecological and economic impacts. This kind of patterns are highly represented on islands, such as New Caledonia, in south West Pacific. New-Caledonia is recognized as a unique biodiversity hot spot with current high pressure from ants invasion, with at least 32 exotic ant species recorded. Two species are particularly of concern, classified among the world's 100 worst invasive species listed by the IUCN: *Anoplolepis gracilipes* (Smith) 1857 and *Wasmannia auropunctata* (Roger) 1863. In Northern New-Caledonia, on Tiébaghi mountain, *A. gracilipes* and *W. auropunctata* coexist together and with a highly endemic lizard community. This co-existence is unusual and not expected as many previous studies considered the co-existence impossible according to their respective high behavioural dominance over community. Many questions arise from this situation : how and why cohabitation is possible? Can cohabitation last? What impacts of invaders on biodiversity? Our study deal with impacts of this multi-invasion at various trophic levels (litter and ground dwelling arthropods to reptile predators) and give us an exceptional and unique insight of a multi-invasion on ecosystem functioning. First results reveal a clear differential impact on two distinct compartments of the ecosystem: When *A. gracilipes* interfere with endangered species of skinks, *W. auropunctata*, impact on native ant community. In order to better assess processes involved in the co invasion maintenance, a longer study is required.

21-BIOCULTURAL RIGHTS OF INDIGENOUS PEOPLES AND LOCAL COMMUNITIES: WHEN RIGHTS EMBRACE RESPONSABILITIES

Giulia Sajevo

Università degli Studi di Palermo

According to K. Bavikatte and Robinson, new 'basket' of group rights is emerging from the interpretation of multilateral environmental agreements, domestic law and case law, and from shifts in the development discourse and the struggles of communities. This new set of rights, 'biocultural rights' encompass all the rights of indigenous peoples and local communities required to secure their stewardship role over their lands and waters. Biocultural rights build on two founding interests: the self-determination and cultural diversity of indigenous peoples and local communities, and the conservation of the environment. This presentation suggests that the second foundation, the conservation of the environment, is what makes biocultural rights potentially more appealing than other human rights but that it is also the reason for their sui generis façade. Unlike human rights generally, biocultural rights seem to be aimed at protecting not only the interests of their right-holders, indigenous peoples and local communities, but also seem to protect a general interest of humankind in the conservation of the environment through the impositions of stewardship duties on rights-holders. Therefore, it is suggested that while biocultural rights provide a promising instrument for the promotion and protection of the interests of indigenous peoples and local communities, they also require such peoples and communities to be conscious of the fact that they, as biocultural rights-holders, take on a duty towards environmental sustainability that limits their self-determination interests. The presentation will explore some of the conceptual tensions emerging from this possibility.

129 TAKING THE OPEN STANDARDS TO SCALE: OUR PATH FOR THE COMING DECADE

Nick Salafsky

Foundations of Success

Amielle DEWAN, IFAW

Over the past decade, the Open Standards for the Practice of Conservation have become one of the world's leading systems for helping conservation practitioners to design, manage, monitor, adapt and learn from their site-based project work. In the coming decade, our challenge is to now take this work to scale. We need to work with conservation practitioners to (1) move beyond a focus on planning to implementation and full-cycle adaptive management and (2) expand our focus from site-based projects to large-scale programs. We need to work with thought leaders and system designers to (3) develop simple tools that enable practitioners to use key

Open Standards concepts without being overwhelmed by the entirety of the process, and (4) incorporate other key tools such as decision support methodologies and spatial analyses into our work. We need to enlist senior organizational leaders and funders to (5) demand that projects and programs have clear theories of change and systematically report on performance, (6) promote open sharing of both success and failures that is the basis of true learning, and (7) provide the necessary institutional support to take on this work. We need to engage with the academic community to (8) systematically vet and test key questions and assumptions and (9) provide training to the next generation of conservation practitioners and researchers. And we need to reach out to our colleagues in the rest of the environmental sector (e.g. climate change, sustainable agriculture, pollution management) and in other fields (e.g. poverty alleviation, public health) to (10) share what we have learned and benefit from their experiences. In the last ten years we have created the foundation of an applied evidence-based science of conservation – in the coming decade, we can now hopefully use this science to improve the effectiveness of our conservation actions at all scales.

ELEPHANT UTILIZATION AND IMPACTS ON THE FUNCTIONAL DIVERSITY OF THE DIOECIOUS PALM TREE BORASSUS AETHIOPUM MART. IN THE PENDJARI NATIONAL PARK, BENIN

Kolawole Valère Salako

Laboratory of Biomathematics and Forest Estimations, Faculty of Agronomic Sciences, University of Abomey-Calavi, Benin

Kowiyou YESSOUFOU, Department of Environmental Sciences, University of South Africa, Florida campus ; Romain L. GLÈLÈ KAKAÏ, Laboratory of Biomathematics and Forest Estimations, Faculty of Agronomic Sciences, University of Abomey-Calavi, Benin

An in-depth understanding of plant-animal interactions is crucial to guide conservation decision especially in protected areas (PAs). Using 60 plots of 0.25-ha in a West African PA, the Pendjari National Park, we investigate the interactions of elephants with natural populations of *Borassus aethiopum*, a dioecious palm tree that provides important nutritional resources for elephants. Specifically, we documented all types of elephant-driven damages to the palm. We then measured the intensity of the damages (number of damaged tree per hectare) and assessed whether the life stage of the palm trees predispose them to intense elephant damages. Finally, we assessed how elephant pressure (low versus high) might affect the structure of the palm populations. We documented four types of damages to the palm tree, and these damages affect mostly sapling and adult palms. All palm populations follow a reversed J structure, irrespective of elephant pressure,

indicating the dominance of seedlings; but very few juveniles were found. As opposed to our expectation, we found no significant effects of elephant-driven damages on sex ratio within the populations of palm trees. However, there was a clear effect of elephants on density, height, dbh, and survival ratios. In particular, the density of saplings, the palm height and the seedling-to-sapling survival ratio track the intensity of elephant pressure (they are high where elephant pressure is high) whilst the density of juvenile and adult trees, the dbh and sapling-to-juvenile ratio followed an opposite trend. Our study therefore indicates that elephant impacts on the palm trees are contingent upon life stages, promoting recruitment of seedlings but preventing their transition to trees. Our findings suggest that elephants limit the functional diversity of *B. aethiopum* in natural ecosystems. **Keywords:** *Loxodonta africana*; *Borassus aethiopum*; herbivory; impacts; population structure.

LANDSCAPE CONNECTIVITY FOR WHOM, WHAT AND WHERE-TO-WHERE: ENGAGING EXPERTS IN CONNECTIVITY MODELING IN HALIFAX, NOVA SCOTIA, CANADA

Saloni Salaria

Dalhousie University

Karen BEAZLEY, Dalhousie University ; Peter BUSH, Dalhousie University

Landscape connectivity is complex to model, given the many species, ecosystems, ecological processes, spatio-temporal scales, landscape measurements and methodologies involved. In this study, we explore these elements by engaging experts (biologists, ecologists, planners and managers) and conducting preliminary analyses of connectivity in Halifax Regional Municipality (HRM) of Nova Scotia, Canada. Our multi-track approach included literature review, focal elements selection, habitat modeling, integration of expert knowledge, and application of GIS-based Circuitscape modeling. Expert engagement in determining who, what and how to connect formed a substantive component of the study. Habitat suitability and connectivity models were created for five focal elements – American Moose, Great Blue Heron, Red Spruce, River Otter and Wood Turtle. For a selected subset of these, alternative models were created using varied parameters of model inputs. As a case example, alternative series of connectivity maps for American Moose were generated for connectivity between habitat patches with (1) ≥ 75 habitat suitability index (HSI), (2) ≥ 80 HSI values, and (3) protected areas. The variations in results obtained highlight the importance of engaging experts and experimenting with model parameters before finalizing model rules and/or a specific connectivity plan. Such practices serve to lend greater credibility and buy-in to the analyses undertaken. The process and its results also speak to the importance of establishing

a clear vision, goals and objectives, delineating priorities around focal elements and target patches, and developing a transparent and defensible analytical framework for landscape connectivity and its application in landscape planning and management.

PREDICTING FUTURE EMERALD ASH BORER *AGRILUS PLANIPENNIS* (COLEOPTERA) INVASION INTO TEXAS USING DISPERSAL RATES AND DISTRIBUTION OF *FRAXINUS TEXENSIS*

Katalina Salas

St. Edwards University

Antoine PASQUIER, St. Edwards University ; Amy BELAIRE, St. Edwards University ; Michael WASSERMAN, St. Edwards University

First reported in North America in 2002, the emerald ash borer (EAB, *Agrilus planipennis*) has been spreading rapidly from its point of invasion in Michigan. This spread has resulted in ash tree mortality in massive amounts on the scale of millions of individual trees. EAB appears to spread at a relatively constant dispersal rate, as over the past 13 years it has moved from southeast Michigan to states that are nearby Texas, including Colorado in 2013, Arkansas in 2014, Georgia and Kansas in 2015. In this study we examined previous models used to estimate EAB invasion from a study conducted at the University of Illinois Urbana and extended them to predict EAB invasion of Texas, allowing us to identify likely entry points for this invasive species. We also determined likely dispersal pathways within the state using known distribution of ash trees that would allow EAB to move from Arkansas to Wild Basin Wilderness Preserve in Austin, Texas using ArcGIS. We then examined the likely impacts of EAB at a local level by measuring the distribution and abundance of ash trees within and surrounding Wild Basin using plots for saplings, complete counts for adults with Wild Basin, and iNaturalist for adults outside of Wild Basin. Texas recently suffered a major drought that killed approximately 102.3 million trees in central Texas alone, so adding pressure from EAB invasion to these extreme climatic events resulting from climate change is highly problematic for Hill Country ecosystems. By estimating arrival times and dispersal pathways, our study provides critical information that can be used to stop the invasion before it occurs.

COMPLEX RESEARCH ON BIODIVERSITY (FLORA, BUMBLEBEE AND COMMON BIRD FAUNA) OF WOOD PASTURES IN THE NORTH HUNGARIAN MOUNTAINS

Dénes Saláta

Szent István University, Faculty of Agricultural and Environmental Science, Institute of Nature Conservation and Landscape Management

Réka BAKOS, Szent István University, Faculty of Agricultural and Environmental Science, Institute of Animal Science Basics ; Ákos MALATINSZKY, Szent István University, Faculty of Agricultural and Environmental Science, Institute of Nature Conservation and Landscape Management ; Tibor JUHÁSZ, Hortobágy National Park Directorate ; Ádám IZSÓ, Aggtelek National Park Directorate ; Miklós SÁROSPATAKI, Szent István University, Faculty of Agricultural and Environmental Science, Institute of Animal Science Basics ; Károly PENKSZA, Szent István University, Faculty of Agricultural and Environmental Science, Institute of Botany and Ecophysiology

Wood pastures are important remnants of traditional land use and preserve high biodiversity. Moreover, they are one of the most endangered woody, semi-natural habitats which are threatened by abandonment due to more intensive livestock production. In this way, nature conservation has major act in the maintenance of these habitats. The six selected wood pastures – located in the North Hungarian Mountains – are typical examples of this habitat in the geographical region and to the different states of use and abandonment. We have classified the main habitat types as treeless, wood pasture, shrubland and woodland parts. To compare the sites and habitats – as within each site as between the sites – we have collected coenological data on vegetation, zoological data by trapping and individual observations in the case of bumblebees and by point counting in the case of common birds. The diversity and distribution relations of the recorded approximately 290 plant species, 6 bumblebee and more than 50 bird species from the researched wood pastures highlight the differences and parallelisms between the habitats and different sites with regard to their various management history. Based on the composition of plant species, the treeless and wood pasture habitats are clearly segregated from the shrubland or woodland parts, moreover their diversity is also higher than the afterward mentioned. The low number of bumblebee species and individuals points to the signs of the pollination crisis, while the distribution of birds shows the importance of complex habitats.

CORAL REEF FISH POPULATIONS CAN PERSIST WITHOUT IMMIGRATION

Océane Salles

USR3278 CRIOBE EPHE-CNRS-UPVD

Serge PLANES, USR3278 CRIOBE EPHE-CNRS-UPVD

Determining the conditions under which populations may persist through time necessitates the use of demographic models, based on reliable estimates of input (recruitment, immigration) and output (mortality, emigration) parameters. Developing such models is especially challenging for marine populations for which recruitment may come from the natal population (self-recruitment) or other sources (larval

connectivity), which are rarely distinguished. The degree to which future population persistence depends on one or both of these inputs is unknown. Here, we evaluate population persistence and turnover for an entire population of the clownfish *Amphiprion percula* at Kimbe Island (Papua New Guinea) by genetic sequencing of all individuals on a bi-annual intervals over 8 years. These data enabled accurate measurement of self-recruitment, larval immigration and mortality through time, and an evaluation of their roles for the persistence of this open population. We found that more than ~50% of the recruits come from local recruitment and that this level of recruitment is stable over five sampling periods. Our demographic model indicates that the Kimbe Island clownfish population can persist without larval connectivity, as can 3 of its 7 small sub-populations. The sub-populations that persist without immigration either have high self-recruitment or low mortality rates. Fundamental approaches are necessary to understand how population can persist, evaluate parameters forcing the dynamics and to be able to develop appropriately targeted and scaled actions. In our own point of view areas that can self-sustain may be among the most important of sites to protect in priority than marginal areas in an era of increasing disturbance frequencies.

CRYOPRESERVATION FOR LONG-TERM CONSERVATION OF DATE PALM (PHOENIX DACTYLIFERA L.) DIVERSITY

Mohammad Salma

IRD (Institut de recherche pour le développement)
Florent ENGELMANN, IRD (Institut de recherche pour le développement)

Date palm (*Phoenix dactylifera*, L.) has a great ecological and socio-economical importance in arid and semi-arid areas of the globe. Date palm displays a large diversity, with over 2,000 varieties identified. However, this diversity is threatened by various diseases and by large-scale dissemination and intensive cultivation of elite varieties. These factors may result in the loss of many local varieties, which have a low productivity but which display interesting characteristics such as disease tolerance. The conservation of date palm diversity is thus a major challenge for date palm cultivation at the global level. Date palm is usually propagated using offshoots sampled on mother-plants. However, the number of offshoots produced per mother-plant is low and highly dependent on the variety. Therefore, *in vitro* propagation protocols have been developed, which allow the rapid and large-scale production of high quality materials. However, large-scale *in vitro* propagation bears the risk of off-type production caused by the occurrence of somaclonal variation. Cryopreservation, i.e. the storage of biological material at ultra-low temperature (liquid nitrogen, -196°C) is currently the only technique available to achieve long-term conservation of local and elite varieties of date palm

and to overcome the risk of somaclonal variation. In this work, we tested the efficiency of two techniques, droplet-vitrification (DV) and dehydration (D) cryo-plate for cryopreservation of proembryogenic masses (PEMs) of two varieties of date palm. With cryopreserved PEMs of variety Sokary, the highest regrowth achieved was 90.9-98.6% with DV and 92.0-97.9% with D cryo-plate. With variety Sultany, DV led to a maximum of 85.6-88.0% regrowth, while D cryo-plate led to a maximum of 67.0-74.6% regrowth. Our results will contribute to the long-term conservation and safeguarding of date palm biodiversity.

INTEGRATING BIODIVERSITY KNOWLEDGE IN VOLUNTARY CONSERVATION PRACTICE

Anna Salomaa

University of Helsinki

Riikka PALONIEMI, Finnish Environment Institute ; Salla RANTALA, Finnish Environment Institute ; Anni ARPONEN, University of Helsinki ; Teppo HUJALA, Natural Resources Institute Finland ; Jari NIEMELÄ, University of Helsinki

While there are calls for scientific evidence based conservation, it is acknowledged that translating science into decision-making and policy implementation is not a linear process and the role of science has to be understood in relation to other forms of knowledge. Including research-based knowledge in decision-making should increase the effectiveness of conservation. Voluntary conservation is based on the premise of increased acceptance, but acceptance does not directly increase the effectiveness of conservation results. In Finland, voluntary conservation has been particularly emphasized in the Forest Biodiversity Programme METSO. METSO aims to halt the ongoing loss of biodiversity in southern Finland by involving landowners in conservation. Forest owners offer sites that are evaluated against ecological criteria and if accepted, the owners receive financial compensation for conserving the sites or for managing them if negotiated in contract. We study empirically the research-implementation gap in voluntary conservation. Data were collected via nine focus group discussions involving forest conservation stakeholders including administration, forest advisers, scientists and forest owners. The groups discussed the bottlenecks in implementation and solutions related to specific conservation issues such as landscape-level planning, old growth forests and the new Forest Act. Based on our findings, different types of knowledge mingle with each other. Discussions reflect that social knowledge is versatile and challenges ecological criteria. Understanding qualities of science, including ecological and other relevant types of knowledge when defining policy instrument, educating forest advisers, informing forest owners, increasing collaboration, creating chances to learn and build trust, carrying out management actions and monitoring effects can increase the flow of information from research to practice and increase effectiveness of conservation.

88 POST-RELEASE BEHAVIORAL MODIFICATIONS IN REINTRODUCED ANIMALS AND THEIR IMPORTANCE FOR CONSERVATION

David Saltz

Ben Gurion University
Oded BERGER-TAL, UCLA

The movement patterns of animals should result from decision-making processes based on the interaction between past experiences (knowledge), the animal's internal state, external conditions, and navigation capacity. Theoretical work supports the notion that organisms should initially invest more in learning when in an unknown environment and, over time, should shift to an exploitation strategy. Reintroductions offer a unique opportunity to study this fundamental theory, as reintroduced animals are completely ignorant of the new landscape they are confronted with and must modify the time allocated to exploration and exploitation as they gain knowledge of their environment. i.e., as an animal is becoming more familiar with its new environment, its knowledge gain should be followed by subsequent changes to its movement behavior. Such post-release behavioral modifications (PRBM) make movement behavior an excellent indicator of reintroduction progress. In this talk we will conceptually describe a logical process that enables the inclusion of behavior (in particular, movement behavior) in management decision-making post-reintroductions, and to do so, we will provide four basic components that a manager should look for in the behaviors of released animals. The suggested components are release-site fidelity, recurring locations, proximity to other individuals, and individual variation in movement behavior. These components are by no means the only possible ones available to a manager, but they provide an efficient tool to understanding reintroduced animals' decision-making based on ecological theory.

PUSHING THE BOUNDARIES ON ISLAND RODENT ERADICATIONS IN THE TROPICS: SHIP RAT ERADICATION ON CAYO CENTRO, BANCO CHINCHORRO, MÉXICO

Araceli Samaniego-Herrera

Grupo de Ecología y Conservación de Islas
Karina RAMOS-RENDON, Grupo de Ecología y Conservación de Islas ; Alfonso AGUIRRE-MUNOZ, Grupo de Ecología y Conservación de Islas ; Federico MENDEZ-SANCHEZ, Grupo de Ecología y Conservación de Islas

The conservation of tropical islands is key for global biodiversity and central to the growing field of island restoration is the removal of invasive rodents. There are 25 biodiversity hotspots at the global scale; 16 of these are in the tropics and nine are mainly or completely made up of islands,

including most tropical islands. The 500+ rodent eradications on islands worldwide reflect the high relevance given by the conservation community to this tool as an effective approach to restore island ecosystems. However, the limited achievements in tropical regions mean that fewer efforts have been done to restore some of the most biodiverse portions of the planet. Furthermore, the lower eradication success rate has raised concern, as it is recognized that rat eradications on tropical islands face inherent challenges not well understood. This is particularly true for evergreen, tropical ecosystems, especially mangrove habitat. The Mexican islands are among the richest insular territories, as Mexico is a megadiverse country with an important tropical area. Unfortunately, invasive mammals have caused at least 17 extinctions of vertebrates on these islands and remain the main threat for many more. The challenging ship rat (*Rattus rattus*) eradication on Cayo Centro (Banco Chinchorro, Mexican Caribbean), scheduled for March 2015, will set a benchmark for rodent eradications on tropical islands worldwide. The closest comparable successful rodent operation is Palmyra, in the tropical Pacific, which at 235 ha is less than half the size of Cayo Centro (539 ha). The associated risks (flooded terrain in mangrove areas, tropical rainforest, land crabs and human settlements), science-based eradication strategy, and results of the operation (the 15th in Mexico) will be discussed. This experience will facilitate future projects in Mexico and elsewhere.

COMMUNITY ENGAGEMENT FOR SEA TURTLES PROTECTION IN LPMSUR, NORTH-WESTERN LIBERIA

Gordon Sambola

Farmers Associated to conserve the environment

The focal project species are the Leather back and Green sea turtles which IUCN Red list considered as endangered. Poachers often kill these turtles for their meat and eggs on the beaches of the project area (Lake Piso Multiple Sustainable Use Reserve, LPMSUR) which are important sea turtle breeding sites. Major beach threats here are sand mining and waste disposal. The project purpose is to stop the killing of sea turtles and harvesting of their eggs on the beaches of LPMSUR. Also the focused turtle species can serve as marine flagship species and their protection can support sustainable beach management and conservation of other important coastal biodiversity habitats/species in the area. The main project methods include (a) Organizing and training sea turtle protection groups in biodiversity conservation (b) Monitoring sea turtles (c) Conducting sea turtle campaign through village forum, nature clubs, drama, song and radio program and (d) Providing alternative livelihood for the sea turtle protection groups as motivational strategy. The expected output includes (1) three functional community sea turtles protection groups established (2) alternative livelihood provided for the group

and (3) a sea turtle data base established. The expected output will reduce threats to sea turtles in the project area

FLORISTIC HOMOGENIZATION CAUSED BY OVEREXPLOITATION OF THE ENDANGERED TROPICAL PALM TREE *EUTERPE EDULIS* MART.

Talita Ariela Sampaio E Silva

Universidade Federal de São Carlos

Raquel Negrão BALDONI, Universidade Federal de São Carlos ;

Dalva Maria Silva Matos, Universidade Federal de São Carlos

The impacts of extraction of non-timber forest products on ecological processes have been underestimated. The tropical palm tree *Euterpe edulis* (Mart.) has high ecological and economical importance, but is subject to intense illegal harvest, which led species to extinction in some remnants of the Atlantic Forest. Our aim was to determine whether the density of palm trees influences the regeneration of plant communities by assessing the forest regeneration in the presence and absence of palm heart harvesting and two densities of palm trees in the tree layer. Our results showed that dominance patterns in the regeneration layer are affected by palm tree density. The diversity of seedlings was higher at intermediate densities of palm trees. Our results indicate that palm heart harvesting caused changes in community structure leading to floristic homogenization. Therefore, we suggest that the conservation of this species should consider the study on sustainable harvest of its resources, as well as improving the surveillance activities in order to conserve their populations and the entire communities.

SHOULD WE BE WORRYING ABOUT ECOLOGICAL TRAPS?: THE CASE OF FOREST BIRDS IN SHADE COFFEE.

Lina Maria Sanchez Clavijo

University of Central Florida

Tropical agroforestry systems retain important elements of native forest biodiversity. However, these intermediately-modified habitats may be functioning as ecological or perceptual traps, making species persistence uncertain in the face of further landscape change. We used birds in shade coffee plantations to evaluate if habitat selection is acting in an adaptive, maladaptive or neutral manner. We assessed habitat preference and quality at different scales by carrying out capture-recapture, capture-resight and visual surveys between 2009 and 2014, in a location known to be a hotspot for endemism and diversity (Sierra Nevada de Santa Marta, Colombia). We analyzed the resulting dataset of 4,539 captures and 2,655 observations for 12 resident focal species using general linear regression models. Conclusions varied depending on how preference was assessed, and

there were differences between the scales and variables that each species responded to. Species were assigned to three groups according to whether they prefer forest, shade coffee or are true generalists. Using size-corrected body mass as an indicator of habitat quality showed that after accounting for the effect of species and breeding condition, only three species showed differences between habitats, and all three exhibited adaptive selection (i.e. preferred the habitat where condition was higher in general or during breeding). Lack of support in any direction for the other species may be evidence for soft perceptual traps but this trend needs to be analyzed in light of varying densities and sampling efforts by habitat. Our work aims to improve the quality of the ecological information used to evaluate and develop conservation tools for birds in shade coffee, specifically, and for mobile animals in heterogeneous landscapes in general.

A SPATIALLY-EXPLICIT MODEL OF ECOLOGICAL TRAPS IN HETEROGENEOUS LANDSCAPES.

Lina Maria Sanchez-Clavijo

University of Central Florida

Jessica HEARNS, University of Central Florida ; Pedro F.

QUINTANA-ASCENCIO, University of Central Florida

Novel habitats in heterogeneous landscapes can become ecological traps for mobile animals if individuals consistently select habitats with detrimental fitness consequences over favourable ones. This phenomenon is hard to detect, which hampers our understanding of the factors that make species and regions vulnerable to it. Most analyses have focussed on animals selecting habitat type as a categorical variable but ecological traps only arise when the original and new habitats share selection cues. We created a spatially-explicit and individually-based simulation model to evaluate effects of landscape structure on population dynamics under different types of habitat selection. The model was parameterized with literature and field data from birds in tropical mountain forests and shade coffee. We ran simulations for 108 scenarios that varied in landscape configuration and composition, individual search distance, and algorithms for habitat choice. The strongest determinant of population size and overall fitness was the proportion of forest in the landscape. With discrete habitat selection (forest vs. coffee) there was a significant interaction between composition and the adaptiveness of selection (adaptive, neutral or maladaptive). Landscape configuration had a minor role, and search distance did not have strong effects. When birds used canopy cover as their preference criteria, the result was a heterogeneous selection surface with fuzzy emergent patterns and outcomes intermediate between neutral and adaptive selection. This result helps explain why habitat preference is so difficult to quantify and ecological traps so hard to detect. Our findings suggest that the negative impacts of ecological traps can be

buffered by managing both habitat structure and landscape characteristics. We hope to combine these outcomes with fieldwork to aid with the creation, evaluation and improvement of conservation tools aimed for forest species in agricultural landscapes.

DOES THE EUROPEAN UNION BIRDS DIRECTIVE CONTINUE TO BENEFIT BIRDS IN A NEW, LARGER EU? TESTING THE EFFECTIVENESS OF AN INTERNATIONAL POLICY INTERVENTION

Fiona Sanderson

RSPB

Alison BERESFORD, RSPB ; Rob POPLE, BirdLife International ; Christina IERONYMIDOU, BirdLife International ; Paul DONALD, RSPB

Whilst considerable time, money and effort are invested in international conservation policy, the effectiveness of such policy and the conservation interventions implemented under it in improving the conservation status of targeted species is rarely evaluated. In one of the first studies of its kind, Donald et al. (Science, 2007) demonstrated that breeding bird species protected under Annex I of the European Union Birds Directive had more positive population trends following the Directive's implementation and more positive population trends in countries where they were protected than those where they were not, up to the year 2000. In this presentation, we consider whether protection under the Birds Directive continues to correlate with more positive population trends of listed species in an enlarged European Union up to 2012, using data on the population trends of all breeding bird species in all EU countries, and whether species which have been protected for longer benefit more. We also examine the impact of conservation interventions implemented under the Birds Directive, including the proportion of a species' range and habitat under protected area designation and the targeting of EU LIFE funding towards conservation action for particular species, to identify mechanisms by which protection under the Birds Directive might drive population trends, how these vary between countries, and how the targeting of such interventions might be improved in the future.

BONDING THROUGH HUNTING: THE ROLE OF ILLEGAL HUNTING AS A SOCIAL ACTIVITY IN THE BATUMI BOTTLENECK, GEORGIA

Anna Sandor

Central European University

Every autumn more than one million birds of prey funnel between the eastern coast of the Black Sea and the foothills of the Lesser Caucasus, in the Republic of Georgia. This

spectacle attracts not only bird watchers and ornithologists from all around the world, but also local people with shotguns. The tradition of autumn hunting of raptors has long been a widespread practice in the region: migration is a part of village customs, and the families' annual rhythm. In these sometimes very remote and infrastructurally underdeveloped poor villages, where unemployment rates are high, people mostly work around their houses, sometimes without going to the nearest town for weeks. For them, the autumn migration period is a red letter day in the calendar that signifies entertainment and free food. Despite its prevalence, there have been few studies on the scale, impacts and drivers of the shooting, and our understanding of its role as a social activity is still limited. According to previous studies, the range of the estimated casualties is very wide (up to 18,000 individuals per year), however, an increase of the number of shots recorded at the migration count stations indicates an increase in hunting pressure. Though Georgia is party to international agreements that protect migratory raptors, the current national legislation contains several loopholes, and its enforcement is close to non-existent. In addition, regional and national governmental institutions are largely ignorant or misinformed about this issue. Local and international NGOs monitoring the migration and hunting activities have recently become increasingly present in the region, which forecasts a potential conflict between conservationists and local people. This paper has a twofold aim: to present conservation questions arising from the illegal hunting of protected species, and to unpack the complexity of the social factors contributing to this.

PINE HEATH FORESTS IN THE HIGH COAST IN NORTHERN SWEDEN

Jennie Sandström

Mid Sweden University

Bengt Gunnar JONSSON, Mid Sweden University

Pine heath forests in the High Coast area in eastern Sweden are old-growth forests with very little human impact. These forests are situated at hill tops and are characterized by nutrient poor and sun-exposed conditions and exposed rock is a common feature. The main tree species is slow-growing and persistent scots pine (*Pinus sylvestris*) and dead wood are abundant. In 2007 a rare beetle was discovered, *Chalcophora mariana*, a species previously thought to be extinct in Sweden. The beetle is entirely dependent on large dead pine wood in warm and sun-exposed environments. In addition a number of other rare species dependent on similar conditions are present in these forest stands, e.g. *Hymenophorus doubleri*, *Cryptophagus lysholmi*, *Dicerca moesta* and *Nothorina punctata*. Pine heath forests in the High Coast have not yet been studied and described. The aim of this study is to describe the structure, dynamics and history of these forests to better understand the environmental demands of several rare dead wood dependent

species. During the summer of 2014 we conducted field surveys using line transects quantifying key features important for the rare species. Tree diameter, age, growth rates, dead wood abundance as well as human influence and signs of fire was examined in seven forests. The result indicates that there has been some human impact since stumps were found in few locations, most likely only for fire-wood use because these forests have never experienced large-scale production. Signs of fire were rare, only a few fire-scarred trees were found, suggesting that perhaps fire has not been frequent, likely due to the low tree density and large areas of exposed rocks which restricts the spread of crown fires and ground fires. To better understand the structure, dynamics and history is of great importance for management of these forests so that the conditions for the threatened species that inhabits pine heath forests in the High Coast can be optimized.

AGRO-FORESTS COMPLIMENT BIODIVERSITY CONSERVATION IN THE WESTERN GHATS OF INDIA

Vishnupriya Sankararaman

Centre for Wildlife Studies

Krithi KARANATH, Centre for Wildlife Studies ; Paul ROBBINS, University of Wisconsin-Madison ; Ashwini CHHATRE, Indian School of Business ; Shashank DALVI, Centre for Wildlife Studies

The pervasive global forest decline has highlighted the importance of secondary habitats like production landscapes in harboring biodiversity. These landscapes are of particular significance in India, where protected areas are small and isolated. The Western Ghats region of India is amongst the hottest of the global biodiversity hotspots. However, with over 50 million people and rapid economic growth, only 9% of the region is protected as wildlife reserves. Studies suggest that matrices of cultivated agroforestry landscapes support wildlife, providing new opportunities for conservation. Our study focused on understanding the ecological and anthropogenic drivers of avian and amphibian community structures across agro-plantations of Western Ghats. We surveyed arecanut, coffee and rubber plantations, the three dominant crop types in the region. A total of 187 plantations were selected from districts with highest annual crop production in Karnataka State. Point counts were conducted in each plantation during the dry season to estimate bird species richness and densities. A subset of the same estates was resurveyed during the monsoons to examine patterns of amphibian occupancy. Coffee plantations ranked highest for their ability to support greater diversity and abundance of all guilds of birds and amphibians. Areca and rubber plantations favored different taxonomic groups. Of the three crop types, rubber hosts second highest species richness and density of birds. On the contrary, we detected more species of amphibians in areca plantations. The difference in management practices in these three crop-types likely influence the community structure of

vertebrates. Since vegetation within coffee plantations is more heterogeneous, its inherent capacity to sustain biodiversity is higher than mono-cropped plantations of rubber and areca. Our findings demonstrate the immense potential of agro-forests in sustaining biodiversity and compliment protected area based conservation.

OBSEA MULTI-SENSORS VIDEO-OBSERVATORY HIGHLIGHTS COASTAL COMMUNITIES' TEMPORAL DYNAMISM

G Santamaria Motis

Instituto de Ciencias del Mar (ICM-CSIC)

Séverine MARTINI, Institut de Recherche pour le Développement IRD, UR 227UMR Entropie, Observatoire Océanologique de Banyuls, avenue du Fontaulé ; J AGUZZI, Instituto de Ciencias del Mar (ICM-CSIC) ; J DEL RIO, SARTI Research Group, Electronics Dept., Universitat Politècnica de Catalunya (UPC) ; V SBRAGAGLIA, Instituto de Ciencias del Mar (ICM-CSIC) ; D TOMA, Instituto de Ciencias del Mar (ICM-CSIC) ; J FERRARIS, Institut de Recherche pour le Développement IRD, UR 227UMR Entropie, Observatoire Océanologique de Banyuls, avenue du Fontaulé ; D PONTON, Institut de Recherche pour le Développement IRD, UR 227UMR Entropie, c/o ARDA station marine, Port ouest, Magasin 10

Multi-sensors observatories are developed nowadays in order to have a survey of marine communities at all depths of the continental margin. The multiparametric Western Mediterranean Expandable SEAfloor OBServatory (www.OBSEA.es) is a video platform used as EMSO testing site, and controlled by SARTI-UPC and ICM-CSIC. That platform is located 4 km off Vilanova i la Geltrú (Catalonia, Spain) at 20 m depth within the Colls i Miralpeix consortium. Using video camera, digital images of the environment have been taken at 360° in the past 3 years, during night and day, at 30 min frequency. Environmental variables (i.e. atmospheric for the surface buoy and oceanographic from the benthic platform; i.e. water temperature, pressure, salinity, chlorophyll, turbidity, air temperature, irradiation, rain, wind speed, sun elevation, and photophase duration) are sampled at corresponding timing. The number of counted fishes is estimated in images, as considered a proxy of overall activity levels within populations. Temporal variability in abundances is described for 2012. Time-frequency decomposition methods on abundances time series are used in order to detect temporal rhythmicity of fish abundances. A strong 24-h periodicity is highlighted. However, the amplitude coefficients of such periodicity vary over time. For all frequencies, 3 distinct periods are described. The first one, from the end of February to mid-April, has low amplitude coefficients for all frequencies. The second one from mid-April to, at least, mid-July is an intermediate period with low coefficients for all frequencies. The third period has the higher

coefficients for all frequencies, with strong 24-h periodicity. This lasted from mid-September to the end of December, as well as in the very beginning of 2012, before mid-February. In order to explain and understand this variability of species count rhythms, we sought for a cause-effect linkage with environmental variables.

HARVESTING RENEWABLE ENERGY WHILE PROTECTING BIODIVERSITY

Andrea Santangeli

University of Helsinki

Tuuli TOIVONEN, University of Helsinki ; Federico POUZOLS, University of Helsinki ; Mark POGSON, Academic Group of Engineering, Sports and Sciences, University of Bolton ; Astley HASTINGS, Institute of Biological and Environmental Sciences, University of Aberdeen ; Pete SMITH, Institute of Biological and Environmental Sciences, University of Aberdeen ; Atte MOILANEN, University of Helsinki

Reliance on fossil fuels is causing unprecedented climate change and is accelerating environmental degradation and global loss of biodiversity. Together, climate change and biodiversity loss, if not averted urgently, may inflict severe impacts on ecosystem processes, functions and services that support the welfare of modern societies. Increasing renewable energy deployment and expanding the current protected area network represent key solutions to these challenges, but conflicts may arise over the use of limited land for energy production as opposed to biodiversity conservation. Here we compare recently identified core areas for the expansion of the global protected area network with the energy potential available from renewable energy sources such as solar photovoltaic, wind and bioenergy. We show, for the first time at the global extent, that these energy sources have very different biodiversity impacts and net energy contribution. Using just 1% of land evenly spread over all viable areas for energy production, we identify a major opportunity for filling most of the global energy demand with solar power without compromising areas of high priority for global biodiversity protection. On the other hand, we find potentially catastrophic impacts on biodiversity from the expansion of bioenergy production, which furthermore can only provide a negligible contribution towards global energy consumption. The evidence provided here helps guide sustainable development of renewable energy and contributes to the targeting of global efforts in climate mitigation and biodiversity conservation.

HARVEST OF PINE TREES AT VARYING RETENTION LEVELS: ECONOMIC RETURN AND EFFECTS ON AMOUNT AND DIVERSITY OF DEAD WOOD

Francesca Santaniello

SLU/Skogforsk

Line DJUPSTRÖM, Skogforsk ; Thomas RANIUS, SLU ; Jörgen RUDOLPHI, SLU ; Olof WIDENFALK, Greensway ; Jan-Olov WESLIEN, Skogforsk

In managed forests, retention of both living and dead trees is fundamental to conserve biodiversity. In Sweden, the current practice is to retain a few percent of the trees on each clear-cut and set aside a few percent of the forest stands. Since retention decreases the revenues from forest harvesting, it is important to understand the consequences of different retention levels for both forestry economy and biodiversity conservation. In this study we compared different levels of retention in stands of Scots pine. The retention consisted of both leaving alive trees and creation of dead and dying trees. The level of retention was ranging from a few percent to all (100%) of the initial tree volume. We estimated the opportunity cost and, as a proxy for nature conservation values, dead wood amount and diversity. This was done in 15 harvested stands in a 140 ha large study area in central Sweden. As expected, we found an increase in opportunity cost with increasing retention level, mainly due to lower harvested volumes but also higher harvesting costs. Since a big part of the retention was killed trees, the amount of dead wood increased with increased retention level. To some extent it also increased because downed dead wood are destroyed to a lower extent in the areas where green trees are retained. The amount of coarse dead wood increased linearly with the retention levels, but it was not the same for the fine dead wood, since it was homogeneously distributed on the whole forest surface. The dead wood diversity increased linearly by increasing the retention up to 35-50%, before leveling off. We conclude that increasing the retention level could be beneficial for the biodiversity and could be an alternative to leave some stands with total retention.

TEMPERATURE-DEPENDENT SEX DETERMINATION CONFERS RESILIENCE TO HIGH TEMPERATURES IN SEA TURTLES BUT EFFECTIVENESS IS OVERRUN BY CLIMATE CHANGE

Pilar Santidrián Tomillo

Institut Mediterrani d'Estudis Avançats (IMEDEA)

Meritxell GENOVART, Institut Mediterrani d'Estudis Avançats (IMEDEA) ; Frank PALADINO, Indiana Purdue University ; James SPOTILA, Drexel University ; Daniel ORO, Institut Mediterrani d'Estudis Avançats (IMEDEA)

Prevailing evolutionary theory is that environmental sex determination (ESD) is beneficial over genotypic sex determination (GSD) when there is differential fitness between the sexes. Temperature-dependent sex determination (TSD) is the predominant mechanism of sex determination in reptiles but its adaptive significance has not been assessed in most groups. In sea turtles, high temperatures produce female offspring and cool temperatures produce male offspring

(TSD type Ia). High temperatures also increase mortality of eggs and hatchlings. We simulated the effects of increasing temperatures on the viability of a population of leatherback turtles (*Dermochelys coriacea*). Then, we compared the results to those of a virtual population with similar characteristics but with fixed sex ratios, as if it had GSD. TSD populations were more resilient to increased nest temperatures than simulated GSD populations. Temperature in the TSD populations increased production of female offspring and future fecundity and compensated for the increased mortality of early stages, buffering the negative effect of high temperature on the population growth rate (λ_s). However, TSD was an effective mechanism only over a range of temperatures. Current climate change models included in the Fifth Assessment Report of the Intergovernmental Panel on Climate Change (IPCC) project increases in temperature between +1°C and +3.7°C by the end of the 21st century. The leatherback population will decline under all contemplated scenarios of climate change and may become extirpated in ~50 years under the high gas concentration scenario.

MODELING SPREAD RATE IN TERRESTRIAL MAMMALS AND THE ABILITY TO TRACK A SHIFTING CLIMATE: A TRAIT SPACE APPROACH

Luca Santini

Sapienza Università di Roma

Thomas CORNULIER, University of Aberdeen ; James BULLOCK, Centre for Ecology and Hydrology ; Steve PALMER, University of Aberdeen ; Steve WHITE, Centre for Ecology and Hydrology ; Greta BOCEDI, University of Aberdeen ; Jenny HODGSON, University of Liverpool ; Carlo RONDININI, Sapienza Università di Roma ; Justin TRAVIS, University of Aberdeen

Population spread rate is an important indication of species' ability to respond to new conditions and is receiving increasing interest in climate change biology. Understanding species' abilities to expand their range is key to assess species vulnerability to climate change, yet empirical data on range shifts are rare, and disentangling the effect of biological traits and local interacting effects has proved challenging. In this study we present a novel approach that allows us to explore species potential spread rate and their ability to track climate change. We generate a multivariate parameter space that follows the trait covariation observed in real terrestrial mammal species, we estimate the relative contribution of individual life history traits to the spread process and the potential spread rate given different combinations traits. Finally, we assess the ability of the terrestrial mammal community to track shifting climate across Earth biomes. Spread rate yields a positive relationship with dispersal distance, litter size and annual survival while a negative relationship with inter-birth interval and sexual maturity age. Almost 30% of species' spreading rate fall below the global predicted climate change velocity,

but the proportion varies across biomes ranging from 7.6% in tropical and subtropical coniferous forests to 44.6% in flooded grasslands and savannas. Our results allow to improve the predictions of species vulnerability to climate change by reducing the uncertainty due to the adoption of extreme and unrealistic dispersal scenarios. Given the lack of knowledge for most species, and the increasing threats to biodiversity and ecological processes, it is important to develop methods that rely on the knowledge of species traits and their covariation, and can be generalized at the species level in order to provide guidelines for management in applied conservation science.

CONNECTIVITY OF THE GLOBAL NETWORK OF PROTECTED AREAS

Luca Santini

Sapienza Università di Roma

Santiago SAURA, Universidad Politécnica de Madrid ; Carlo RONDININI, Sapienza Università di Roma

Millennia of human activity have drastically shaped the Earth's surface confining wildlife in ever more rare and sparse habitat fragments. Within the strategic Plan for Biodiversity 2011-2020, Aichi target 11 aims at the expansion of the current protected area (PA) system and the maintenance and improvement of its connectivity. The present study aims at providing the first overview of the functionality of the PA networks across the six continents at different spatial scales as perceived by terrestrial mammals. We used a graph theory approach to compare the PA networks of different continents across a wide range of dispersal distances. We assessed networks at the country level, both as isolated networks within countries and as part of the continental network, in order to assess their potential role at a larger scale and identify transboundary areas along which connectivity should be improved.

National and continental networks are characterized by very different spatial arrangements which translate into different levels of connectivity, ranging from networks where the reachable habitat is mostly determined by habitat structural connectivity within reserves to networks where connectivity mostly depends on animal dispersal among reserves. These contrasting arrangements may be equivalent for long-dispersing species but result in different connectivity levels for less vagile species. Continental networks tend to perform worse than national networks; transboundary connectivity is often weak and should be improved, especially for countries that play an important role for upholding continental connectivity. The ability of species to move among PAs is heavily dependent on PA size and total coverage, while being less affected by species dispersal abilities whose effect size depends on the number of PAs. This suggests that increasing PA coverage and investing in PA size represents a good strategy for improving multi-species connectivity.

MANAGED LANDSCAPES AS SPATIALLY STRUCTURED ENVIRONMENTS FAVOURING COEXISTENCE: SPATIO-TEMPORAL NICHE PARTITIONING AMONG MEDITERRANEAN MESOCARNIVORES

José Gonçalo Santos

Evolutionary Biology Centre, Uppsala University
Tiago MARQUES, Centre for Research into Environmental and Ecological Modelling, University of St Andrews ; Mats BJÖRKLUND, Evolutionary Biology Centre, Uppsala University ; Margarida SANTOS-REIS, Centre for Ecology, Evolution and Environmental Changes, University of Lisbon

Successful conservation and management efforts require the understanding of mechanisms underlying species coexistence and assemblage organisation. In the biodiverse agroforestry cork oak landscapes of Iberia (Montado), management practices promoted landscape mosaicism and created intricate habitat and resource availability patterns, shaping the volume of available ecological spaces. Previous studies have assessed the association between these landscapes structure and patterns of carnivore diversity, but the mechanisms through which anthropogenic derived heterogeneity influences carnivore guilds organisation remain unclear. It rests uncertain whether human influence in managed landscapes stimulates differential selective behaviours and promotes niche segregation or increases inter-specific niche overlap due to the reduction of suitable habitats. We used camera-trap surveys to investigate niche relationships across a spatiotemporal axis among five mesocarnivore species (red fox *Vulpes vulpes*, Eurasian badger *Meles meles*, Egyptian mongoose *Herpestes ichneumon*, common genet *Genetta genetta*, and feral cat *Felis sp.*) in a managed Montado landscape in central Portugal. Interspecific differences in patterns of habitat use and activity supported a hypothesis of spatio-temporal niche partitioning. Results suggest indirect effects of human activity may greatly influence niche relationships. The anthropogenic-induced contrast between Montado patches preserving dense shrubby understory and semi-disturbed mosaics of sparse shrubs mediated spatial segregation patterns between the most abundant mesocarnivore species. We argue human-derived environmental heterogeneity in agro-silvo-pastoral landscapes creates new ecological spaces, acting as additional sources of niche differentiation to promote coexistence of generalist mesocarnivore species. Our findings can support informed management decisions reconciling exploitation of natural resources with conservation principles.

ATLANTIC FOREST: REMOTE SENSING DATABASE TO INVESTIGATE ECOLOGICAL PROCESSES

Juliana Santos
UNESP

Daniel AGUIAR, Agrosatélite ; John RIBEIRO, UNESP ; Milton Cezar RIBEIRO, UNESP

Remote sensing and GIS are important tools to evaluate ecological processes. Remote sensing data enables to observe ecological processes in large and small scales and making consistent observations across time of these process. Here, our object was to structure a database from available remote sensing data for a part of Atlantic Forest Biome and estimate the habitat amount available for different groups of species in this Biome and provide this database for ecological studies. Our first step was to define from literature data the habitat requirements and matrix permeability informations for different group of terrestrial mammals. Our second step was explore all remote sensing data available of different periods of the time and adjust this data in the same size, spatial resolution and number of land use classes to 30 landscapes of 20 by 20 kilometres. Last, the mammals were classified in groups of size: small, medium and large and by habitat preferences and we estimated the habitat amount for each group including matrices as habitat areas preferences and also were calculated the percentage of each class by landscape. Our results showed the low conservation of the Atlantic Forest landscapes with high rates of the agricultural areas, where generalist species are more abundant and has more habitat amount available, due to these species use the matrices areas as resource. Remote sensing data are important tools for monitoring ecological processes and provide data for ecological analyses.

OCCUPANCY PROBABILITY OF ENDEMIC BIRDS IN GALLERY FOREST FRAGMENTS IN A TROPICAL SAVANNA

Luane Santos

Universidade de Brasília
Miguel MARINI, Universidade de Brasília ; Paul DOHERTY JR., Colorado State University

Little is known about effects of habitat loss and fragmentation on birds' occupancy patterns in the Cerrado. This biome is one of the largest tropical savannas in the world composed of a mosaic of vegetation physiognomies including forests. Its landscape structure may affect both richness and occupancy probability of forest birds. Here we used a single-season occupancy model to estimate the occupancy and detection probability of five endemic forest bird species. We evaluated hypotheses related to forest cover (NDVI - Normalized Difference Vegetation Index, and NDVI Standard Deviation) and to the landscape composition (amount of forest, native and non-native surrounding vegetation). We conducted 589 point counts surveys at a total of 310 points in 59 sites within gallery forests during September to December from 2011 to 2013. Model-averaged occupancy estimates ($\hat{\psi}$) ranged

from 0.33 to 0.75, and detection probability (p) was less than one (0.29-0.71) for all species. Forest cover (NDVI in a 100-m buffer) was an important predictor variable and occupancy probability increased with NDVI values for three bird species. Landscape composition variables had a weak effect on occupancy probabilities. NDVI is an indirect measure of primary production and sites with higher NDVI values might have more resources available to birds. Considering this, in a local scale, the effect of habitat quality on birds' occupancy may be more important than the amount of available habitat. Thus, conservation efforts should be focused in activities that directly affect habitat quality, like selective logging and cattle presence into gallery the forests in the Cerrado.

RECONSTRUCTING CALIFORNIA CONSERVATION HISTORY: WHERE, WHEN, WHAT, HOW AND WHY

Maria J. Santos

Utrecht University

James THORNE, University of California Davis ; Stephanie PIN CETL, University of California Los Angeles ; Iris HUI, Stanford University ; Jon CHRISTENSEN, University of California Los Angeles ; Zephyr FRANK, Stanford University

In an era when biodiversity is highly threatened by changes in climate and land use, it is unclear whether our past conservation efforts will remain effective, and we do not know whether they have been effective so far. Reconstructing conservation history aims to digitally record and understand the development of conservation actions over time. We applied this framework to California to reconstruct where and when Open Space land was acquired, what these areas were acquired to conserve, how the process of acquisition was conducted, which governance levels and actors were involved, and which policies and other drivers explain their acquisition. Today, about ¼ of California is Open Space. Fewer and larger areas acquired at the beginning of the 20th century; and this conservation network was complemented with a larger number of small sized properties. The process of land acquisition was uneven, mostly due to the large efforts in the 1900s, followed by 1930s and 1940s. Forest ecosystems were the ones to be first protected, followed by coastal ranges and ocean-front landscapes, and deserts lands were mostly acquired in the 21st century. This process was a result of a comprehensive set of legislation that evolved through time, and resulted from the competing needs for development and conservation. Several actors were involved in the process of land acquisition, but polycentric governance does not seem to have an effect on conservation land purchases both in number and area. Governance levels, however, showed complementarity in their goals in that different government levels focused on acquisitions of different land-cover types. The framework we present here can, and should, be applied to other geographies and conservation strategies. Future conservation decisions are

not independent of the history of the conservation practice, as conservation in any decade is influenced by what has already been accomplished.

INTEGRATIVE APPROACH TO ASSESS GENOTOXIC RISKS AND ECOLOGICAL RISKS OF RIVER CONTAMINATION FOR WILD FISH POPULATIONS

Raphael Santos

Université de Lyon, UMR 5023 LEHNA [INSTITUTE] Institut National de l'Environnement Industriel et des Risques (INERIS)

Aurélien BESNARD, Centre d'Ecologie Fonctionnelle et Evolutive - UMR 5175 ; Aude JOYEUX, Institut National de l'Environnement Industriel et des Risques (INERIS) ; Sylvie BONY, Université de Lyon, UMR 5023 LEHNA ; Alain DEVAUX, Université de Lyon, UMR 5023 LEHNA ; Wilfried SANCHEZ, Institut National de l'Environnement Industriel et des Risques (INERIS)

Water pollution is considered as one of the main threat to explain fish declines observed worldwide. Because of human activities, a large array of hazardous substances impairing aquatic organisms and leading to population disturbances are discharged into surface waters. Genotoxic compounds including pesticides, polycyclic aromatic hydrocarbons or heavy metals have been considered as hazardous substances inducing deleterious effects to exposed organisms, as well as progeny developmental defects. The first objective of the present study was to investigate a large panel of biomarkers including a genotoxicity biomarker to assess biological impacts of contamination on wild sticklebacks (*Gasterosteus aculeatus*). As a second objective, the relationship between the level of primary DNA damage in sperm from fish sampled in polluted rivers and their progeny survival was investigated. Finally, an approach integrating i) chemical analysis, ii) biomarker responses as early warning signals of contamination impacting individuals and iii) the Fish Based Index as an indicator of fish communities "health status" in French rivers was developed to assess ecological risks for fish populations. Biomarker responses showed some correlations between genotoxicity, biotransformation and oxidative stress biomarkers thus discriminating impacted sites under urban pressures. A significant lower probability of progeny survival was highlighted between the reference and contaminated sites. A trend for a correlation between the level of paternal DNA damage in sperm and progeny survival has also to be noted. Finally, the integrative approach underlined the complementary role of biomarkers, of chemical and of ecological indexes to point out biological disturbances at low levels of biological organization before affecting the community level.

CHARACTERIZATION OF A GENOTOXICITY BIOMARKER IN THREE-SPINED STICKLEBACK AND IMPLICATIONS FOR ENVIRONMENTAL MONITORING

Raphael Santos

Université de Lyon, UMR 5023 LEHNA[INSTITUTE]Institut National de l'Environnement Industriel et des Risques (INERIS)

Melissa PALOS-LADEIRO, Institut National de l'Environnement Industriel et des Risques (INERIS) ; Aurélien BESNARD, Centre d'Ecologie Fonctionnelle et Evolutive - UMR 5175 ; Aude JOYEUX, Institut National de l'Environnement Industriel et des Risques (INERIS) ; Sylvie BONY, Université de Lyon, UMR 5023 LEHNA ; Alain DEVAUX, Université de Lyon, UMR 5023 LEHNA ; Wilfried SANCHEZ, Institut National de l'Environnement Industriel et des Risques (INERIS)

Water pollution is considered as one of the main threat to explain aquatic species decline observed worldwide. In order to assess exposure, fate and effects of chemical contaminants, aquatic ecotoxicologists have developed a large array of early-warning biomarkers proving that toxicants have entered organisms and have triggered toxic effects. In this context, investigating a large panel of biomarkers is relevant to assess the "health status" of aquatic organisms. For an optimal use of biomarkers in environmental monitoring, in-depth knowledge of the kinetics of response and of the natural variability of biomarker responses are required. As genotoxic environmental pollutants induce deleterious effects to aquatic species, this work aims to define as a first step of a validation process, the kinetic response of a genotoxicity biomarker recently developed in the three-spined stickleback (*Gasterosteus aculeatus*) through a 32 days laboratory experiment. Then, natural confounding influences of biotic factors (age, gender and reproductive status) on the biomarker response were investigated in a reference site before integrating the biomarker in a battery of 9 biomarkers to study fish populations from 5 rivers. The kinetic response of the biomarker underlined a fast induction and a slow recovery considering this biomarker as an integrative biomarker "ideal" for environmental monitoring. Gender, age and reproductive status did not influence the biomarker response in fish from the reference site. Finally, the genotoxic biomarker was among the four most discriminating biomarkers investigated discriminating fish from sites under urban pressure. The present work highlights in-depth knowledge necessary to avoid misinterpretation leading to false diagnostic of pollution impacts on aquatic organisms and demonstrated that integration of a biomarker of genotoxicity in a multi-parametric approach is relevant to assess ecotoxicological risk in freshwater aquatic organisms.

116. CONSERVATION FOR PEOPLE AND NATURE, A MAJOR EVOLUTIONARY TRANSITION?

François Sarrazin

Université Pierre et Marie-Curie

Jane LECOMTE, Université Paris-Sud

The debate about "old" and "new" conservation, or conservation for nature, for people or for both is mostly based on cultural, economic, or historic arguments concerning humans and ecological ones concerning non-humans. However we often miss an evolutionary point of view, despite conservation might induce major changes in micro and macro evolutionary trajectories of both human and non-humans. Indeed analysing conservation strategies in the framework of human and non-human evolution would not only allow us considering the evolutionary consequences of our actions on non-humans but also identifying the depth of the challenges that these strategies may constitute. Indeed conservation for people or for nature, e.g. through the definition of instrumental or intrinsic values of biodiversity, is all but neutral for the evolutionary dynamics of humans and non-humans. Conservation to sustain the basic needs of present and future generations and/or maximise their well-being puts a clear focus on the biodiversity required to maintain human fitness on the one hand, and human phenotypic comfort on the other hand. This appears to be a direct heritage of selective pressures and cultural evolution on human individuals and groups. It involves the reduction of predation, competition, parasitism and the enhancement of mutualism or symbiosis as well as the domestication of plants and animals to secure resources. On the contrary, the conservation of nature for itself, the acceptance of spontaneous dynamics and evolutionary trajectories, the maintenance of wildness beyond human needs constitute a fully new strategy at the scale of evolution. Thus, "old" conservation is paradoxically far evolutionary "newer" than the so called "new" one and this may explain the resistance to its implementation. We will explore evolutionary scenarios associated with conservation strategies, particularly for people and nature, and the possibilities of such evolutionary transition in the Anthropocene era.

DROSOPHILID ASSEMBLAGE STUDY AS A TOOL FOR BIODIVERSITY ASSESSMENT, CONSERVATION AND SUSTAINABLE DEVELOPMENT

Manisha Sarswat

HNB GARHWAL UNIVERSITY

Saurabh DEWAN, HNB GARHWAL UNIVERSITY ; Rajendra Singh FARTYAL, HNB GARHWAL UNIVERSITY

Very few studies to date have exploited *Drosophilids* as potential bio-indicators of biodiversity or ecological integrity. Here we investigate the *Drosophila* assemblage as a bio-indication system especially for the management of areas

with high rates of habitat destruction and biodiversity loss especially aftermath Uttarakhand disaster. Several sampling surveys were carried out for about a year at several disaster hit stations in the Uttarakhand region to provide information about the composition of the Drosophilid community. Various diversity indices, constancy method and cluster analysis were used to analyse species occurrence. We analysed and compared this drosophilid assemblage data with our past years data record. Drosophilid community structure was found to be adversely affected for all disaster hit regions. Further, the ecological indexes also showed a possible positive association between species abundance and environmental heterogeneity of the studied areas. Mandal (1600m) being a transition area between sub-tropical and temperate zones, with a high degree of integrity as well as heterogeneity in climate & vegetation, proved to be most diverse of all stations studied. Thus, analysing drosophilid assemblage composition could help us better understand biodiversity of the region at different scales, and can help in identification of more accurate and resourceful biodiversity reserves. It can be also useful in recognizing the pattern and practices related to biodiversity loss and also the effect of anthropogenic activities, allowing the design of efficient conservation policies, and improved in-time future presumptions.

NICHE DEVELOPMENT FOR CERTIFICATION OF FOREST ECOSYSTEM SERVICES - ARE WE THERE YET?

Sini Savilaakso

Center for International Forestry Research
Manuel R. GUARIGUATA, Center for International Forestry Research

The rise of the concept ecosystem services has meant changes in the way forests are seen but so far the implications to their management have been limited. Despite the minimal market demand so far, certification standards have foreseen a potential market niche and have moved into certification of ecosystem services. Forest Stewardship Council is one of the standards developing its certification system to cover forest ecosystem services (FES) more explicitly. It is currently testing its strategy in a pilot project covering Nepal, Vietnam, Indonesia, and Chile. In this presentation we discuss the development of FSC's FES certification using multi-scalar multi-level perspective framework. We focus on niche internal dynamics as modifications of the system under development are possible based on the lessons learned. We look at three key processes of strategic niche management: expectations and visions, social networks, and learning processes. In addition to niche internal processes we identify macro-level processes that can influence niche development for FES certification. Our results suggest that developing a niche for FES certification is still at its infancy. Although the concepts "ecosystem services" and "certification" are well known among practitioners, they

remain rather abstract at implementation level. This has meant weak participation in creation of the vision that guides the development of FES certification. When we look at the social networks, we can see emphasis on different aspects at local and global level. Whereas at local level the focus has been on building a constituency, at global level the focus has been on further development of the system. Among the macro-level processes that can influence niche development for FES certification are market developments, other standard systems and governance instruments as well as the global efforts to improve effectiveness of governance interventions.

HEATED DEBATE BUT LITTLE EVIDENCE: USING SYSTEMATIC REVIEWS TO BUILD BRIDGES BETWEEN STAKEHOLDERS

Sini Savilaakso

Center for International Forestry Research
Manuel R. GUARIGUATA, Center for International Forestry Research ; Gillian PETROKOFKY, Biodiversity Institute, Department of Zoology, University of Oxford

The media is full of stories about the damage done to the environment by oil palm plantations and it is equally full of stories of the huge success of palm oil production for countries trying to raise their economic standards. Green business for the future will mean having economic success without damaging the environment. But just how much damage is being done by palm oil production? What does the science tell us? A systematic review is the best method for assessing this type of question where there is plenty of disagreement and not much robust analysis. Systematic reviews are transparent and replicable and seek to avoid the potential biases found in most literature reviews. They were developed in medicine to provide policymakers and practitioners with robust evidence that is as free from vested interests as possible. They are increasingly used for the same purpose in the area of natural resource management. In this presentation we discuss the opportunities systematic reviews offer to build bridges between different stakeholders. We use our own systematic review as an example. Our systematic review addressed the biodiversity impacts of oil palm cultivation and whether those impacts differ between industrial plantations and smallholder plantations per volume of fuel produced. We also want to share perspectives from our experience on conducting a systematic review in order to lift the veil to the world of systematic reviews and encourage more people to partake them to fully realize their potential in decision-making relevant to environmental management.

EFFECTIVENESS OF TRADITIONAL STRATEGIES IN REGULATING THE FISHERIES RESOURCES OF A SMALL COASTAL LAGOON IN GHANA

Louisa Sawyerr

Department of Animal Biology and Conservation Science, University of Ghana

Jones Kpakpa QUARTEY, Department of Animal Biology and Conservation Science, University of Ghana ; Yaa NTIAMOA-BAIDU, Centre for African Wetlands, University of Ghana

Many Africa cultures have practices that regulate the exploitation of fisheries and other wildlife resources. The Sakumo Lagoon is a small coastal lagoon situated between Accra and Tema and within the Sakumo Ramsar site. The traditional owners of the land regard the lagoon as a god and use a strategy of closed and open season enshrined in religious beliefs to regulate the lagoon fisheries. We tested the effectiveness of this traditional strategy by measuring the fishing intensity, catch per unit effort as well as length-weight relationship, condition factor and reproductive status of the common fish species during the closed and open seasons of 2014-2015. Five fish species were recorded in fishermen's catches: *Sarotherodon melanotheron* and *Oreochromis niloticus* together accounted for 98% of the catch, *Alestes baremoze*, *Heterobranchus bidorsalis* and *Mugil cephalus* constituted the remaining 2%. The number of fishermen recorded on the lagoon in the daytime was much lower during the closed season, however the catch per unit effort was higher. Analysis of the weight-length relationships showed that for both *O. niloticus* and *S. melanotheron* individuals caught in the closed season were significantly heavier and longer (*O. niloticus*, mean weight (gm) closed season 19.4 ± 1.56 ; open season 11.98 ± 0.88 , $t=4.14$, $df=217$, $p < 0.0001$; *S. melanotheron*, closed season 19.4 ± 1.56 ; open season 7.11 ± 0.27 , $t=3.61$, $df=64$, $p < 0.001$). The condition factor (*k*) computed on the monthly samples ranged from 1.37 to 5.36 and 2.14-2.91 for *O. niloticus* and *S. melanotheron* respectively, indicating that the fish were in healthy condition in both seasons. While the traditional strategy was disregarded by several of the fishermen, it had a significant impact in reducing the pressure on the fisheries and allowing the fishes to grow bigger.

CURRENT STATUS OF STRIPPED HYENA IN SOUTHEASTERN TURKEY: PRELIMINARY FINDINGS OF THE RECENT CONSERVATION EFFORTS

Ali Onur Sayar

Ankara University, Graduate School of Natural and Applied Sciences, Department of Biology

Alper ERTURK, Kastamonu University, Game and Wildlife Programme ; Hasan EMIR, Republic of Turkey, Ministry of Forest & Water Affairs , General Directorate of Nature Conservation

and National Parks ; Taner HATIPOGLU, Republic of Turkey, Ministry of Forest & Water Affairs , General Directorate of Nature Conservation and National Parks ; Evren KOBAN, TUBITAK, Marmara Research Center, Genetic Engineering and Biotechnology Institute

As one of the Turkey's cryptic mammals, striped hyena is still remains its mystery in Turkish wildlife due to the lack of information on its behavior and ecology. However, thanks to the increasing number of studies in last ten years, the fundamental knowledge about the Anatolian populations of the species has been raised. Although the ancient records suggest that the species has once distributed through the Mediterranean and southeastern region of Turkey, current studies points out that western Mediterranean populations may have been extirpated, but southeastern populations are still viable. From this point of view, Central Hunting Commission has declared striped hyena as protected species in 2004 and Turkey's first wildlife reserve where the striped hyena is the target species has been designated in Antioch at 2013. To understand the current status and the major threats of the species in southeastern Turkey, camera trap studies, den site observations and the mortality data analysis has been performed in four different study sites between 2013 and 2014. According to the current data, species is highly nocturnal in Turkey unlike the Middle Eastern populations. Also the current data shows that the individuals closely dependent to the den sites especially those are surprisingly very close to the rural settlements and highest mortality on individuals are caused by highway collisions and poaching. Consequently, we believe that the findings of this ongoing study will contribute to the conservation and management of the striped hyena in the middle-eastern turkey

USING SOCIAL MARKETING CAMPAIGN AS EDUCATIONAL TOOL ON TIGER CONSERVATION

Santi Saypanya

Cornell University

The social marketing campaign designed to stimulate human behavior change in order to promote biodiversity conservation in developing countries. Lao People's Democratic Republic (Lao PDR) fits into the criterion. Specifically, Nam Et Phou Louey (NEPL) National Protected Area (NPA) that is considered to be among the best tiger habitats in South-East Asia. Significantly, it supports a tiger population of international importance. However, direct killing of tigers for trade and hunting tiger prey for trade lead to a high potential of losing key species forever. Therefore, the social marketing campaign was used as an educational tool to address the threats. The campaign used proven social marketing activities "theory of change" and "flagship species".The theory of change is key

component to address human behavior by addressing multiple educational materials at following stages knowledge, attitude, interpersonal communication, barrier removal and behavior change. Simultaneously, the flagship species represented the campaign as mascot. The presence of mascot is found every material in order to capture the prompt of the audiences on the campaign. At the end, the theory of change was measured by using a set of standard questionnaires developed by Rare. The results yielded significant increase in every stage of theory of change in campaign site as compared to the control site where there was no significant increase. At the end, the theory of change was measured by using a set of standard questionnaires developed by Rare. The results yielded significant increase in every stage of theory of change in campaign site as compared to the control site where there was no significant increase. In addition, in summer 2013 an additional research on understanding the relations between attitudes and behaviors on ungulate hunting will be conducted at the site and the finding will be added to this presentation.

SYMPOSIUM 34: SATELLITE REMOTE SENSING, FRONTAL ZONES AND THE IDENTIFICATION OF PRIORITY CONSERVATION AREAS IN THE OCEANS

Kylie Scales

NOAA Southwest Fisheries Science Center
Peter MILLER, Plymouth Marine Laboratory ; Elliott HAZEN, NOAA Southwest Fisheries Science Center ; Steven BOGRAD, NOAA Southwest Fisheries Science Center

Identifying priority areas for biodiversity conservation in the vast and dynamic oceans is a major challenge in marine management. Oceanographic features such as upwelling regions, major currents, fronts (physical interfaces at the transitions between water masses) and eddies (circular currents with warm or cold water cores) can create conditions suitable for the development of biophysical hotspots in pelagic systems. Predictable mesoscale (10s to 100s km) regions of persistent frontal activity, 'frontal zones', appear to be particularly important. A taxonomically diverse range of marine predators such as seabirds, sharks, turtles, pinnipeds and large teleost fish are known to associate with these habitats for foraging and migration, making them important candidate sites for conservation. Frontal zones can also be hotspots of overlap between critical habitat and spatially explicit anthropogenic threats, such as the concentration of fisheries activity. As such, they represent tractable conservation units, in which to target measures for threat mitigation. Satellite front mapping facilitates identification, monitoring and management of these hotspots of vulnerability. Seasonal or climatological products can locate biophysical hotspots, while near-real-time front mapping augments the suite of tools supporting spatially dynamic ocean management. These insights are informative for marine spatial planning and marine biodiversity

conservation, both within Exclusive Economic Zones and in the open oceans.

SYMPOSIUM #133 SACRAMENTAL MOTIVATION FOR RESTORING AND CONSERVING PRAIRIES, WOODLANDS, AND LAKES IN MIDWESTERN USA

Jame Schaefer

Marquette University

Partnering with environmental, civic, and community groups and aided by conservation biologists, the Sisters of the Order of St. Benedict have been restoring prairies and woodlands and protecting a 10,000 year old glacial lake in the middle of the State of Wisconsin of the United States of America for all people to enjoy and native species to flourish. They hope that all who experience the 138 acres that constitute Holy Wisdom Monastery will respect and nurture the harmonious functioning of the diverse animals, vegetation, land, water, and air. To advance this goal, they offer volunteer restoration opportunities, nature walks, tours of seasonal changes, educational programs, and spiritual retreats. Motivating their efforts is their reverence for God's creation through which the faithful can experience the presence of God. Conceptualized as the "sacramentality of creation," the Sisters' reverence for Earth (the "Book of Nature") has a long theological tradition that is explored in this presentation and paralleled with other religious faiths that variously express a "sense of the sacred" in the world. This spiritual perception can inspire the faithful to collaborate constructively and meaningfully with scientists in restoring, conserving, and preserving ecological systems and the biosphere.

THREE DECADES OF HABITAT USE REVEALS FOOD LIMITATION OF NEWFOUNDLAND CARIBOU

James Schaefer

Trent University
Shane MAHONEY, Conservation Visions ; Jackie WEIR, Newfoundland & Labrador Department of Environment & Conservation ; Glenn LUTHER, Newfoundland & Labrador Department of Environment & Conservation ; Colleen SOULLIERE, Newfoundland & Labrador Department of Environment & Conservation

The identification of limiting factors is paramount in population ecology and conservation, but often demands sustained observations in the case of long-lived species. Indeed, numerical changes of migratory caribou typically unfold over decades; few studies have examined habitat use at similar timeframes. We analyzed three decades of habitat use by caribou in Newfoundland, Canada – based on radio-tracking of almost 500 adult females, and analysis of diet and age-

specific tooth wear from harvested animals – coincident with the numeric growth ($r \approx 0.064$ in 1980s, 1990s) and decline ($r \approx -0.099$ in 2000s) of this population. Based on landcover composition in the vicinity of each radio-location, females in the 2000s generally displayed diminished use of open and closed coniferous forests, especially during fall and winter, and increased use of barrens, a habitat with greater vascular plant resources, although patterns were not wholly consistent among herds. Based on histological analysis of rumen and faecal samples, diet in the 2000s was increasingly composed of moss and other low-quality forages at the expense of lichens. Teeth of prime age and older caribou exhibited premature wear, likely indicative of depletion of high quality forages and cropping of foods close to the ground. These patterns mirror other responses – declines in calf weight, female body size, number of male antler points, herd affinities, and time spent on the summer grounds. We surmise that they are consistent with density-dependent forage limitation of this island population.

33: THREATENING MESSAGES IN ENVIRONMENTAL COMMUNICATION: A DREADFUL IDEA?

Tim Scharks

University of Washington

People concerned about an issue may attempt to use fear or threats of negative outcomes to persuade others to care about that issue and modify their behavior accordingly. But this tactic rarely works, and may even backfire by polarizing opposition instead of persuading. Threatening messages may cause psychological reactance, defined as anger and counterarguments, increasing resistance to the desired behavior change. This talk presents results from an experimental test of threatening climate change messages on donation behavior. Participants were randomly assigned to a variety of advertisements and could then choose to donate part of their compensation either to environmental nonprofits or to conservative organizations working against climate policy.

INTEGRATED SPATIAL CONSERVATION PRIORITIZATION

Laura Scherer

ETH Zurich

Michael CURRAN, ETH Zurich ; Miguel ALVAREZ, University of Bonn

Biodiversity is declining worldwide at an alarming rate. There is an urgent need to expand conservation efforts to save as many species as possible. To assist this effort, we mapped conservation priorities in Kenya based on maximising complementary richness of plant communities while minimizing economic costs. Complementary richness accounts for both alpha and beta diversity, represented by

species richness and community uniqueness, respectively. We predicted such patterns spatially by relating biological data to environmental variables based on a dataset of 1936 plots and 1432 vascular plant species. To do this, we used generalised additive models and generalised dissimilarity models. We applied nonmetric multidimensional scaling to community dissimilarity to delimit floristic management units. We used these data, as well as existing protected area (PA) coverage, habitat condition, agricultural opportunity costs and conservation management costs to conduct a conservation prioritization using the software Zonation. Zonation iteratively removes the least valuable cells of a landscape based on a pre-defined “biodiversity benefit function” while accounting for land use competition and cost-effectiveness. Our results indicate that Kenya’s current 10% PA coverage does not represent all 37 delineated floristic management units. Expanding the PA network should focus on the Coast and North-Eastern provinces. Meeting the Convention on Biological Diversity (CBD) target of 17% terrestrial coverage by 2020 would increase representation of plant complementary richness by 69%. However, this would require up to USD 400 million per year in management costs, 20 times more than Kenya has received thus far from the Global Environment Facility. Additional opportunity costs could amount to up to USD 68 million per year. This implies serious practical challenges for meeting the CBD targets. Regardless, our models can still be useful to guide existing funding more effectively.

126 - CONSERVATION AND DEVELOPMENT IN A VUCA WORLD: THE NEED FOR A SYSTEMIC, RISK-ROBUST AND ECOSYSTEM-BASED APPROACH

Axel Schick

Eberswalde University for Sustainable Development
Pierre L. IBISCH, Eberswalde University for Sustainable Development

Overcoming traditional approaches biodiversity conservation is becoming an integral part of an ecosystem-based sustainable development targeting the maintenance of functional ecosystems that provide the significant basis for human well-being. The framework conditions that challenge sustainable development are shaped by increasing Volatility, Uncertainty, Complexity and Ambiguity (VUCA concept). Drivers of system dynamics such as climate change, rapid interacting socioeconomic, technological and political changes are often unmanageable on a local scale and require a new approach to planning and action. We analyzed 12 conservation areas (covering 9 protected areas and 5 administrative areas) on 3 different continents with the MARISCO method (adaptive Management of vulnerability and RISks at COnservation sites). This method follows an ecosystem-based approach to natural resource management that systematically encourages managers to include uncertainties and risks into the

process of decision-making and sensitizes for the frequently underestimated complexity that easily leads to strategic failure. Guided by a set of standardized steps, the method provides a systemic reflection of complex conservation situations elaborating a conceptual model. The participatory analyses illustrate that human wellbeing depends to a high proportion on the functionality of ecosystems, which face a high diversity of stresses and threats of varying criticality. Worldwide, local stakeholders and experts rated impacts of global climate change on ecosystems as the most critical problems. Institutional and governance-related weaknesses imply a relatively high vulnerability of management. To achieve an ecosystem-based sustainable development most management teams strive for more risk-robust and adaptive strategies, envisioning an active risk management. A general trend is the need for cooperative management of smaller conservation sites in order to jointly face bigger challenges.

CATTLE FOR CONSERVATION? CATTLE-WILDLIFE COEXISTENCE ON SHARED RANGELANDS IN EAST AFRICA

Jennifer Schieltz

Princeton University

Daniel RUBENSTEIN, Princeton University

Forty percent of earth's land surface is used for grazing domestic animals. These lands also support many wild large mammals and are vital to their continued existence. Consequently, conservation efforts are increasingly aimed at managing land for wildlife-livestock coexistence. In East Africa, many ranches and conservancies have now adopted policies of wildlife-livestock integration, combining cattle production and wildlife tourism. However, there are still many unanswered questions about how species will respond in these systems. This work aimed to quantify the response of a range of wild grazers to cattle grazing in central Kenya and provide data directly to land managers to further conservation goals. One explanation for why so many grazing species coexist in African savannas is that they divide up food resources. I investigated how body size and digestion affect responses of five focal species, three ruminants (Thomson's gazelle, hartebeest, buffalo) and two non-ruminants (warthog, plains zebra) spanning a range of body sizes, to cattle grazing. Detailed spatial data on cattle use intensity was obtained using GPS collars on cattle herds. I then examined the impact of cattle on vegetation, and in turn on wild grazers. Results show that cattle change both the quantity and quality of grass, and may improve vegetation for several species. Small species preferred low biomass areas grazed more by cattle, while buffalo were found mostly in high biomass areas away from cattle. When grass is not limiting, zebra are also drawn to areas of high cattle use after rain. Non-ruminant species were more evenly distributed and utilized more of the available habitats than

their similar-sized ruminant counterparts. Understanding the effect of cattle on different species will allow ranchers to adjust management plans to promote coexistence. We are examining how adaptive cattle management can even be used as a tool to manage rangelands for wildlife.

GLOBAL DATA, SCIENCE, AND CONSERVATION: ARE WE TALKING TO EACH OTHER?

Dmitry Schigel

Global Biodiversity Information Facility

Tim HIRSCH, Global Biodiversity Information Facility ; Siro

MASINDE, Global Biodiversity Information Facility

Explorative and experimental scientists have been mostly collecting, analysing and interpreting their own data. The nature of questions faced by conservation biology calls for use of aggregated data at various temporal, spatial and taxonomic scales. Development of biodiversity and environmental data standards improved the compatibility and the trust in the aggregated data. The relatively new phenomenon of digital availability of massive and heterogeneous biodiversity data has not yet fully permeated the culture and traditions of biological research and conservation management. The Global Biodiversity Information Facility (GBIF) is an international open data infrastructure, funded by governments, allowing free and open access to biodiversity data collected and stored anywhere on Earth. GBIF provides a single point of access to more than 500 million records of nearly 1.5 million species, shared freely by hundreds of institutions worldwide (www.gbif.org). The records, some backed by multimedia files, vary from geo-referenced and time-stamped observations, provided both by researchers and citizen scientists. GBIF collaborates with major organisations active in biodiversity conservation and data, including IUCN, Biodiversity Heritage Library, Encyclopedia of Life, International Barcode of Life Consortium, Catalogue of Life, UNEP-WCMC, and the Intergovernmental Oceanographic Commission, and is recognised as a complementary partner of the Convention on Biological Diversity (CBD) and Intergovernmental Platform on Biodiversity and Ecosystem Services (IPBES) for data mobilization, integration and access. There is strong potential for substantial global benefits to improve the quality, completeness and accessibility of biodiversity data and information in closer collaboration between institutions and expert communities, data aggregators and research infrastructures, conservation biology and other biodiversity sciences, conservation management and decision making.

MAPPING A SUSTAINABLE FUTURE FOR GABON'S FRESHWATER RESOURCES

Steven Schill

The Nature Conservancy

The Gabon Freshwater Conservation Atlas is a multi-stakeholder effort to balance government commitments to freshwater habitat conservation with ongoing planned economic development. As a decision support system, the Atlas was created by combining available data, literature, and expert knowledge within a framework designed to evaluate conservation and development scenarios-- guiding decisions about habitat protection, natural resource development, and mitigation. We provide a comprehensive aquatic ecosystem classification for the entire country as well as measures of disturbance or cumulative impacts, and an analysis of conservation priorities based on the representation of biodiversity elements, connectivity, and ecological condition of these resources. A unique aspect of the Atlas is that it uses the model RIOS to incorporate ecosystem services such as erosion control, nutrient retention, and groundwater recharge into conservation planning scenarios in order to evaluate tradeoffs between natural resources development and protection of habitat and ecosystem services. The compilation of these data and models have been a benefit to a variety of stakeholders since they have provided a way to locate high value servicesheds, while systematically identifying data gaps and prioritizing areas where additional field surveys are needed. Areas identified in the model as conservation priorities are not intended to be prescriptive or static, but to provide a dynamic user-friendly and accessible platform that permits users engaged in development, conservation and management activities (e.g. hydropower, mining, forestry, palm oil, etc.) to have the best available spatial information on freshwater resources and better understand their options for avoidance, offsetting, and mitigating potential impacts of their economic activities for promoting sustainable economic growth into the future.

MOSS INVASION EFFECTS ON COASTAL DUNE ARTHROPODS

Jens Schirmel

University of Koblenz-Landau

Invasive plants can have significant ecological impacts. One of the most invasive moss species worldwide is *Campylopus introflexus*, which is known to affect the native vegetation in dune and heathland ecosystems. This project aims to investigate its potential impact on the structure and function of multiple arthropod taxa in grey dunes on the island of Hiddensee, Germany. In particular, the effect of the moss invasion was analyzed on (i) the community structure and diversity of ground-dwelling arthropods with a special focus on carabids and spiders, (ii) soil biological activity as a main ecosystem function, and (iii) the oviposition behavior of grasshoppers. As main results, the moss influenced the

community structure of arthropods and reduced the soil biological activity compared to native lichen-rich grey dunes. It decreased alpha diversity of carabids and spiders and changed the functional trait composition with more herbivore and smaller carabids and more web-building spiders occurring in native sites. Grasshoppers preferred to oviposit in *Campylopus* moss patches compared to native lichen-rich patches. The shifts in arthropod community structure were taxon-specific and can be explained by changes in vegetation structure, microclimate and soil moisture associated with the moss invasion. The reduced soil moisture was identified as the main driver for the decreased soil biology in moss invaded sites. The reduced habitat complexity associated with the moss invasion can explain the displacement of single carabid and spider species and shifts in functional trait composition. In contrast, the reduced habitat complexity might facilitate the oviposition of grasshoppers into the moss patches. The results demonstrate the various and taxon-specific effects of the invasive moss *C. introflexus* on arthropods and highlights the importance of approaches which consider multiple taxa and ecosystem functions for a better understanding of plant invasion impacts.

76-EVALUATING IMPACTS OF CONSERVATION INITIATIVES ON DEFORESTATION AND FOREST DEGRADATION IN THE PERUVIAN AMAZON AND FACTORS INFLUENCING THEIR SUCCESS

Judith Schleicher

University of Cambridge

In light of the persisting conservation pressures despite considerable conservation efforts, there have been increasing calls for interdisciplinary approaches to rigorously evaluate conservation impacts to ensure that conservation efforts are effective and have their intended impacts. However, such evaluations of conservation efforts are still relatively rare. In addition, the establishment of state-controlled protected areas (PAs) has dominated conservation strategies globally, although an extensive literature has highlighted that no single governance regime is a silver bullet solution to sustainable resource use. As a result one emerging strategy, which has so far not received much research attention, has been to draw on the contribution of non-state actors to protect conservation areas. To contribute towards addressing these research gaps we therefore evaluated conservation impacts of Conservation Concessions (CCs), a novel conservation tool promoted in a number of Latin American countries. These concessions comprise public land given to non-state actors, whether individuals or collectives, for conservation purposes. We integrated quantitative and qualitative data derived from remote sensing, GIS datasets, a questionnaire survey and semi-structured interviews to better understand: 1) whether CCs

have helped to reduce deforestation and forest degradation in the Peruvian Amazon compared to non-protected lands and state-controlled PAs, using a counterfactual approach; and 2) the factors influencing these conservation impacts. The study highlights the contributions that CCs have made to conservation in the Peruvian Amazon in terms of reducing the likelihood of deforestation and forest degradation. However, several institutional, social and economic challenges have constrained their conservation impacts and should therefore be strengthened to improve conservation impacts.

SUSTAINABLE USE OF ECOSYSTEM SERVICES IN JORDAN: EXPERIENCES FROM THE FIRST MONTHS OF A MULTILAYER PROJECT

Oliver Schlein

Deutsche Gesellschaft fuer Internationale Zusammenarbeit (GIZ) GmbH

Jordan, with its very limited natural resources, is seriously affected by desertification, urbanization and a rapidly growing population. Obvious effects of climate change like erosion and land degradation, as well as unsustainable practices like overgrazing, illegal logging and environmental pollution, cause all dramatic pressures on the highly vulnerable ecosystems and threaten their numerous services provided to the people. Ecosystem services are still rarely evaluated and neither considered in the political decisions of the Jordanian government, nor recognized by the Jordanian society. On behalf of the German Federal Ministry for Economic Cooperation and Development (BMZ), the Deutsche Gesellschaft für Internationale Zusammenarbeit (GIZ) strengthens different Jordanian relevant stakeholders with the project "Sustainable Use of Ecosystem Services in Jordan" from 2014 to 2019. The Jordanian Ministry of Environment is supported in the development of a national biodiversity policy with guidelines for the evaluation of ecosystem services. Field case studies are implemented in selected communities in the Jordan Rift Valley to demonstrate best practice examples for rangeland and grazing management, combined with strategies to enhance ecotourism. Results of these case studies are shared with the Jordanian public and related stakeholders, to feed it into political decision making. The establishment of a national information system about ecosystem services, based on professional evaluation, monetary calculation and related aspects of biodiversity conservation, is another main objective of the project. Preliminary results of the start up of the project are presented, with a focus on the involved field case studies, the evaluated ecosystems, the main ecosystem services used by the local population, as well as the positive impact of sustainable practices on the conservation of natural resources and biodiversity of Jordan.

CAN WE INFORM EBVS WITH THE CURRENTLY AVAILABLE DATA ?

Dirk Schmeller

Helmholtz-Center for Environmental Research

The main source of information on biodiversity originates from biodiversity monitoring under an enormous effort. Biodiversity data is however scattered and difficult to assemble, access and analyze. Despite efforts deployed in the global mobilization and the standardization of (digital) biodiversity data, progresses are still insufficient to integrate all information, making access to unbiased biodiversity status and trends difficult on a global level. Despite such difficulties, data from biodiversity monitoring remains central to document change and therewith evaluate the conservation status of species or to assess biological responses to environmental changes (such as climate change, and to conservation policies. In that regard, it is important to know, if we can really inform important biodiversity changes and the relevant Essential Biodiversity Variables. I will elucidate on the currently available biodiversity information with a look backward in time.

151-MICROSCOPIC AQUATIC PREDATORS DICTATE INFECTION DYNAMICS OF A GLOBALLY EMERGED PATHOGEN

Dirk Schmeller

Helmholtz-Center for Environmental Research

Adeline LOYAU, Ecolab Laboratoire écologie fonctionnelle et environnement ; Mark BLOOI, University of Ghent ; An MARTEL, University of Ghent ; Frank PASMANS, University of Ghent

Research on emerging infectious wildlife diseases has placed particular emphasis on host-derived barriers to infection and disease. This focus neglects important extrinsic determinants of the host/pathogen dynamic, where all barriers to infection should be considered when ascertaining the determinants of infectivity and pathogenicity of wildlife pathogens. Those pathogens with free-living stages, such as fungi causing catastrophic wildlife declines on a global scale, must confront lengthy exposure to environmental barriers before contact with an uninfected host. Hostile environmental conditions therefore have the ability to decrease the density of infectious particles, reducing the force of infection and ameliorating the impact as well as the probability of establishing an infection. Here we show that, in nature, the risk of infection and infectious burden of amphibians infected by the chytrid fungus *Batrachochytrium dendrobatidis* (Bd) have a significant, site-specific component, and that these correlate with the microfauna present at a site. Experimental infections show that aquatic microfauna can rapidly lower the abundance and density of infectious stages by consuming Bd zoospores, resulting in a significantly reduced probability of infection in anuran tadpoles. Our findings offer new perspectives for explaining the divergent impacts of Bd

infection in amphibian assemblages and contribute to our understanding of ecosystem resilience to colonization by novel pathogens.

CAPACITY BUILDING IN BIODIVERSITY MONITORING

Dirk Schmeller

Helmholtz-Center for Environmental Research
Working Group 2 GEO BON, GEO BON

It is incontestable that human-driven global change is causing ongoing declines in biodiversity worldwide. The assessment of status and trend of biodiversity is heavily constrained by incomplete and uneven spatial, temporal and taxonomic coverage. For instance, data from developed regions, such as Europe and North America, are currently used overwhelmingly in biodiversity assessments due to lack of suitable data from other regions, and despite developing countries having in general the highest biodiversity on Earth and the strongest negative pressures. There is an urgent need to fill the existing gaps in global biodiversity monitoring. Without a global perspective that encompasses the terrestrial, freshwater and marine realms, decision-makers, scientists and the wider public are left misinformed and with a highly skewed image of the status and trends of biodiversity. We give examples of how new technologies and remotely sensed imagery can be used to improve our knowledge on the status and trend of biodiversity globally and particularly in remote areas. This review describes a range of opportunities and requirements to build capacities for biodiversity monitoring. The literature examined showed that each situation, with its specific socio-ecological background, may demand strategies for capacity building to be adjusted. Monitoring networks may also function most efficiently via key individuals or institutions, which are inter-linked with each other, and which can act as regional hubs to interact with many individuals/institutions at a more local level. That approach maximizes the interplay between expert input and standardization and adaptation of prevailing methods to unique socio-economic backdrops at a local or regional scale, as well as flow of information, information exchange and training.

142 ASSESSING THE POLICY INTEGRATION POTENTIAL OF THE EU GREEN INFRASTRUCTURE STRATEGY ON THE EXAMPLE OF THE EU COMMON AGRICULTURAL POLICY (CAP)

Jenny Schmidt

Helmholtz-Centre for Environmental Research - UFZ
Jennifer HAUCK, Helmholtz-Centre for Environmental Research - UFZ

Environmental Policy Integration (EPI) aims at incorporating environmental issues into decision-making and policy formulating processes of different sectoral policies. The Green

Infrastructure (GI) strategy of the EU aims at integrating GI protection and enhancement into different policies like climate adaptation, nature conservation, regional and agricultural policy, and spatial planning which is of particular concern to ensure connectivity between important biodiversity areas. Based on the analytical concept of EPI we assessed the integration potential of the GI strategy and the greening measures (ecological focus areas, grassland protection, and crop diversification) of the recent CAP reform. We analysed official documents concerning the EPI dimensions 'output' and 'process' using the categories objectives, instruments and addressees. The GI strategy formulates the objectives much more detailed, while the goals of the CAP greening measures remain rather vague concerning environmental aspects with fragmentation and connectivity being not addressed at all despite the fact that the measures are meant to enhance biodiversity protection in intensively used agrarian landscapes. Regarding the addresses of the policies, the CAP mainly focuses on farmers while the GI strategy is targeting a wider audience, including for example civil society, private businesses and conservation practitioners, agricultural stakeholders, rural and urban spatial planners, or potential investors. The analysis of the process revealed that the two policies differ in their participatory approaches. While the CAP greening is rather top-down, the GI strategy encourages bottom-up approaches based on stakeholder participation which could help to make measures more effective and applicable at the same time. Including local and regional stakeholders' views on implementation options could help to understand obstacles and chances of GI integration through the CAP greening measures.

EFFECTS OF DENSITY-DEPENDENT DISPERSAL BEHAVIOUR AND LANDSCAPE STRUCTURE ON DISPERSAL DISTANCES

Andreas Schmitz

Helmholtz Centre for Environmental Research - UFZ
Guy PE'ER, Helmholtz Centre for Environmental Research - UFZ ; Justin TRAVIS, University of Aberdeen ; Greta BOCEDI, University of Aberdeen ; Yiannis MATSINOS, University of the Aegean

Dispersal is a key process for understanding and predicting species' viability in fragmented landscapes, and their performance under land-use- and climate-change. Many decision-support tools and models in conservation describe the dispersal potential of a species by its "typical dispersal distance", as derived from empirical observations. Yet, under which circumstances is this approach really valid? Namely, to what extent can one expect dispersal distances observed in a specific study site to resemble distances occurring in other landscape contexts or at different population densities? Answering these questions requires accounting for the three phases of dispersal (emigration, transfer and immigration),

embedded in the demographic processes occurring in the landscape. We used a simulation study with hypothetical terrestrial animals over virtual landscapes, to investigate the impacts of dispersal behaviour (density-dependent emigration, movement rules and density-dependent settlement), landscape structure and population density on the frequency distribution of dispersal distances (dispersal kernel). We analysed how these factors affect the shape of the dispersal kernel, their relative importance in different scenarios, and the overall dispersal success. We demonstrate that the same species can show a markedly different dispersal kernel, depending on the spatial and population dynamical context. By exploring this sensitivity, we hope to improve the ability to interpret empirical observations on dispersal events and contribute to a refined, process-based representation of functional connectivity in tools and models for conservation.

CONSERVATION AS HYBRID KNOWLEDGE: THE CASE OF THE CALAKMUL BIOSPHERE IN SOUTHERN MEXICO

Birgit Schmook

ECOSUR

Nora HAENN, North Carolina State University ; Sophie CALMÉ, Université de Sherbrooke ; Yol REYES, ECOSUR

We describe conservation built on local expertise such that it constitutes a hybrid form of traditional and bureaucratic knowledge. Researchers regularly ask how local knowledge might be applied to programs linked to protected areas. By examining the production of conservation knowledge in southern Mexico, we assert local expertise is already central to conservation. However, bureaucratic norms and social identity differences between lay experts and conservation practitioners prevent the public valuing of traditional knowledge. We make this point by contrasting two examples. The first is a master's thesis survey of local experts regarding the biology of the King Vulture (*Sarcoramphus papa*) in which data collection took place in communities adjacent to the Calakmul Biosphere Reserve. The second is a workshop sponsored by the same reserve that instructed farmers on how to monitor endangered species, including the King Vulture. In both examples, conservation knowledge would not have existed without traditional knowledge. In both examples, this traditional knowledge is absent from scientific reporting. On the basis of these findings, we suggest conservation outcomes may be improved by recognizing the knowledge contributions local experts already make to conservation programming.

RANGE SHIFT OF EUROPEAN BUTTERFLY: INCREASING COLONIZATION-EXTINCTION RATIO AT THE MARGIN

Reto Schmucki

Museum National d'Histoire Naturelle & CESAB

Guy PE'ER, Helmholtz Centre for Environmental Research ; Tom BRERETON, Butterfly Conservation ; Jofre CARNICER, CREAL ; Alexander HARPKE, Helmholtz Centre for Environmental Research ; Janne HELIÖLÄ, Finnish Environment Institute ; Mikko KUUSSAARI, Finnish Environment Institute ; Elisabeth KÜHN, Helmholtz Centre for Environmental Research ; Martin MUSCHE, Helmholtz Centre for Environmental Research ; Tom OLIVER, NERC Centre for Ecology Hydrology ; Leslie RIES, University of Maryland ; David ROY, NERC Centre for Ecology Hydrology ; Oliver SCHWEIGER, Helmholtz Centre for Environmental Research ; Josef SETTELE, Helmholtz Centre for Environmental Research ; Constanti STEFANESCU, Museu de Ciències Naturals de Granollers ; Arco VAN STRIEN, Statistics Netherlands ; Chris VAN SWAAY, De Vlinderstichting ; Romain JULLIARD, Museum National d'Histoire Naturelle

Butterflies are an ideal focus to understand global drivers of biodiversity change. Their short generation times, high fecundity and sensitivity to temperature make them particularly good indicators to assess species response to climate change. While distribution shifts have been documented from atlas data, such large-scale analyses have never been computed with standardized long-term monitoring data. Here we use dynamic occupancy models with count data extracted from six national Butterfly Monitoring Schemes (BMS) to examine how variation in colonization and extinction affect species occupancy over time and space. In our model, we explicitly account for imperfect detection related to sampling effort and species life-history and allow demographic parameters to vary between regions and over time. First results show that the ratio between colonization and extinction vary substantially with range position. Most interestingly, a large proportion of species shows increasing trends in colonization/extinction at the cold margin of their distribution, but no change at the core nor at the warm margin. We expect these patterns in demographic response to be strongly related to species temperature preference and their mobility. By combining the strengths of dynamic occupancy models and extensive monitoring programs supported by thousand of skilled volunteers across Europe, our study provides new insight into butterfly response to climate change and how local and regional demographic processes can affect distribution patterns at the continental scale.

#156 GLOBAL SCALE EXPLORATION OF THE POTENTIAL OF TERRESTRIAL BLOOD-FEEDING LEECHES AS A VERTEBRATE MONITORING TOOL

Ida Bærholm Schnell

University of Copenhagen

Mads F. BERTELSEN, Copenhagen Zoo ; Michael BUNCE, Curtin University ; Marcus Thomas Pius GILBERT, University of Copenhagen

Estimating abundances and distributions of vertebrate species is one of the fundamental challenges to appropriately guide conservation efforts. Thus, any methodological 'breakthroughs' in species monitoring that lower the impact on the target species, and/or reduce the financial and physical costs, are extremely valuable. An emerging discipline is 'iDNA', where genetic material ingested by invertebrates is used to characterise the biodiversity of the species that served as hosts. These methods are promising as they enable collection of "blood/tissue samples" that are usually difficult to obtain, especially from vertebrate species that are difficult to monitor because they are e.g. shy, nocturnal, dangerous or live in inaccessible habitats. Although promising, using leech-derived iDNA as a source of vertebrate DNA is still in its infancy and thus, to verify the potential of this method, we examined haematophagousterrestrialleeches collected over almost their full geographical range (thus, where this method might apply). Specifically, this included leeches representing both morphologically distinct groups of terrestrial leeches, the duognathous (two-jawed) and trignathous (three jawed) leeches, collected in South-East Asia, Madagascar, and Australia; areas that are known for their extensive tropical or subtropical rainforests, rich biodiversity, and high number of endemic or threatened vertebrate species. Host DNA extracted from the examined leeches were assigned to approximately 40 vertebrate families from four different vertebrate classes including mammals, birds, reptiles, and amphibians; demonstrating that blood ingested by many different species of haematophagous leeches is a viable source of vertebrate DNA and is a tool applicable to numerous geographic locations.

SYMPOSIUM 156: TARGETED DETECTION OF MAMMALIAN SPECIES USING CARRION FLY - DERIVED DNA

Grit Schubert

Robert Koch Institute

Melanie STOCKHAUSEN, Robert Koch Institute ; Constanze HOFFMANN, Robert Koch Institute ; Kevin MERKEL, Robert Koch Institute ; Linda VIGILANT, Max-Planck-Institute for evolutionary Anthropology ; Fabian LEENDERTZ, Robert Koch Institute ; Sébastien CALVIGNAC-SPENCER, Robert Koch Institute

DNA analysis from carrion flies (iDNA analysis) has recently been promoted as a powerful tool for cost and time efficient monitoring of wildlife. While originally applied to identify any mammalian species present in an area, it should also allow for targeted detection of species and individuals. Using carrion flies captured in the Taï National Park, Côte d'Ivoire, we

assessed this possibility by i) screening carrion fly DNA extracts with non-specific and species-specific PCR systems respectively targeting mitochondrial DNA (mtDNA) fragments of any mammal or of Jentink's duiker (*Cephalophus jentinki*), three colobine monkeys (subfamily Colobinae) and sooty mangabey (*Cercocebus atys*) and ii) genotyping carrion fly extracts containing sooty mangabey mtDNA. In comparison with the non-specific PCR assay, the use of specific PCRs increased the frequency of detection of target species up to three fold. Detection rates partially reflected relative abundances of target species in the area. Amplification of seven microsatellite loci from carrion flies positive for sooty mangabey mtDNA yielded an average PCR success of 46 %, showing that the identification of individuals is, to some extent, possible. Regression analysis of microsatellite PCR success and mtDNA concentration revealed that, among all carrion flies analysed for this study, 1 % contained amounts of mammal mtDNA sufficient to attempt genotyping with potentially high success. We conclude that carrion fly-derived DNA analysis represents a promising tool for targeted monitoring of mammals in their natural habitat.

EXAMINING THE RELATIONSHIP BETWEEN STAKEHOLDERS AND U.S. NATIONAL PARKS: THE CASE OF EVERGLADES NATIONAL PARK

Michael Schuett

Texas A&M University

Yunseon Choe, Texas A&M University ; David Matarrita, Texas A&M University

Over the last few decades, diverse groups of stakeholders have become increasingly involved with parks and protected areas that are impacted by impending development, population shift and other natural processes. A collaborative approach to landscape conservation is necessary to cultivate natural resource stewardship but challenging given the diverse backgrounds of external partners. In keeping with the theme of the 2015 ICCB-ECCB conference, this study examines the relationships between stakeholders and one of the most biologically diverse national parks in the United States National Park System, Everglades National Park (EVER). Located in the southeastern U.S., this park was added to the World Heritage List in 1979. At 1.5 million acres, EVER is home to over 20 rare, endangered/threatened species and provides habitat for over 400 species of birds. However, EVER is also on the World Heritage Danger list threatened by poaching, disruption in water flow, pollution, and development. This poster presentation will report on interviews with 51 stakeholder groups representing government, businesses, conservation organizations, local residents, and adjacent national parks. Study participants were asked about meanings of the park, change over time, involvement with the park, relationships, and the future. Results showed several key themes emerging from the interviews: environment, community participation, culture/

history, education and partnerships. Theoretically, the findings will provide a better understanding of diverse stakeholders' and their relationships with national parks. For park managers, the results will facilitate more effective strategies to guide conservation in and beyond park boundaries.

CHIPMUNK IN THE CITY: EFFECTS OF URBANIZATION ON INDIVIDUAL BEHAVIOR AND ECOLOGY OF EASTERN CHIPMUNKS

Albrecht Schulte-Hostedde

Laurentian University

Jeremy LYONS, Laurentian University ; Darryl EDWARDS, Laurentian University ; Gabriela MASTROMONACO, Toronto Zoo

Human-altered landscapes provide ecological and evolutionary challenges for all organisms, and urban environments are such an example. Cities offer habitats, stressors and resources that are significantly different from natural habitats. For example, the presence of people, roads, cars, and domestic pets may elicit different behavioral and stress responses. We examined differences in behavior, cortisol and body condition (size-corrected mass) of eastern chipmunks (*Tamias striatus*) that were captured from urban and natural populations. The eastern chipmunk is a small diurnal, solitary rodent that occupies forests and parkland. We predicted that chipmunks captured in urban areas would be (i) more vigilant and exhibit more locomotory behaviour, (ii) have higher cortisol levels, and (iii) be in poorer body condition, than chipmunks captured in natural habitats. Chipmunks were sampled from two urban sites and two natural habitats. Upon capture, chipmunks were subjected to an open field test, weighed, measured, and both fecal and hair samples were collected for cortisol analysis. Chipmunks from urban sites showed more vigilant behavior and reduced locomotory behavior compared with counterparts from natural habitats. In addition, urban chipmunks had lower cortisol levels and higher body condition. Our results indicate that chipmunks in urban environments seem to enjoy relatively benign conditions relative to their counterparts in natural habitats. Chipmunks may need to be more vigilant in urban habitats to enhance awareness of novel threats, yet urban habitats appear to be less stressful for chipmunks and may contain more or higher quality food resources than natural habitats.

97 - WHAT'S IN YOUR BACKYARD? CITIZEN SCIENCE CAMERA TRAPPING AS A LENS TO STUDY MAMMAL DIVERSITY IN CLASSROOMS.

Stephanie Schuttler

North Carolina Museum of Natural Sciences, North Carolina State University

Rob DUNN, North Carolina State University ; Roland KAYS, North Carolina Museum of Natural Sciences, North Carolina State University

A current concern among conservationists is that people are increasingly becoming disconnected from nature, living in urban environments and spending more time indoors, which may cause an "extinction of experience" resulting in a decline in support for conservation and wildlife initiatives. Our goal was to provide opportunities for connecting kids to nature in the classroom by engaging them in authentic research through the eMammal program. Students collect data with camera traps, archiving raw results with eMammal, a citizen science camera trapping project. By working with citizen scientists, eMammal has collected a large range of data, providing a rich set of comparisons with schools. Camera traps are ideal for science classrooms because the species recorded by these cameras can be verified by experts. We are working with teachers from North Carolina public schools to develop lesson plans that integrate the latest national and state science standards. The implementation of these lessons will result in peer-review quality scientific research, while also providing structure for teachers to allow scaling across the state and nation. We are extending the lesson plans for use in cross-cultural learning between schools in North Carolina, Mexico, and India. All lesson plans will be available for other schools, and accompanied by instructional videos. Finally, we are also studying the attitudes of students towards local mammals to determine if participation in eMammal improves attitudes and perception of wildlife. The data collected by students, and research questions addressed in lesson plans, will be used by scientific publications extending our knowledge of mammal ecology. We hope that the excitement of studying charismatic animals through camera trapping will not only motivate students to expand our knowledge of mammal ecology, but also have a stronger sense of place, and understanding that nature can be experienced in urban settings.

L'ARBRE À PALABRES" INCUBATOR AS SOCIAL ISSUES BINDING CLIMATE AND BIODIVERSITY.

Lionel Scotto

GDR PARCS

Although there is a tendency to reverse technocratic logic top-down control of ecological and environmental issues, there is yet a constant lack of dialogue between Sciences and Societies on climate issues and their impacts on biodiversity. This communication proposes to present the first results of the research device called in French « l'arbre à palabres », the "Tree Palabres" designed specifically for climate issues, and also invite participants of this original session to effectively participate in this participatory engineering. Following a logical

bottom-up, the objective is to synergize citizen initiatives with representatives of civil life to bring out a proposal for action for public authorities. Inspired by the African tradition, « l'arbre à palabres » is designated a gathering at which villagers discuss "freely" social and political problems. In this session we will discuss climate issues and their impact on biodiversity by placing them in their social context as for example the monetary compensatory mechanisms related to biodiversity loss. In a participatory action research approach each participant is required to express its view in relation to the others. L'« Arbre à Palabres » acts as a social and political kaleidoscope where are in are closely intertwined epistemological dimensions, norms and values.

IMPROVING FOREST CONSERVATION OUTCOMES: A CASE STUDY IN MADRE DE DIOS, PERU

Jason Scullion

McDaniel College

Kristiina VOGT, University of Washington ; Sophia Winkler-Schor, University of Washington ; Alison SEINKIEWICZ, University of Washington ; Carlos PEÑA, Universidad Nacional Amazonica de Madre de Dios ; Frank HAJEK, Nature Services Peru

As global forests decline, targeting conservation policy is becoming increasingly important. Though much progress has been made to target forest conservation policies, there is much room for refinement. To improve policymaking in forest landscapes we present a case study from the Manu-Tambopata biological corridor in Madre de Dios, Peru, which includes a diverse mix of land-use activities, including actively exploited gold deposits, agricultural expansion, and commercial logging. To identify policy "leverage points," or places in a system where small interventions can result in large system changes, farmers and miners actively working in the corridor were surveyed. The surveys included questions related to land-user demographics, current and future land-use practices, and preferences for alternative conservation policies. The results of the surveys show that despite rapidly increasing deforestation in the study area, many local land-users are implementing conservation measures to improve forest conservation outcomes, including the majority of both miners and farmers who stated they partake in at least one form of forest conservation. Additionally, both miners and farmers expressed high interest in various forest conservation policies proposed. Farmers held a strong preference for technical support in exchange for private forest conservation (97%) and 73% of miners were interested in alternative jobs. Additionally, 67% of farmers said they were interested in payments for ecosystem services at double voluntary carbon market pricing. The results of this case study demonstrate the strength of using field surveys to understand local conditions and to identify conservation policies that are both desired and effective. Lastly, due to the high variability

in local socio-economic conditions, designing effective forest conservation policies is particularly challenging because of wide variations in forest vulnerability and uncertainties in future socio-economic conditions.

IMPROVING GENETIC STATUS DESPITE FRAGMENTATION AND SMALL EFFECTIVE POPULATION SIZE IN HILL'S THISTLE (CIRSIMUM HILLII)

Leah Sefton

Central Michigan University

Chelsea BUTCHER, Central Michigan University ; Chelsi ABBOTT, Central Michigan University ; Joanne DANNENHOFFER, Central Michigan University ; Bradley Swanson, Central Michigan University

Small, fragmented populations are at greater risk of extirpation due to reduced genetic diversity from inbreeding and genetic drift. These processes ultimately reduce the ability of a population to adapt, and decrease individual fitness. Hill's thistle (*Cirsium hillii*) is classified as a threatened species throughout much of its range, primarily due to the destruction and fragmentation of its habitat. This study addresses the impact of population size and isolation on the genetic diversity of Hill's thistle. We used microsatellite markers to genotype plants collected from the Lower Peninsula of Michigan in 2001, and from the Lower Peninsula and Drummond Island in 2012, in order to assess genetic differentiation across time and space, as well as to investigate rates of inbreeding in isolated and non-isolated populations. Genetic differentiation between the sample sites in the mainland population of Hill's thistle increased significantly since 2001 (all $P < 0.01$), indicative of increased fragmentation and isolation of the sample sites. However, the 2012 population exhibited lower inbreeding ($P < 0.001$) and higher heterozygosity ($P = 0.018$) compared to 2001, suggesting that the population is growing in spite of isolation. Conversely, the population on Drummond Island had higher levels of inbreeding ($P < 0.001$) and lower allelic richness ($P = 0.04$) and heterozygosity ($P = 0.0055$) compared to the mainland, typical of a small, isolated population. Our results indicate that the mainland population of Hill's thistle is persisting, but should continue to be monitored due to ongoing habitat loss.

HOW CAN GENETICS GUIDE TRANSLOCATIONS - LESSONS LEARNED FROM ENDANGERED BIRD SPECIES

Gernot Segelbacher

University Freiburg

Translocations are seen as a valid option for many species when populations become extinct or too small to survive on their own. A number of facts (demographic, logistic, ...) need to be considered for successful translocations and genetic methods now can help us in monitoring these projects closely and evaluate the success or failure of management action. I will here present a case studies in several endangered bird species (capercaillie tetrao urogallus, black grouse tetrao tatrix, and the pale-headed brushfinch atlapetes pallidiceps), where genetic tools helped us in developing proper management plans and to evaluate the outcome of this actions. Genetic information can be used in assessing the genetic status of the population in focus, identifying the appropriate individuals for a given translocation and further on in monitoring the respective populations. Proper genetic surveys during this process are crucial to avoid the failure of such projects and I will highlight where and how genetic tools can make a difference.

CONSERVING BIODIVERSITY OF SAPROXYLIC INSECTS - A MATTER OF DEAD-WOOD AMOUNT OR DEAD-WOOD DIVERSITY?

Sebastian Seibold

Technical University of Munich

Jörg MÜLLER, *Technical University of Munich*

Dead wood is a crucial factor for biodiversity in forests and thus, various conservation strategies aim on increasing the amount of dead-wood in managed forests. Many field surveys have shown a positive relationship between dead-wood amount and species diversity, but dead-wood amount is, however, strongly correlated with dead-wood diversity. For conservation strategies, detailed knowledge about this relationship is of high interest as an independent positive effect of dead-wood diversity would mean that lower dead-wood amounts are sufficient when dead-wood substrates are diverse. This could help to reduce costs for conservation by means of unharvested timber while increasing the number of species that benefit from such strategies. To disentangle the single effects of both parameters on biodiversity, we manipulated 800m³ of freshly cut logs and 5000 branches of two tree species (*Fagus sylvatica* and *Abies alba*) in a large field experiment covering gradients of dead-wood quantity and dead-wood diversity on sunny clearings and in shady forest stands. All treatments and control plots without dead wood were replicated five times in the Bavarian Forest National Park, Germany. Saproxylic beetles were sampled over the first three years using flight-interception traps. Species communities differed greatly according to sun exposure. Generalized linear mixed models revealed positive effects of both dead-wood amount and dead-wood diversity on species richness of all saproxylic beetles and red-listed species only. This indicates

that not only the amount of dead wood is crucial to maintain diversity of saproxylic beetles, but also the diversity of dead-wood substrates as well as microclimatic conditions. Based on these results, we recommend forest and conservation managers to provide sufficiently high dead-wood volumes, but moreover, to provide a high diversity of dead-wood substrates regarding tree species, diameter class, decay stage and sun exposure.

RESEARCH CAN INFORM MANAGEMENT PRACTICES TO DETER CROP RAIDING BY MOUNTAIN GORILLAS

Nicole Seiler

Max Planck Institute for Evolutionary Anthropology

Martha M. ROBBINS, *Max Planck Institute for Evolutionary Anthropology*

A challenge facing wildlife conservation is the conflict between humans and wildlife due to competition for resources. Crop-raiding and ranging outside the park by the critically endangered mountain gorillas (*Gorilla beringei beringei*) of Bwindi Impenetrable National Park, Uganda has negative impacts on wildlife conservation and local livelihoods, thereby compromising conservation efforts. The objective of this study was to assess the ecological factors influencing mountain gorilla ranging outside the national park and crop-raiding to help guide management practices in areas bordering the park. Using Mixed Models, we examined the relationship between the availability of crops, including tea plantations, grown adjacent to Bwindi as well as food availability inside the park and the number of days gorillas ranged outside the park and crop-raided. We found that incidences of gorillas' ranging outside Bwindi and crop-raiding to be positively related to the availability of tea and other land-use types immediately bordering the park. Food availability inside Bwindi did not have an impact. We suggest that gorillas do not range outside the park and crop-raid due to food scarcity, but are attracted by certain food resources outside Bwindi. Our results show that tea does not deter gorillas from leaving the park, largely because tea plantations are interspersed with other land-use practices, which attract gorillas, and currently do not form a contiguous barrier to stop gorillas from ranging further into community land. However, if planted continuously in areas vulnerable to crop-raiding, tea may best serve as a buffer crop and a deterrent against gorillas. We suggest establishing buffer zones and implementing wildlife sensitive land-use planning strategies along the boundary. This study emphasizes how it is crucial to gain a better understanding of the determinants of wildlife ranging and crop-raiding to guide conservation strategies based on the species' behavioral ecology.

UNDERSTANDING MOTIVATIONS, SATISFACTION, AND COMMITMENT OF LANDOWNERS TO CONSERVATION STEWARDSHIP

Matthew John Selinske

Imperial College

Jan COETZEE, Nelson Mandela Metropolitan University ; Kerry PURNELL, CapeNature ; Andrew KNIGHT, Imperial College

Private land conservation is an increasingly popular approach to protect critical biodiversity. In the Western Cape Province of South Africa private land conservation is the focal strategy for CapeNature, the provincial conservation agency. Despite its importance, little is known about the drivers of landowner participation in the CapeNature program and how these varied motivations influence participant satisfaction and retention. Our psychometric survey of 75 enrolled landowners found that the highest ranked motivations to participate were Conservation and Place Attachment but Social Learning had a stronger influence on program satisfaction. Landowners participate to fulfill a motivation or set of motivations but their satisfaction and commitment may hinge on other unforeseen motivations or factors. Understanding the relationship between motivations, satisfaction, and commitment is necessary for a successful retention strategy in any conservation program, especially on private lands where success is dependent on landowner commitment. Evaluating the social and not simply the biological or ecological “ingredients” of effective PLC programs is critical for understanding obstacles to implementation and measuring effectiveness. Application of psychology theory and practice can improve the effectiveness of conservation programs by the fostering stewardship commitment that facilitates sustained behavioral change.

CURRENT EVOLUTION AND FUTURE OF THE VEGETABLE BIODIVERSITY IN THE NORTH-WEST OF THE ALGERIAN SAHARA

Chouaib Selkh

Adrar university. Algeria

Seghir HADJADJ AOUL, Université Oran Sénia

In the Northwest of the Algerian Sahara, several authors, like Guinochet and Quezel (1954), Monod (1972) Barry et al. (1985) Gehu et al. (1990), have tried to propose a phyto-sociological typology of the different habitats, taking into account the plant communities that develop there. Barry et al. (1985) note that these habitats “are highly representative phytocenosis of the conditions characterized Sahara habitats, and are stable through time, because there is no regressive or evolutionary dynamics,” but are all these phytocenosis really as stable now? Trying to find an answer to this question, we chose, in 2010, the Great Western Erg, an area described 65 years ago by Guinochet and

Quezel (1954). This area is about 600 km straight line distance south of Oran, Algeria, and extends between 29 ° and 32 ° north latitude and 20°W to 3 °E longitude, covering an area of 270,000 km². We followed the same way as Guinochet et al. (1954), and we have made a phyto-ecological survey of 52 different sites; rigorously scoring all the site conditions such as soil type, slope, the vegetation and various offenses such as overgrazing, logging and mowing. Our results show that the environment is deteriorating. This resulted from natural factors such as drought and the proliferation of wood-eating insects. On the other hand, human is involved, as well, in this deteriorating. Human increases desertification, e.g. Acacia trees are increasingly disappearing as a result of logging and collecting of gravel for building. «Everywhere ... we would have thought that the use of butane gas would reduce the need for plant fuels ... everything converges in the sense of the devastation of the Saharan flora» (Bisson, 2003). We look forward to continue this work with other complementary studies. We could propose to create a vegetation map that would be considered a tool for any development. In addition, local people are to be advised to help preserve local ecosystems.

RELATION BETWEEN FORMER FOREST MANAGEMENT AND HABITAT DEGRADATION IN A RIPARIAN OAK FOREST

Marianna Selmeçi

Szent István University, Faculty of Agricultural and Environmental Sciences Institute of Botany and

Ecophysiology, Department of Botany

Eszter S.-FALUSI, Szent István University, Faculty of Agricultural and Environmental Sciences Institute of Botany and

Ecophysiology, Department of Botany ; Dénes SALÁTA, Szent István University, Faculty of Agricultural and Environmental

Sciences, Institute of Nature Conservation and Landscape Management

Detailed information on earlier stages is required to understand ongoing processes since landuse and management change was proved to have significant effect on natural vegetation. For that reason long-term studies are important to reveal degree of change at different levels, where the former state serves as a reference point to evaluate present conditions, plan or predict future processes. The research area – Tölgy-erdő/Oak-forest – is located at the eastern periphery of Hanság in Hungary. Based on checking of historical maps (1784-1944) the extension and landuse type of the research area was identical (110 ha). According to written data significant change in the use of the floodplain forest started after 1952 and economic view in forest management had begun after the 70's but fortunately the area was declared protected on national level in 1999 and accepted as Natura 2000 SCI due to threatened floodplain

habitat (91F0). To follow the effect of the former management on the vegetation we defined 4 disturbance categories to group the forest units based on available detailed forest plans (1968-2000), completed and controlled with geographical information and aerial photographs from the same period. The coenological survey was implemented in 30 homogeneous management units (6-6 quadrat/A-B-C vegetation layer/unit) in year 2013. The hierarchical cluster analysis of plant diversity showed the separation of units previously managed with clear-felling and renewed partly with alien ligneous species. Although significant difference couldn't be confirmed among units covered with native species but higher cover of invasive heliophilous plant species was detected dormant in the shrub layer close beside former intensively managed units. In consequence of that forest management with permanent cover is required in the future to fulfill sustainable protection and appropriate management which corresponds to the ecological state of the natural habitat type.

95. WHY REMAINING ROAD-FREE MATTERS: THE IMPORTANCE OF PROTECTING ROADLESS AND LOW-TRAFFIC AREAS FOR CONSERVING BIODIVERSITY UNDER GLOBAL CHANGE

Nuria Selva

Institute of Nature Conservation Polish Academy of Sciences
Stefan KREFT, Centre for Ecnics and Ecosystem Management, Faculty of Forest and Environment, Eberswalde University for Sustainable Development ; Vassiliki KATI, Department of Environmental & Natural Resources Management. University of Patras ; Monika HOFFMANN, Centre for Ecnics and Ecosystem Management, Faculty of Forest and Environment, Eberswalde University for Sustainable Development ; Guy PE'ER, Department of Conservation Biology, Helmholtz Centre for Environmental Research - UFZ ; Adam SWITALSKI, 5InRoads Consulting LLC ; Maria PSARALEXI, Department of Ecology, School of Biology, Aristotle University of Thessaloniki ; Nefta-Eleftheria VOTSI, Department of Ecology, School of Biology, Aristotle University of Thessaloniki ; Antonios MAZARIS, Department of Ecology, School of Biology, Aristotle University of Thessaloniki ; Pierre L. IBISCH, Centre for Ecnics and Ecosystem Management, Faculty of Forest and Environment, Eberswalde University for Sustainable Development

The road network shapes the environment worldwide. Road impacts are numerous, very complex, time-lagged and extend far beyond the road itself. Among the most detrimental effects is the "contagious development" triggered by roads, i.e. roads provide access to remote areas, thus promoting more roads and developments, land-use changes, resource extraction and human disturbance. In this context, keeping road-free the remaining large unfragmented patches of natural ecosystems is of crucial importance for biodiversity conservation. Roadless

and low-traffic areas represent relatively undisturbed natural habitats and functioning ecosystems. They increase landscape connectivity, act as barrier against pests and invasions, and render many ecosystem services. Roadless areas contribute to the preservation of native biodiversity and of species with large spatial requirements and sensitive to human disturbance. They get special relevance in the context of climate change because of their higher resilience and buffering capacity. We propose that planning of new transport routes should avoid dissecting valuable roadless areas. It is important to evaluate whether a road is really needed and, if so, assess different route options before dissecting roadless areas. Road-free areas should be maintained by concentrating traffic on existing highly travelled roads and bundling infrastructure close together. Contagious development should be avoided through sustainable development schemes at large spatial scales. We propose the implementation of compensation policies of "no-net-loss" of unfragmented lands. Unnecessary and ecologically damaging roads may also be reclaimed to enlarge roadless areas and restore landscape-level processes. Roadless and low-traffic areas conservation is a timely tool to preserve intact functioning ecosystems at local and global scales in the face of climate change.

210. THE SCB ROADLESS AREAS INITIATIVE

Nuria Selva

Policy Committee of the Society for Conservation Biology-Europe Section
Vassiliki KATI, Policy Committee of the Society for Conservation Biology- Europe Section ; Stefan KREFT, Policy Committee of the Society for Conservation Biology- Europe Section ; Pierre L. IBISCH, Policy Committee of the Society for Conservation Biology- Europe Section

The main aim of the Roadless Areas Initiative is to highlight the importance of roadless areas as a cost-efficient instrument for biodiversity conservation and the need to consider them explicitly in legislation. The Roadless Areas Initiative was launched in 2007 by the Policy Committee of the Europe Section of the Society for Conservation Biology (SCB). In the last years, the initiative has turned global, with most SCB Regional sections involved, and has established a growing network of partners. It has also been presented at high-level policy fora, such as the Rio + 20 event. The Roadless Areas Initiative represents an alternative approach to the species and habitat protection focus in nature conservation, as well as to the traditional mitigation and compensation measures in road ecology. Additionally, it combines conceptual considerations, including ecological theory and conservation policies, with practical aspects and methodology developed to identify areas free of road disturbance. The inclusion of roadless areas into road design, biodiversity conservation and policy is a formidable challenge.

THE IMPORTANCE OF FLOODPLAINS AS POTENTIAL DROUGHT REFUGIA FOR TERRESTRIAL BIRDS

Katherine Selwood

Monash University

James Thomson, The University of Canberra ; Ralph Mac Nally, The University of Canberra

Climate change has led to more, and more severe, droughts. Climate refugia are locations in landscapes in which the physical effects of drought are less owing to topography or access to water and potentially allow populations to resist and recover from droughts. Floodplains are potential drought refugia in that they are more productive, have more water or more moderate microclimates than the surrounding uplands. The Murray-Darling Basin of eastern Australia experienced an unprecedented 13-year drought (the 'Big Dry') followed by 3 wet years, which allowed us to assess how terrestrial birds responded spatially to the drought and afterwards. We estimated temporal trends in reporting rates for 145 birds over the 14 years using Atlas of Australian Birds survey data for 28,000 sites in floodplain and non-floodplain areas. There was greater resistance to drought in floodplain zones; fewer species declined in floodplain zones (19%) than in non-floodplain zones (29%) during the Big Dry, and more species had increased reporting rates (13% vs 8%). As expected, more species recovered in non-floodplain zones (40.3%) than in floodplain zones (15.3%) after the drought, given the greater number of declines during the Big Dry in non-floodplain zones. Just 17.9% of species that declined in floodplain zones during the drought subsequently recovered, suggesting limited resilience. Floodplains enhance resistance to drought for many birds, and are likely to be particularly important as refugia in more arid areas. Floodplain ecosystems require long-term management to ameliorate human pressures and to restore ecological condition so that their role as drought refugia is maintained or enhanced.

LINKING HISTORIC LAND-USE CHANGE AND SHIFTS IN POLLINATOR COMMUNITIES

Deepa Senapathi

University of Reading

Luisa G CARVALHEIRO, University of Leeds ; Jacobus C. BIESMEIJER, Naturalis Biodiversity Centre ; Cassie Ann DODSON, University of Reading ; Rebecca L EVANS, University of Reading ; Megan MCKERCHAR, University of Leeds ; R Dan MORTON, Centre for Ecology and Lancaster ; Ellen D MOSS, University of Reading ; Stuart P M ROBERTS, University of Reading ; William E KUNIN, University of Leeds ; Simon G POTTS, University of Reading

Pollinators are not only an important component of biodiversity in their own right, but they also provide vital

pollination services both to agriculture and to wild plant populations. There is growing evidence that wild and managed insect pollinators have declined in both abundance and diversity and while the main causes of decline in pollinators remain unclear, one of the most likely causes is shifts in land use, mostly due to agricultural intensification. Our study is the first of its kind to test for the impact of historic land-use change in Britain, and explores land cover changes over 80 years and relates them to concurrent shifts in insect pollinator communities. Utilising historic data from 20 sites across four counties, we quantified the key land cover changes within and around these sites by utilising a land-cover map of 1930s Britain as well as a current land-cover map (LCM 2007). We then analysed spatial correspondence between past land use change and the corresponding shifts in pollinator communities by estimating the changes in richness and composition of bees and wasps. Land cover changes within sites, as well as changes within a 1km radius outside the sites, were found to have significant effects on pollinator richness and composition, with changes in edge habitats between major land classes also having a key influence. Our results highlight not just the land cover changes that may be detrimental to pollinator communities but also provides an insight into how changes from a single land cover type to a more diverse habitat may benefit species diversity and could help inform policy and practice for future land management

IMPACT OF HISTORIC SEASONAL CLIMATE ON BEE FLIGHT PERIODS

Deepa Senapathi

University of Reading

Rebecca L EVANS, University of Reading ; Stuart P M ROBERTS, University of Reading ; Simon G POTTS, University of Reading

There is immense current interest in the impact of seasonal climate on insect phenology. Research to date however has focussed solely on the impact of spring climate as the major driver of emergence dates and flight times. There is however evidence to suggest that key developmental stages like insect diapause which have knock-on impacts on spring emergence as well as voltinism could be driven by temperature changes in the summer, autumn and winter. As yet there is no research looking at how long-term climatic trends in summer, autumn or winter have impacted spring emergence or flight times of insects. Using historic climate data from 32 weather stations in Britain from 1900 onwards combined with long-term data on flight times and first emergence dates of bees for the same period and landscape we explore the impact of seasonal temperature trends on bee behaviour and analyse if these relationships vary on latitudinal basis. In addition to providing information on the impact of seasonal climatic trends on insect phenology, this study also provides the basis for further

research on mismatches between flight time of pollinators and flowering times in plants.

META-ANALYSES OF WHALEWATCHING IMPACT STUDIES: DIFFERENCES AND SIMILARITIES IN DISTURBANCE RESPONSES AMONG SPECIES

Valeria Senigaglia

University of Aberdeen

Fredrik CHRISTIANSEN, University of Aberdeen ; Lars BEJDER, Murdoch University ; Diane GENDRON, Instituto Politecnico Nacional ; Dave LUNDQUIST, Otago University ; Dawn NOREN, NOAA Northwest Fisheries Science Center ; Aline SCHAFFAR, Opération Cétacés ; Jodi SMITH, Naked Whale Research ; Rob WILLIAMS, University of St Andrews ; David LUSSEAU, University of Aberdeen

Whalewatching activities are known to induce behavioural changes that are compatible with anti-predatory responses. However anti-predatory responses can vary depending on the species, population and/or site-specific environmental features. This variability makes it challenging to evaluate whalewatching disturbance and multiple metrics should therefore be used for any impact study. In this study we used meta-analyses to assess the consistency of anti-predatory responses among several studies on whalewatching disturbance. Changes in swimming speed, activity budget, inter-breath intervals, and deviation and directness index were used as proxies to measure whalewatching disturbance. We also assessed if these changes were due to extrinsic factors (the presence of whale watching regulations), intrinsic factors (species and animal body size) or environmental factors (habitat type). Our results showed that changes in the activity budget and directness and deviation index were the most consistently reliable metrics in capturing cetacean responses to whalewatching disturbance. Animals were more likely to travel and less likely to rest and forage as a consequence of whalewatching presence. Body size also had an effect on resting activity with smaller animals being less likely to rest in the presence of boats. Our results showed a generalized tendency of cetaceans to increase their path sinuosity (deviation index) and decrease path linearity (directness index) in response to whalewatching disturbance. Path linearity and predictability also increased in corridor type habitats. We found that cetaceans overall showed similar anti-predatory responses to whalewatching activities. These behavioural changes reflect greater direct energy expenditure and fewer opportunities for energy recovery and may cause long-term consequences to population fitness.

TRANSFERABILITY OF PREDICTIVE MODELS FOR CORAL REEF FISHES

Ana Micaela Martins Sequeira

The University of Western Australia

Camille MELLIN, Australian Institute of Marine Science ; Hector LOZANO-MONTES, CSIRO Marine and Atmospheric Research ; Matthew A VANDERKLIFT, CSIRO Marine and Atmospheric Research ; Russ C. BABCOCK, CSIRO Marine and Atmospheric Research [INSTITUTE] CSIRO Marine and Atmospheric Research ; Michael HAYWOOD, CSIRO, Marine and Atmospheric Research ; Jessica J. MEEUWIG, The University of Western Australia ; M. Julian CALEY, Australian Institute of Marine Science

Transferring predictive models developed for one ecosystem to another could prove a cost-effective tool for understanding biodiversity patterns in under-studied systems - an urgent and challenging task in the current context of accelerating rates of biodiversity loss. Applications of model transferability are, however, still in their infancy and research is required to optimize model transferability. We developed a framework for improving model transferability based on the spatial and temporal resolutions used during model calibration, and tested it by transferring predictive models for coral reef fish species density and abundance developed for the Great Barrier Reef (GBR) on Australia's east coast, to Ningaloo Reef (NR) on Australia's west coast. Our results suggest that transferred models can retain predictive ability despite substantial differences in the biogeography and local ecology (NR is a fringing reef, while the GBR is a lagoonal system), and the degree of separation between the two ecosystems (Indian and Pacific oceans, respectively). Transferability of models of species density between these two ecosystems was considerably improved (models were > 70 % transferable) when the GBR model was calibrated with datasets of similar spatio-temporal scales (i.e., sampling duration, sampling year and transect size) to those available from NR. For fish abundance, transferability was possible (i.e., > 50 %) but variable for different fish families. The modelling framework we have developed can provide insights in to how species-environment relationships vary with the biogeography of the biological system of interest and how this should be accounted for in ecological modelling studies. Our work shows that transferability of predictive models has the potential to become a cost-effective tool for understanding biodiversity patterns in under-studied ecosystems and provide ecologically meaningful information to support management and conservation.

EVOLUTIONARY ECOLOGY AND CONSERVATION OF BAMBOO BREEDING FROGS IN THE WESTERN GHATS BIODIVERSITY HOTSPOT

Kadaba Shamanna Seshadri

National University Of Singapore

Patrick David BICKFORD, National University Of Singapore

Amphibians face threats of extinction and population declines globally. Effective conservation interventions have often been

challenging to implement due to knowledge gaps in the species' ecology and behaviour. The Western Ghats biodiversity hotspot of India is a centre for adaptive radiations of frogs. In the last decade, over one hundred new species have been discovered. The conservation status and ecology of many of these frogs are unknown. Members of the tree frog genus *Raorchestes* possess the greatest diversity with 52 extant species and several lineages yet to be described. With such rapid increase in species discovery and description, natural history and ecological information are sparse and anecdotal. In an attempt to bridge this gap, field surveys were conducted in the Southern Western Ghats. This led to the discovery of new species and novel reproductive mode in one critically endangered frog *Raorchestes chalazodes* and its sister taxon, *R. ochlandrae*. In this mode, adult frogs enter *Ochlandrae* bamboo via narrow natural openings, deposit direct developing eggs, and provide parental care. However, bamboo habitats where frogs breed are threatened by overharvesting and habitat destruction during the breeding season. This study focuses on determining the range of bamboo breeding frog species using niche modeling; characterizing their reproductive strategy; identifying factors affecting reproductive success and drivers for the evolution of parental care in the group. Reproductive success is quantified using adult removal experiments and nest cavity examinations aided by camera probes. Organisms making openings in bamboo are quantified using field surveys. Forest managers and harvesting agencies are involved during the study to facilitate capacity building and identifying suitable protected breeding habitats for frogs and regulate harvesting practices in order to both protect the frogs and deliver provisions to humans using the forest.

ECOLOGICAL FACTORS INFLUENCING THE PERSISTENCE OF ANURAN ASSEMBLAGES IN WET-PADDY AGRICULTURE FIELDS IN SOUTH INDIA.

Kadaba Shamanna Seshadri

National University of Singapore

Allwin JESUDASAN, Ashoka Trust for Ecology and The Environment ; T GANESH, Ashoka Trust for Ecology and The Environment

Loss of habitat, intensification of agriculture and pesticide abuse has contributed significantly to amphibian decline. Studies documenting amphibian distribution; community assemblage; ecological correlates and their response to human induced changes are scant in developing countries like India with over 20% of all land being irrigated for agriculture. In South India, wet paddy agriculture is an important agricultural activity. Vast expanses of land near rivers and deltas are converted for cultivating rice and the impacts of these on the ecosystem not well understood. Abuse of subsidized availability of agrochemicals could potentially harm biodiversity in such human dominated landscapes. This study

examines the ecological correlates on anurans in an agro-ecosystem framework. Sixty sampling sites across three villages were surveyed in five minute audio-visual survey units. The community complexity was low and only six anuran species and 1705 individuals with an average of 12.1 ± 9 individ./unit were recorded. A generalized linear mixed effects model was used for analysis. Encounter rates varied and were positively affected by water depth and negatively affected by crop height and the presence of wet bund. Pesticide inputs were assessed by interviewing the farm owner and incorporated into the model. It appeared that pesticides did not significantly affect anurans. It is likely that pesticides get leached and diluted and anurans may be affected by pesticide concentrations in the water. This was however not accounted for in the model. Subsequent studies would need to focus measuring the soil and water chemistry in paddy fields to determine precise correlates of agricultural practices on amphibians. Findings from this study serve as a benchmark for ecological assessment of amphibians in agro-ecosystems and other human modified landscapes across South-South East Asia and framing best practice socio-economic and agro-ecosystem policies.

TEMPORAL AND SPATIAL POPULATION FLUCTUATIONS OF MEDIUM SIZED MAMMALS IN A MEDITERRANEAN AGRICULTURAL MATRIX

Hila Shamoon

Tel Aviv University [INSTITUTE] Ramat Hanadiv Nature Park
David SALTZ, Swiss Institute for Dryland Energy and Environmental Research, Blaustein Institutes for Desert Research, Ben Gurion University ; Tamar DAYAN, Tel Aviv University

Mediterranean ecosystems are human-dominated landscapes composed of a mosaic of agricultural, natural and semi-natural habitats alongside urban areas. The size, spatial pattern and connectivity of these "modified landscapes" have a crucial effect on wildlife behavior, movement patterns and habitat use. We used a camera trap grid located in an agricultural valley in the Mediterranean region of Israel to determine how wildlife respond to human mediated resource changes. We quantified multi-season activity rates, density and occupancy from encounters data using N-mixture models. Twenty cameras were located in 25 sites, divided into 5 categories: isolated nature reserve; large natural area; vineyards within natural area; vineyards near settlements and vineyards within the agricultural matrix. Each sampling season was divided to 5 intervals and cameras were rotated between sites. Five carnivore and 5 herbivore species were captured on cameras. The depletion of natural food resources during the dry season shifted animals to the agricultural system. Different species demonstrated unique responses to human disturbance based on their ecological and behavioral adaptations: Canid (*Canis aureus*, *Vulpus vulpus*) co-occurrence was influenced

by anthropogenic food availability and European hare (*Lepus europaeus*) densities. European wildcat (*Felis silvestris*) and European badgers (*Meles meles*) co-occurred with red fox in natural patches more often than with golden jackals and had low activity rates in the agricultural system. Mountain gazelles (*Gazella gazella*) were restricted to natural patches and expressed different behavioral responses to human presence in protected or hunting areas thus emphasizing the importance of planning protected ecological corridors between the remaining natural patches. Our results demonstrate that wildlife responses to a patchy and dynamic agricultural matrix vary across species and present a challenge for conservation planning.

99. THE CONNECTION BETWEEN PEOPLE, NATURE AND HEALTH.

Danielle Shanahan

University of Queensland

Robert BUSH, University of Queensland ; Kevin GASTON, University of Exeter ; Brenda LIN, CSIRO ; Julie DEAN, University of Queensland ; Elizabeth BARBER, University of Queensland ; Richard FULLER, University of Queensland

There is compelling evidence for a range of physical, mental and social health benefits that people gain from urban nature. Yet our research shows that a large proportion of the population does not spend time in urban parks on a regular basis. This represents a substantial missed opportunity given the potential scale of the health and wellbeing benefits. Here we use an Australian data set to explore who in society is less likely to engage with nature, showing links with socio-economic factors and nature orientation. We then go on to examine the connection between key health responses (depression, high blood pressure and social cohesion) and exposure to nature. Ultimately we show that the prevalence of depression and high blood pressure could potentially be reduced within the general population by up to 14% and 8% respectively if those who do not currently engage with nature experiences were encouraged to do so. Our results show that urban nature already makes a substantial contribution to the social and economic wellbeing of communities. However, this contribution could be further enhanced through the use of social or educational interventions that enhance people's connection to nature.

HOW WELL IS RAIN FOREST PHYLOGENETIC DIVERSITY CONSERVED IN SOUTH EAST QUEENSLAND? A CASE STUDY IN THE USE OF DNA BARCODES TO ASSESS BIODIVERSITY AND CONSERVATION.

Alison Shapcott

University Sunshine Coast

Paul I FORSTER, Queensland Herbarium ; Gordon P GUYMER, Queensland Herbarium ; William J F MCDONALD, Queensland Herbarium ; Daniel P FAITH, Australian Museum ; David ERICKSON, Consultant ; W John KRESS, National Museum of Natural History, Smithsonian Institution

The application of DNA barcodes to plants has been rapidly expanding as reference libraries are generated for ever more species. Community phylogenies of forest habitats based on DNA barcode data are now commonly used to understand the evolution and assembly of these communities and have been mostly confined to forest species within long term monitoring plots. We have sampled an entire rainforest plant species assemblage within a bioregion to assess species and phylogenetic diversity and the adequacy of conservation. Australian rainforests have been fragmented due to past climate change and human-based clearing. The subtropical rainforests of south eastern Queensland are significantly more fragmented than the tropical rainforests and are subject to greater population pressures. The Australian rainforest flora is relatively diverse at the family-level but less so at the species-level. Current methods to assess biodiversity based on species numbers fail to adequately capture this richness at higher taxonomic levels. We developed a DNA barcode library for the SE Qld rainforest flora for biodiversity assessment that incorporates both taxonomic diversity and phylogenetic relationships. We compared phylogenetic diversity measures, species composition and richness and ecosystem diversity, to identify which bio-subregions contain greatest rainforest diversity, subregion relationships and their level of protection. Diversity was not correlated with rainforest area in SE Qld subregions, but PD was correlated with both the percent of the subregion occupied by rainforest and the diversity of regional ecosystems (RE) present. The patterns of species diversity and phylogenetic diversity suggest a strong influence of historical biogeography. Some subregions contain significantly more PD than expected by chance, consistent with the concept of refugia, while others are significantly phylogenetically-clustered consistent with recent range expansions.

REAL, ADDITIONAL, MEASURABLE, PERMANENT AND VERIFIABLE? COMMUNITY-BASED FOREST CARBON OFFSETS IN MEXICO

Elizabeth Shapiro-Garza

Duke University

Susan SANDFORD, Duke University

Conservation trading mechanisms, in which degrading activities are offset by conservation or restoration in other areas, are currently widely implemented for biodiversity conservation, habitat restoration and reduction of greenhouse gas emissions. However, these projects have been heavily critiqued for perceived failures in creating real, additional,

permanent and verifiable offsets and for the potential for negative environmental and social impacts. The central focus of this study was to test the validity of these critiques in the context of a community-based forest carbon project in Mexico that sells offsets on a voluntary, national market. Our analysis is based primarily on interview data from key actors at multiple scales: the participating communities, intermediary non-profit organizations and carbon credit buyers. We find that the project avoided many of the potential pitfalls of forest carbon offset projects. Whether this model could be replicated would likely depend on the presence of key conditions: preexisting institutional strength at the local level; high levels of social capital between buyers, intermediaries and producers; and the ability to operate in the voluntary market. In particular, we find that a voluntary offset market can allow for higher, more stable prices, avoids the high transaction costs of certifications, and permits activities tailored to the local conditions and context of the producers.

DOES LIVESTOCK BENEFIT SNOW LEOPARDS?

Rishi Kumar Sharma

Nature Conservation Foundation

Yash Veer BHATNAGAR, Snow Leopard Trust ; Charudutt MISHRA, Snow Leopard Trust

Large carnivores commonly prey on livestock when their ranges overlap. Pastoralism is the dominant land use type across the distributional range of the endangered snow leopard *Panthera uncia*. Snow leopards are often killed in retaliation against livestock depredation. Whether livestock, by forming an alternative prey, could potentially benefit snow leopards, or, whether livestock use of an area is detrimental to snow leopards is poorly understood. We examined snow leopard habitat use in a multiple use landscape that was comprised of sites varying in livestock abundance, wild prey abundance and human population size. We photographically sampled ten sites (average size 70 sq. km) using ten camera traps in each site, deployed for a period of 60 days. Snow leopard habitat use was computed as a Relative Use Index based on the total independent photographic captures and the number of snow leopard individuals captured at each site. We quantified livestock abundance, wild prey abundance, human population size and terrain ruggedness in each of the sites. Key variables influencing snow leopard habitat use were identified using Information Theory based model selection approach. Snow leopard habitat use was best explained by wild prey density, and showed a positive linear relationship with the abundance of wild ungulates. We found a hump-shaped relationship between snow leopard habitat use and livestock stocking density, with an initial increase in habitat use followed by a decline beyond a threshold of livestock density. Our results suggest that in the absence of direct persecution of snow leopards, livestock grazing and snow leopard habitat use

are potentially compatible up to a certain threshold of livestock density, beyond which habitat use declines, presumably due to depressed wild ungulate abundance and associated anthropogenic disturbance.

GENETIC VARIATION, STRUCTURE, AND GENE FLOW IN A SLOTH BEAR (*MELURUS URSINUS*) METAPOPULATION IN THE SATPURA-MAIKAL LANDSCAPE OF CENTRAL INDIA

Sandeep Sharma

Smithsonian Conservation Biology Institute

Trishna DUTTA, Columbia University ; Jesus MALDONADO, Smithsonian Conservation Biology Institute ; Hemendra Singh PANWAR, Peace Charitable Institute ; John SEIDENSTICKER, Smithsonian Conservation Biology Institute

Sloth bears (*Melursus ursinus*) are endemic to the Indian subcontinent. As a result of continued habitat loss and degradation over the past century, sloth bear populations have been in steady decline and now exist only in isolated or fragmented habitat across the entire range. We investigated the genetic connectivity of the sloth bear meta-population in five tiger reserves in the Satpura-Maikal landscape of central India. We used noninvasively collected fecal and hair samples to obtain genotypic information using a panel of seven polymorphic loci. We identified 55 individuals from this meta-population. We found that this meta-population has moderate genetic variation, and is subdivided into two genetic clusters. Further, we identified five first-generation migrants and signatures of contemporary gene flow. We found evidence of sloth bears in the corridor between the Kanha and Pench Tiger Reserves, and our results suggest that habitat connectivity and corridors play an important role in maintaining gene flow in this meta-population. These corridors face several anthropogenic and infrastructure development threats that have the potential to sever ongoing gene flow, if policies to protect them are not put into action immediately.

RELEVANCE OF TRADITIONAL ECOLOGICAL KNOWLEDGE IN AGRICULTURAL SUSTAINABILITY OF THE SEMI ARID TROPICS

Seema Sharma

KSKV Kachchh University, BHUJ, GUJARAT, INDIA

The semi arid tropics are resource scarce in agriculture in terms of soil quality and harsh climatic conditions and the sustainability of agro-ecosystems in these areas is an important issue. In India there is enormous wealth of Traditional Ecological Knowledge (TEK) but it is being lost and is surviving only in bits and pieces. Kachchh, is a very unique ecological terrain of Western India where some progressive farmers

in spite of harsh climatic conditions are adopting the long lost traditional farming practices which needs to be given a sound scientific backing to make it feasible as synthetic inputs based farming practices are deteriorating the soil health and quality of produce. Indiscriminate use of chemical fertilisers and pesticides in farming practices has threatened the ecosystem in many ways. The agricultural activities in past two decades have become intensive chemical inputs based due to government policies to promote chemical fertilizers and farmer's greed to have higher yields in short term. As a consequence the resource poor farmers are giving up their indigenous knowledge of organic and natural farming practices which can sustain them and the agro-ecosystems in the long run. The resource poor farmers of the semi arid tropics have lost their ancient knowledge of sustainable farming practices. The present study was undertaken to assess how ecosystem sustainability is achievable using the NRI (Natural Resource Integration). Agro-ecosystems practising different amendments viz. Natural, integrated and chemical inputs were evaluated in a long term study for their physico-chemical and biological parameters. The results of the study have shown that agri-management systems need to be geared to more inputs of traditional manures, pesticides and practices like indigenous seeds, mulching, best suited for the native climatic conditions, which can help in long term sustainability of the agriculture, soil and the society.

DNA METABARCODING- APPLICATION TO COMMON LEOPARD DIET

Wasim Shehzad

Institute of Biochemistry & Biotechnology (IBBT) University of Veterinary & Animal Sciences, Lahore, Pakistan
Pierre TABERLET, Laboratoire d'Ecologie Alpine (LECA), Universite Joseph Fourier. ; Francois POMPANON, Laboratoire d'Ecologie Alpine (LECA), Universite Joseph Fourier.

Metabarcoding is a rapid method of biodiversity assessment that combines two technologies: DNA taxonomy and high-throughput DNA sequencing. Short sequences of DNA are widely used to differentiate and assign taxonomies to specimens of animals, plants, and fungi and other microbes. The common leopard diet was characterized from prey DNA present in fecal samples collected from Ayubia National Park, after amplification of a diagnostic fragment and sequencing of polymerase chain reaction (PCR) products, using next-generation (Illumina) sequencing. This provides diet information without any a priori knowledge about the prey and is a cost-effective method as millions of readings can be generated from a single sequencing run. This method has several advantages over classical microscopy, which requires substantial skill and time and is prone to misidentification in the case of closely related species. Of 111 putative fecal samples, sixty samples were identified as of leopard. While

three samples showed no prey item. Eleven prey taxa were identified in the remaining 57 samples. Three prey items were identified in one sample, two prey items in seven samples, and single prey items in 49 samples. Based on the frequency of occurrence of prey items in the 57 faecal samples, the domestic goat predominated the diet (64.9%), followed by dog (17.5%) and cow (12.3%). Domestic animals (goat, dog, cow, water buffalo *Bubalus bubalis*, horse *Equus caballus* and sheep) occurred in 54 of 57 samples, corresponding to a frequency of occurrence of 0.95, and five samples contained two items of domestic prey.

MAPPING OF CULTURALLY SENSITIVE AREAS IMPORTANT TO BIODIVERSITY: SACRED NATURAL SITES IN COASTAL KENYA

Emma Shepheard-Walwyn

University of Kent

Peter BENNETT, University of Kent

Despite their importance for biodiversity conservation, little accurate mapping of the Mijikenda sacred natural sites (SNS) in coastal Kenya has been performed. SNS are often culturally sensitive areas with limited and/or no access zones in certain locations. While these restrictions hinder biodiversity surveys, it is important that researchers respect and adhere to the traditional practices and values of local communities. This study used habitat mapping as an alternative method to investigate the potential biodiversity of the SNS; their relative contribution to the amount of remaining coastal forest in Kenya; and the level of threat that they face from development and encroachment. The results show that the sites contain a significant proportion of coastal forest and are important for biodiversity conservation. However, all sites suffer from encroachment, which was found to correlate with the level of development surrounding the sites. The current management plans for SNS are based on traditional practices, however they do not account for the threat of encroachment and development that they are facing. In addition, development in the region is likely to increase, which is likely to increase the threats to the SNS. Due to their importance for biodiversity it is vital that management approaches are modified to encompass the current threat of development and encroachment. The results show that habitat mapping is a useful tool for evaluating the biodiversity of, and threats to, culturally sensitive areas. In addition, it provides a standard methodology which can be used to compare sites across the region and on a global scale.

EFFECTS OF CLIMATE CHANGE ON THE ENDANGERED RAINFOREST SHRUB TRIUNIA ROBUSTA (PROTEACEAE), ENDEMIC TO SOUTHEAST QUEENSLAND, AUSTRALIA

Yoko Shimizu

University of the Sunshine Coast

Arnon ACCAD, Queensland Herbarium (DSITIA) ; Scott BURNETT, University of the Sunshine Coast ; Richard WARRICK, University of the Sunshine Coast ; Alison SHAPCOTT, University of the Sunshine Coast

The potential impacts of climate change on biodiversity are predicted to be extensive, and it is expected that species with small populations and limited dispersal will be highly vulnerable. This study investigated the potential impacts of climate change on the endangered subtropical rainforest shrub *Triunia robusta* by integrating species distribution models and population models. All populations were re-censused to obtain demographic data at two time steps for model parameterisation. Seed dispersal dynamics of *T. robusta* were also investigated. The current and future habitat distributions were modelled at four time steps (2010, 2030, 2050 and 2070) under IPCC A1F1 emission scenarios at continental and regional scales. Finally the potential effects of climate change (habitat loss, changes in rainfall and temperature) on the viability of *T. robusta* populations were examined over a 90-year period (2010 - 2100) with the integrated models. The results revealed high vulnerability of small populations (<30) to local extinction regardless of geographical location, whilst larger populations (>100) in the southern range are likely to show persistence in-situ for the next 90 years, highlighting the importance of maintaining larger population sizes for long-term survival. Despite results indicating a dramatic contraction of the species habitat range, the model predicted greater impacts on the species viability due to changes in temperature and rainfall. Inter-population dispersal was practically negligible, indicating the species limited potential for migration or rescue effects under climate change.

EQUITABLE GOVERNANCE OF INTEGRATED CONSERVATION AND DEVELOPMENT - THE VIEWS OF LOCAL PEOPLE AND IMPLICATIONS FOR CONSERVATION POLICY AND PRACTICE IN UGANDA

Mahboobeh Shirkhorshidi

Imperial College London

Julia BAKER, Parsons Brinckerhoff ; Medard TWINAMATSIKO, Institute of Tropical Forest Conservation ; E.j. MILNER-GULLAND, Imperial College London

The Convention on Biological Diversity (CBD) has set an agenda for conservation through poverty alleviation in its 2011-2020 Strategic Plan. This requires that issues of

governance, human rights, equity and power are addressed at all levels, from international to local. However, efforts to improve local community participation, such as Integrated Conservation and Development (ICD) interventions, often do not take into account local people's understanding of good governance, which can lead to inappropriate or ineffective function of institutions and negative outcomes. Understanding community views on what constitutes 'good governance' and adopting locally appropriate governance systems may enable conservation managers to involve local communities more effectively in decision-making, and adopt more equitable approaches in collaborative natural resource management. We assessed local perceptions of governance of ICD programmes around Bwindi Impenetrable National Park in Uganda through Focus Group Discussions with community groups and interviews with members of the Multiple Use Programme (MUP), which is one of the prominent ICD interventions at Bwindi. MUP enables local people to harvest certain natural resources in specified areas of Bwindi NP. Local people identified the MUP as an important mechanism for sustainable natural resource harvesting within the Park and expressed their strong desire to be actively involved in the management process. They also identified governance issues that hindered their involvement, notably equitable benefit sharing and more effective communication with conservation managers. Given a choice of potential governance structures, local people preferred a power sharing system. Based on this research, the Uganda Wildlife Authority carried out immediate actions on the ground to improve the governance of the MUP. MUP identity cards for authorized resource users were renewed, in order to improve equity of access to NP benefits.

123-ECOSYSTEM SERVICES AND BENEFITS FROM PRIMEVAL BOREAL FORESTS

Ekaterina Shorohova

Saint Petersburg State Forest Technical University

Ilkka VANHA-MAJAMAA, Natural Resources Institute Finland (Luke)

Criteria of human well-being create demands for ecosystem services. The potentials for ecosystem services depend on ecosystem structures and functions. Neither ecosystem services provided by primeval forests nor human benefits from them are completely understood and valued. This study reviews the regulating and cultural ecosystem services and human benefits obtained from primeval boreal forests. Natural disturbance regimes ensure self-organization and long-term resilience of primeval forest ecosystems. Some essential natural forest structures and functions have been transformed or disappeared owing to forest management. Dead wood in all its forms and decomposition stages is one of the most noticeable examples of such structures. The ecosystem functions related to it include carbon, nutrient and energy cycles, tree species

recruitment, soil formation etc. The full range of natural variability of dead wood of different size, decomposition class and position type safeguards the high quality of regulating ecosystem services. The carbon and nutrient stores of dead wood in primeval European boreal Norway spruce forests exceed those in managed forests by tens and hundreds of times. Numerous ecological niches created by dead wood result in high diversity of dead wood dependent organisms and successful tree species regeneration in northern forests. In general, the primeval forests, as enclosed systems, secure sustainability of key ecosystem services, such as the regulation of global and local climate, carbon sequestration, water balance, insect outbreaks and other natural hazards. The rarity of primeval forests increases the attractiveness of their cultural ecosystem services and non-material human benefits such as spiritual, religious, educational, inspiration and aesthetic values as well as genetic and information resources. In conclusion, primeval forests in a socio-ecological system indicate its resilience and secure the flow of ecosystem services.

DISENTANGLING THE NET: THE SOCIO-ECOLOGICAL DYNAMICS OF MOSQUITO NET FISHING

Rebecca Short

Imperial College London

Ej MILNER-GULLAND, Imperial College London ; Marcus ROWCLIFFE, Institute of Zoology ; Nicholas HILL, Zoological Society of London ; Sergio ROSENDO, University of East Anglia

Anti-malarial programmes, supported by the World Health Organisation, have distributed millions of mosquito nets (MNs) across sub-Saharan Africa in recent years with great success; in 2013 almost half of the population at risk had access to an insecticide-treated net, compared to 3% in 2004. Misuse of MNs within artisanal fisheries is now anecdotally widespread in these regions but formal investigation is lacking. Artisanal and subsistence fisheries globally have been referred to as “the occupation of last resort”, attracting developing nations’ dispossessed. As growing populations become unable to survive on depleted terrestrial resources, new entrants to what are generally already overexploited fisheries are an increasing problem. Small mesh sizes undermine traditional fisheries management which have been founded on increasing selectivity for mature adults, meaning use of MNs as fishing gear is generally illegal. However, ready availability, lack of necessary skill for deployment and low cost means they appeal to these new entrants and Mozambique’s most vulnerable people, whose dependence on them is unquantified. Recent paradigm shifts promote the theory of balanced fishing; where exploitation of juveniles (using fine mesh gears) may play a valuable role in ecosystem-based management of artisanal fisheries. This questions the validity of bans on gears like MNs. This study investigates the dependence of local people on MNs for food security, wellbeing and livelihoods in five

coastal communities in Cabo Delgado, Northern Mozambique, building on a previous case study from Kenya. These case studies are contextualised by a global review of the extent and prevalence of the issue. Additionally, we will explore how increasing fishing pressure interacts with the use of MNs in ecological communities, framing the issue within co-management of the wider fishery and integrating the results into participatory scenario analyses.

UNDERSTANDING DYNAMICS OF HUMAN-LEOPARD CONFLICT IN NEPAL: A COMPARATIVE STUDY BETWEEN LOWLAND TERAI AND HIGHLAND MID-HILL

Anil Shrestha

Green Governance Nepal

Aashish GURUNG, Freelance researcher[INSTITUTE]Kathmandu University

Human-leopard conflict (HLC) has been recently increasing throughout its range in Nepal. As a consequence, HLC cause emotional, physical and/or financial hardships for local people due to depredation of livestock, injury and death of humans which likely erodes decades of community support for local conservation efforts in Nepal. On the other hand, HLC cause retaliatory killings of these responsible leopards as a revenge causing reduced population viability of already near threatened species. The conventional hypothesis that cause increased HLC is of anthropogenic nature. However, recently, it has been proposed that such increase in HLC in and around Terai protected areas is a recent increased tiger population in Terai protected area (as much as 50%) that displaces leopard from their original habitat, hence, leopards inhabits in fringe habitat and has to rely more on livestock as major source of survival defined here as displacement hypothesis. To test this hypothesis, this study investigates and compares nature, extent and pattern of spatio-temporal HLC incidences along an altitudinal gradient: one in Terai lowland where leopard is living sympatrically with apex predator tiger and another one in Mid-hills, where leopard is an apex predator. We collected 538 incidences of HLC in Terai while 388 incidences in case of Mid-hills by using field observations, semi-structured interview, focus group discussion, key informant survey and records of human leopard conflict maintained by protected area in Terai and district forest office in Mid-hills. The first author will discuss the results to understand the mechanisms, by which such conflicts are caused and sustained with an attempt to test the displacement hypothesis of HLC, which eventually helps to formulate management actions to reduce HLC and hardship of local people for conservation of near threatened leopard.

EDUCATIONAL AND OUTREACH ACTIVITIES: THEIR TYPES AND EFFECT ON BIODIVERSITY CONSERVATION

Samridhi Shrestha

Arizona State University

A commonly expressed goal of environmental education programs (EEPs) is to encourage environmentally responsible behavior. However, balancing conservation goals and needs of local residents is always challenging. While some believe protected areas are a safe paradise for wildlife, others suggest that ignoring social and economic challenges that surround protected areas is not realistic to meet conservation objectives. The purpose of this research was to evaluate the effectiveness of EEPs offered by different organizations in three different protected areas of Nepal: Bardia National Park, Chitwan National Park and Parsa Wildlife Reserve. This research was conducted in the Terai Arc belt of Nepal which is home to some of the largest surviving populations of the Greater One Horned Rhinoceros and Royal Bengal Tiger. Data were collected through questionnaire surveys of local people living in the buffer zones adjacent to these protected areas and interviews with park officials. The questionnaire consisted of four parts, social context (age, income, education and gender), environmental attitude, environmental behavior and participation in EEPs provided by schools, non-governmental organizations and international non-governmental organizations. Results of the study show that EEPs provided by both schools and non-governmental and international non-governmental organizations failed to change local people's attitude and behavior. Poverty and lack of alternative resources is mainly blamed for failure of such EEPs.

SYMPOSIUM 97: CITIZEN SCIENCE AS A POTENTIAL TOOL TO PREVENT THE EXTINCTION OF EXPERIENCE

Assaf Shwartz

Technion - Israel Institute of Technology

Broad-based public support is needed to achieve biodiversity conservation goals. However, the very global processes that threaten biodiversity, such as urbanization and agriculture intensification, also separate people from the experience of nature, affecting the way people value and benefit from nature's quality. This "extinction of experience" is therefore a major concern, first given the important role interaction with nature plays in people's health and wellbeing. Second, because this estrangement can undermine people's action and public support for biodiversity conservation. Recent studies exploring the relationship between people and biodiversity have unveiled a "people-biodiversity paradox" comprising a fundamental mismatch between: (1) the preferences people

have for biodiversity, the wellbeing they claim to obtain from it and (2) their limited ability to perceive and benefit from this diversity. The extinction of experience could explain this paradox, as it could cause a reduction in people's abilities to experience the complexity of nature (i.e., biodiversity). In a study conducted in Paris France, we experimentally increased the diversity of birds, butterflies and flowering plants in small public gardens. We found that people underestimated species richness in the gardens and only noticed the changes in native flower richness in the gardens where advertisement and public involvement were organized. In additional studies we explored which animal species people want to have in the public gardens near their homes. We found that people showed a tendency to prefer colourful species they were familiar with. Therefore, we argue that enhancing conscious interaction between people, biodiversity and learning processes could potentially lead to a win-win situation, aligning the agendas of public health and conservation. Citizen science could help achieving this goal by consolidating people's ecological expertise and reinforcing their experience biodiversity.

REVEALING BETA DIVERSITY PATTERNS OF BREEDING BIRD AND LIZARD COMMUNITIES IN FRAGMENTED HABITATS BY THE TURNOVER AND NESTEDNESS COMPONENTS

Xingfeng Si

Zhejiang University

Andrés Baselga, Universidad de Santiago de Compostela ; Ping Ding, Zhejiang University

Beta diversity describes changes in species composition among sites in a region that has particular relevance for potential applications in conservation planning in fragmented habitats. However, it is difficult to reveal the mechanisms and develop specific conservation strategies if broad sense beta-diversity indices (i.e. yielding identical values under nestedness and species replacement) are used. Partitioning beta diversity into turnover (caused by species replacement from site to site) and nestedness-resultant components (caused by nested species losses) could provide a unique way to understand the variation of species composition in fragmented habitats. Here, we collected long-term occupancy data of breeding birds and lizards on islands in an inundated lake in China. We decomposed beta diversity of breeding bird and lizard communities into spatial turnover and nestedness-resultant components to assess their relative contributions and respective relationships to differences in island area, isolation, and habitat richness. Our results showed that spatial turnover contributed more to beta diversity than the nestedness-resultant component. The degree of isolation had no significant effect on total beta diversity or their components, neither for breeding birds nor for lizards. In turn, in both groups the nestedness-resultant component increased with larger

differences in island area and habitat richness, respectively, while turnover component decreased with them. The major difference among birds and lizards was a higher relevance of nestedness-resultant dissimilarity in lizards, suggesting that they more prone to local extinctions derived from habitat fragmentation. Despite the existence of some nested patterns, according to the dominance of the spatial turnover component of beta diversity, we suggest that all islands have potential conservation values and deserve protection for breeding bird and lizard communities.

POPULATION TRENDS OF 3 AMPHIBIANS FROM THE NAPO RIVER, PERU: HOW DO THESE COMPARE WITH CLIMATE CHANGE VULNERABILITY ASSESSMENTS

Marcy Sieggreen

Detroit Zoological Society

Marked effects of climate change on amphibians have been demonstrated, including increasing and decreasing population sizes and ranges. To anticipate how such impacts will affect amphibians and their conservation in the medium and longer terms, much research has focused on assessing their vulnerability to extinction due climate change. Species distribution modeling is often used to predict long-term change, but more recently species' biological traits and their effects of contributing to or reducing climate change impacts have begun to be included in these assessments. The results of both and combined climate change vulnerability assessment approaches, however, are seldom tested to determine whether they hold true in the field. Validation and verification of the accuracy of assessments using documented species changes is a high priority for this field. In this study, I explore the population trends of 3 amphibian species from the lower elevations of the Napo River, Peru. While these species are currently listed as of Least Concern species on the International Union for the Conservation of Nature (IUCN) Red List, I find strong fluctuations in population sizes between 2010 and 2014 and compare these to climate change vulnerability assessments conducted using both species distribution modelling and trait-based approaches. The results have important implications both for amphibians and the assessment of climate change vulnerability of species.

FROM BASIC SCIENCE TO HANDS ON CONSERVATION AND EVERYTHING IN BETWEEN: THE JANOS BIOSPHERE RESERVE, CHIHUAHUA MEXICO, A CASE STUDY.

Rodrigo Sierra-Corona

Universidad Nacional Autonoma de Mexico

Eduardo PONCE-GUEVARA, Universidad Nacional Autonoma de Mexico ; Rurik LIST, Departamento de Ciencias Ambientales,

Universidad Autonoma Metropolitana ; Jesús PACHECO, Universidad Nacional Autonoma de Mexico ; Gerardo CEBALLOS, Universidad Nacional Autonoma de Mexico

The Janos Biosphere Reserve (1,300,000 acre), is located on the northwestern corner of the Mexican state of Chihuahua, just across the US-Mexico borderline. This natural protected area was recently designated (2009) with the main objective of preserve its massive native Chihuahuan Desert grasslands, some of the last remains of this threatened ecosystems in North America, as well as its biodiversity. Our research team arrived during late 1980's to Janos, attracted by reports of black tailed prairie dog colonies, and extensive grasslands, discovering at the time, the biggest prairie dog colony in North America and the only free ranging bison herd of Southwestern USA and Northern Mexico, inhabiting in a vast prairie environment, on a extraordinary conservation state. By late 1990's the whole region started to transform, because of the shift of the local inhabitants production practices. Electricity distribution infrastructure was built, and unregulated industrial agriculture has been devouring these invaluable ecosystems and together with unsustainable cattle ranching practices and natural drought cycles, this once healthy ecosystem was being degraded with some areas in advanced decertified conditions, treating its biological integrity. Being primary witness of this rapid transformation, prompted us to adapt our research focus and expand our activities in to activism and lobbying in order to stop and revert this degradation. The Biosphere Reserve decreed was the culmination of a decade long campaign to preserve this amazing area and the beginning of our full time involvement on community based conservation, ecological restoration, sustainable cattle management and policy making, while continuing our ecological research, achieving important successes. This talk addressed this process from the beginning to date, offering a clear example of the complexity of a successful science-based conservation effort in Mexico, one of the most biodiverse countries in the world.

CONFLICTING CONSERVATIONS GOALS: WHEN A THREATENED SPECIES JEOPARDIZES RESTORATION OF AN ENDANGERED PLANT COMMUNITY

Marie Sigaud

Université Laval

As the rate of biodiversity loss driven by human activities continue to accelerate unabated, conservation challenges are becoming increasingly numerous and diverse, as are the management and conservation programs being developed to address these challenges. Conservation conflicts arise when competing conservation projects being implemented in the same space hinder each other's progress. Conflicts can become even more complex when sanctioned management measures

to favour a specific threatened species impede ongoing management efforts aimed towards another threatened species, resulting into an inextricable conservation dilemma. Resolving conflicting conservation goals, and preventing them from arising in the first place, requires a detailed understanding of the ecological mechanisms that create such conflicts. We used a combination of vegetation surveys, fecal analysis, GIS data, and GPS collar data, to explore whether free-ranging bison (*Bison bison*) transport non-native seed species and by doing so impede ongoing efforts toward fescue grassland restoration in Prince Albert National Park (PANP). We showed that bison facilitate long distance dispersal and establishment of non-native plant species by transporting seeds via endozoochory and epizoochory and depositing them in sites where they are more likely to get established (i.e., sites that are locally disturbed and intensively used by bison). As the bison range largely overlaps with fescue grasslands, it appears that bison conservation endangers the persistence of these threatened fescue plant communities. Our analysis illustrates the ecological mechanism resulting in the spatially structured conservation conflict, and we demonstrate how this mechanistic understanding can be used to identify priority areas where conservation actions will benefit both conservation objectives.

EXAMINING COMMUNITY STRUCTURE AND INVENTORY TEMPORAL PATTERNS OF TURTLE SPECIES SOLD IN THE WILDLIFE MARKETS OF GUANGZHOU, CHINA

Amanda Sigouin

Columbia University

Mingxia ZHANG, Wildlife Conservation Society ; Colin POOLE, Wildlife Conservation Society ; Aili KANG, Wildlife Conservation Society ; Tien Ming LEE, Princeton University

Globally, chelonians face many threats including loss of habitat, increased pollution levels, and pressure from invasive species; however, the biggest single threat is the international turtle trade. Freshwater turtles and tortoises are some of the most valuable fauna in the wildlife trade in Asia, in demand for food, use in traditional Chinese medicine and increasingly for the international pet trade. China is the largest consumer of freshwater turtles and tortoises in the world, and as such its demand has a significant impact on the size and dynamics of the trade. Following the depletion of many native Chinese turtles, and due to increased regional and international trade, turtles from neighboring Southeast Asian countries and other regions of the world have been harvested to meet the growing Chinese demand. Given the conspicuous nature of the wildlife trade, market data can provide conservationists and regulators important information regarding its size, scope, and dynamics. We analyze empirical data from a decade of market surveys of wild-caught and farmed freshwater turtles and tortoises sold

in the food and pet markets of Guangzhou, China, a major hub of wildlife trade in Southern China. We find that the underlying pattern and structure of turtle species on sale across 141 shops over 24 months from 2011-2013 varied substantially. In particular, the community structures across shops in both food and pet markets reveal the stark differences in the prevalence and distribution of threatened, CITES-listed, and China Protected List species. This community analysis provides important insights into turtle sourcing patterns and end-market demand trends. Work such as this can have important conservation implications such as identifying indicator species and specific shop inventory patterns that are useful in improving the efficiency of enforcement and monitoring efforts of endangered and protected turtle species.

SYSTEMATIC CONSERVATION PLANNING USING INFORMATION FROM STRUCTURED EXPERT JUDGMENT ASSESSMENT: TARGETING PROTECTION OF CONTINENTAL BIODIVERSITY IN LATIN AMERICA AND THE CARIBBEAN

Juha Siikamaki

Resources for the Future

Roger COOKE, Resources for the Future ; Francisco SANTIAGO-AVILA, Resources for the Future ; Rebecca EPANCHIN-NIELL, Resources for the Future ; Peter VAIL, Resources for the Future

Determining the optimal design of networks of nature reserves, known as the reserve site selection (RSS) or systematic conservation planning (SCP) is an important problem in conservation science. These problems are framed as constrained optimization to maximize an ecological value function by targeting conservation on a set of land parcels. SCP can be subject to considerable uncertainties and information gaps. For example, conservation often seeks to reduce future threats to biodiversity, but future threats to species and habitat themselves are regularly poorly understood. In this study, we develop a new approach to addressing information gaps and uncertainties in SCP by using structured expert judgment assessment (e.g. Cooke and Goossens 2004). Structured expert judgment assessment is an approach developed in risk analysis to systematically elicit and aggregate information from a pool of experts with intimate knowledge of the relevant subject. Our study concerns prioritization of continental biodiversity in Latin America and the Caribbean (LAC). Using ecoregions as the main units of analysis, we used currently available sources to develop rich data on biodiversity and its threats. We designed, tested, and implemented a structured expert judgment assessment of LAC conservation experts. It yields data from almost 100 experts from throughout the region and many relevant fields. The survey elicited data for current species richness (by taxa) and current and future threats to species and habitat. The survey is spatially explicit so the data

are developed at local level relevant to the SCP problem. We construct performance-based information weights by expert and use them for final predictions. Finally, we develop an RSS model which directly incorporates key data from the structured expert judgment assessment. Results from conventional and expert data based SCP show similarities and differences, indicating broader potential for expert judgment in conservation planning.

#171 - TRAINING CONSERVATION LEADERS: HOW WILL WE KNOW IF WE'VE DONE IT?

Janet Silbernagel

University of Wisconsin-Madison

At the time of this symposium in August 2015, the first cohort of 25 students in our newly redesigned professional masters in Environmental Conservation will be completing their degrees. The programme's mission, to train conservation leaders, has been attractive to those who apply, and to the many professional partners with whom we work. While it makes a compelling pitch for a program, and we have incorporated a variety of leadership training requirements into the curriculum, at the end of the day (or programme), how do we assess the effectiveness of such training? Is it enough to establish specific learning outcomes for a curriculum that define the leadership skills expected? Or rather, might we rely on alumni employment statistics and employer feedback demonstrating that graduates are in high-level positions? These questions are germane beyond the conservation sector. Recognition of the need for training in environmental and sustainability leadership continues to grow. As it does, academic leaders are beginning to ask, can leadership be taught, or is leadership capacity developed only through experience? In this talk I will further describe the approach our program takes to prepare students as conservation leaders to tackle complex decisions and challenges in a changing world. I will place our experience within the context of current literature on teaching conservation leadership, sharing some of our lessons learned and successes in light of that research. Most importantly, I will pose provocative questions to the panel to encourage the debate and collective thinking around training conservation leaders.

THE POWER OF VISUALIZING CHANGE: ASSESSING THE IMPACT OF INTEGRATING SATELLITE IMAGERY INTO ENVIRONMENTAL EDUCATION

Majory Silisyene

University of Minnesota

Environmental education (EE) is considered a critical element in conservation, as it has proven to yield positive influence on peoples' environmental behaviors. While EE has been implemented using various tool, including printed materials, videos, smart phones, and tablets, satellite images have never been employed as EE tool. I evaluate the impact of participating in marking earth's features on satellite photos, on local peoples' knowledge of a community owned forest in Loliondo, Tanzania. This study emulates the designed controlled experiment, where individuals in a treatment group participate in marking various earth features within boundaries of the forest, while the individuals in a control group do not. The study uses survey data from both before and after the intervention to determine whether the observed results in control and treatment groups are significantly different. In order to determine the reliability of participants' knowledge about the condition of their forest, I compare survey findings to land cover change percentages of the community forest between two time periods. Results suggest that PPM can significantly improve local peoples' understanding of their resources; i.e., local people understand better to what extent their forest resources have been depleted, and places where these resources are being cleared most.

95-USING VOLUNTEER SCIENCE, SOCIAL NETWORKING AND EMERGING TECHNOLOGIES TO EFFICIENTLY AND ACCURATELY COLLECT DATA ON THE IMPACTS OF ROADS AND TRAFFIC ON WILDLIFE

Neftalí Sillero

Universidade do Porto

John A. BISSONETTE, Utah State University ; Fraser SHILLING, University of California ; Sarah PERKINS, Cardiff School of Biosciences

Collecting, processing and validating data on roads impacts can be a challenging and time-consuming task. New technologies are currently being developed to increase the efficiency and accuracy of data collection. Recently, these technologies have increasingly been supported by collaboration with volunteers. Coupled with social networking, volunteer science is an emerging tool for collecting and analysing data for multiple purposes. In road ecology, volunteer participation is critical to establish extensive and frequent data collection. Social networks (Facebook, Twitter for example) bring new ways of collecting and sharing data as well as discussing science. We present several projects and applications that collect data on wildlife-vehicle collisions (WVC) and other road impacts on wildlife. Numerous applications for smartphones deals with data collection of WVC. GPS location points for a WVC observation can be input directly into a database. Some databases are predefined

(e.g. Urubu project, ObsMapp), but others can be completely customized (e.g. Cybertracker, EpiCollect+), defining as desired any type of fields and their associated values. Several applications are associated with websites where the user can store his/her own data (e.g. EpiCollect+, iNaturalist, Observado) and share them with others. In fact, there has been a burst of websites for storing chorological data, many dedicated to WVC, or live observations of wildlife (e.g. www.wildlifecrossing.net). Other projects deal with intelligent systems for collecting systematic data on WVC. Volunteers can generate huge amounts of data, making validation a very time-consuming task. Data sharing between projects poses challenges due to different database structures and data upload systems. The Darwin Core initiative proposes to use a common system for collecting chorological data. Understanding and standardizing volunteer-based wildlife observation systems will change data supply for road ecology studies.

HABITAT SUITABILITY MODELLING OF AMPHIBIANS AND REPTILES IN FIRE-PRONE REGIONS UNCOVER CONTRASTED RESPONSES ACCORDING TO SPECIES-SPECIFIC BIOGEOGRAPHIC AFFINITIES

Neftalí Sillero

CICGE: Centro de Investigação em Ciências Geo-Espaciais, Faculdade de Ciências da Universidade do Porto (FCUP)
Xavier SANTOS, CIBIO/InBIO, Centro de Investigação em Biodiversidade e Recursos Genéticos, Universidade do Porto ; Françoise POITEVIN, Centre de Ecologie Fonctionnelle et Evolutive, Ecole Pratique des Hautes Etudes, Biogéographie et Ecologie des Vertébrés ; Marc CHEYLAN, Centre de Ecologie Fonctionnelle et Evolutive, Ecole Pratique des Hautes Etudes, Biogéographie et Ecologie des Vertébrés

Wildfires are considered within the disturbances that produce major impact in ecosystems functioning and composition in many areas of the world. In the Mediterranean region, natural fire regimes contribute to maintain habitat heterogeneity and biological diversity at a landscape scale. Within a community, species show contrasted responses to fire, varying the community composition from unburned to burned habitats. Some species are resilient or early colonizers whereas others are late-colonizers of burnt areas. Species may be adapted to particular stages of this succession. Reptiles are often dependent on habitat structure and type, these characteristics varying along the post-fire succession. Amphibians have also specific responses to fire according to habitat preferences and activity. We hypothesize that Mediterranean herps will respond positively to fire with an increasing distribution range due to an increase of suitable habitats. In contrast, non-Mediterranean herps are expected to respond negatively to fire by a degradation of suitable points linked to the openness of the habitat. We examined the response on amphibians and

reptiles to fire in the Massif des Maures (Provence, Southern France), a Mediterranean area with Centro-European influence due to moderate rainfall and non-degraded vegetation cover. We modelled the habitat suitability of 7 amphibian and 16 reptile species with a data set of 3612 exact locations collected along 63 years. We divided the set of locations into two periods (before and during the fire occurrence, 1958-2003 and 2004-2011) and calculated the realised niche models with Maxent and Bioclim methods. We included fire-related variables (time since fire and number of fires) only in models of the second period. Our preliminary results suggest that Mediterranean species increased the extent of habitat suitability as the fire frequency increase in the study region, meanwhile Centro-European species did not present a similar increment.

PLANT PHYLOGENETIC DIVERSITY AS A TOOL TO IDENTIFY PRIORITY AREAS FOR CONSERVATION

Danilo Silva

Universidade Federal de São Carlos

Biodiversity measures are used as criterium to define areas for biological conservation. But, in most cases, phylogenetic relationships among species are neglected, taking into account only the species number. However, phylogenetic diversity brings useful information on evolutive history of species. Moreover, considering that phylogenetic diversity is an important component of biodiversity, being related to many ecosystem functions and ecological process; there is a risk to lose those species that contribute more to many levels of diversity if we ignore phylogenetic information. Thus, we seek to incorporate phylogenetic diversity into the current models of biological conservation to improve them. Here, we used plant species lists for an entire Brazilian state to calculate three measures of phylogenetic diversity: Faith's phylogenetic diversity, mean pairwise distance and mean nearest taxon distance. Faith's diversity was highly correlated to the species number, therefore was not used in further analyses. The other two measures were lowly correlated to number of species and between themselves, therefore were good candidates to model adjustments. We are testing if these new models would lead to the conservation of more species in regional scale than the models considering only species number.

THE RETURN OF THE KING: REINVENTING THE IMAGE OF THE KING COBRA (OPHIOPHAGUS HANNAH) AS A FLAGSHIP SPECIES IN RURAL THAILAND

Inês Silva

University of Lisbon

Colin STRINE, Suranaree University of Technology ; Matthew CRANE, Suranaree University of Technology ; Taksin ARTCHAWAKOM, Sakaerat Environmental Research Station

Locally supported flagship species can serve as a rallying point for conservation activities and increased fundraising. Reptiles, and particularly snakes, are often viewed more negatively than other taxa, and thus generally forgotten for flagship consideration. Despite the fear attached to snakes they may prove efficient flagships for conservation education as many species are commonly found in human-dominated landscapes. We selected the king cobra, the largest venomous snake in the world, as a flagship species candidate in Thailand due to its high profile, large home range, and its Vulnerable status under the IUCN Red List. Our work with Thai student groups found that the king cobra is the most feared snake; however, hospital records for the area contained no king cobra hospitalizations. These results showcase the major gap between local perception and reality, and the demand for educational outreach to reinvent the image of the king cobra. While radio-tracking king cobras in the disturbed areas of Sakaerat Biosphere Reserve in Northeastern Thailand, we have engaged in in situ conservation education, which has successfully changed how both king cobras and other venomous snake species are perceived by local communities: many villagers have shifted from killing the snakes to using our removal program, which has led to the rescue of 7 king cobras since its inception. Additionally, we have taught over 5,000 students from 58 different schools on king cobra ecology and conservation. King cobras show potential to be the anchor of a conservation action plan to preserve both intact areas and forest fragments within human-dominated landscapes, by harnessing the support of local communities and students. Our end goal is to drive the conservation of multiple species and habitats within the Southeast Asia region.

WILD POPULATIONS AND PROTECTION OF DISPERSAL CORRIDORS ARE VITAL FOR THE CONSERVATION OF GENETIC DIVERSITY AND GENE FLOW IN NORTH AFRICAN DORCAS GAZELLE

Teresa L Silva

CIBIO/InBIO, Centro de Investigação em Biodiversidade e Recursos Genéticos, Campus Agrário de Vairão[INSTITUTE] Departamento de Biologia, Faculdade de Ciências, Universidade do Porto, Rua do Campo Alegre s/n[INSTITUTE] Estación Experimental de Zonas Áridas (EEZA), CSIC, Carretera de Sacramento s/n

Universidade do Porto, Rua do Campo Alegre s/n ; Paulo Célio ALVES, CIBIO/InBIO, Centro de Investigação em Biodiversidade e Recursos Genéticos, Campus Agrário de Vairão[INSTITUTE] Departamento de Biologia, Faculdade de Ciências, Universidade do Porto, Rua do Campo Alegre s/n[INSTITUTE] Wildlife Biology Program, University of Montana, ; José Carlos BRITO, CIBIO/InBIO, Centro de Investigação em Biodiversidade e Recursos Genéticos, Campus Agrário de Vairão[INSTITUTE] Departamento de Biologia, Faculdade de Ciências, Universidade do Porto, Rua do Campo Alegre s/n

Wild populations face extinction risks caused by deterministic factors, such as habitat loss, and by stochastic events of demographic, genetic, or environmental nature. Populations experiencing range and demographic reductions due to poaching are particularly sensible to population fragmentation, genetic drift and inbreeding. For such species, captive programs are important to maintain genetic diversity for potentially supplementing wild populations. North African gazelles are excellent models to understand factors determining genetic structure in wide-range vertebrates that have undergone strong population declines. This is the case of *Gazella dorcas*, a Vulnerable antelope threatened by population reduction and habitat loss. We aim to quantify genetic diversity/structure in differently managed populations of Dorcas gazelle and to estimate gene flow levels between wild populations across the north-western range of the species, an area subjected to intense poaching. Invasive and non-invasive molecular methods were used to sequence five fragments of mitochondrial and nuclear DNA and genotype 222 individuals from the differently managed populations with 15 microsatellite loci. Genetic diversity in all markers showed that wild populations exhibited higher levels of genetic diversity in comparison to captive/semi-captive populations. Gene flow levels were high between wild populations resulting in shallow genetic structure and weak spatial isolation. The isolated population from Tidra Island (Banc d'Arguin National Park, Mauritania) exhibited unique genetic characteristics that should be effectively preserved. High-dispersal ability is probably associated to high gene flow levels detected along the Atlantic Sahara and the Sahel. Integrative conservation strategies, combining ecological niche modelling and landscape genetics, are needed to fundament conservation action plans for wild populations. The protection of dispersal corridors allowing gene flow is paramount.

THINKING ABOUT ECOLOGICALLY UNBALANCED NATIVE SPECIES - EXAMPLES FROM BRAZIL

Dalva Maria Silva Matos

Universidade Federal de São Carlos
Vânia Regina PIVELLO, Universidade de São Paulo ; Sidinei Thomaz MAGELA, Universidade Estadual de Maringá ; Flavia

BOTTINO, Universidade Federal de São Carlos ; Maria Tereza GROMBONE-GUARATINI, Instituto de Botânica/SMA ; Marcus Vinicius VIEIRA, Universidade Federal do Rio de Janeiro ; Helena G. BERGALLO, Universidade do Estado do Rio de Janeiro

The understanding of the meaning of invasive species remained very inconsistent for several decades, perhaps understandably, because the notion of invasive species brings together a series of concepts from different fields, such as biogeography, demography, ecological succession, and community ecology. Compared to exotics, native species are much less likely to develop invasive behavior in a community because co-evolution tends to accommodate species requirements and attenuate competition. In this work we aim to draw the attention of the scientific community, managers of protected areas and policy makers to the super-dominant native species (or "native-invasives") in order to stimulate more research on the topic and the development of management actions. We tried to select native terrestrial and aquatic species of plants and animals that most frequently show the "invasive" behavior in their original habitats, as well as to discuss the possible causes of their atypical dominance and the negative impacts they may cause. We performed a non-systematic review of published material, including thesis and gray literature, as well as from our own experience. We present a list of 24 taxa (species or genera) of terrestrial plants, aquatic macrophytes and mammals that have shown explosive population growth in their original habitats, and we discuss the causes and consequences of such behavior. Disturbance is the main driver of their spread. For terrestrial species, habitat fragmentation, forest gaps, wildfires, and climate change, although eutrophication and the construction of reservoirs are the main drivers of the aquatic plants super-dominance. In the future scenario disturbances may promote not only invisibility by exotic species but also changes the dynamics of native species, which may spread and threaten the persistence of natives. Management strategies must identify how land use, habitat fragmentation and climate change interact to cause explosive population growth.

LA MACHORRA" HILL DIVERSITY

Beatriz Silva-Torres

UNIVERSIDAD AUTONOMA METROPOLITANA
Minerva GONZALEZ-IBARRA, UNIVERSIDAD AUTONOMA METROPOLITANA ; Aurora CHIMAL-HERNANDEZ, UNIVERSIDAD AUTONOMA METROPOLITANA

"La Machorra" hill is located between 100° 16' North latitude and 20° 31' East longitude, in Querétaro State, Mexico. The studied area is located in the semiarid zone of central Mexico; It is considered an large area with an important industrial activity and population growth. The investigated area presents a particular arid vegetation, its thorn shrub association, which

at the highlands presents the characteristics of low deciduous forest and the low fields features as a crasicaule shrub. Currently the landscape of "La Machorra" hill is surrounded by cultivated fields, small communities and an industrial park is located 3 km from it. The area has a private land tenancy and it has remained preserved at the top of the hill, mainly due to this is an area of steep slopes. A current estate development seems to be underway by environmental authorities have requested that "La Machorra" Hill to be kept as a preserved area. The main objective of this work was to characterize the Hill physically (soil, water, geology, climate) and biologically (vegetal plants and wild animals). The knowledge of this specific diversity is considered basic information to develop a management plan. For the study of biotic component, cluster sampling was performed, recording 75 species of flora and 89 of fauna. Some of the recorded species have protected status in accordance with Mexican law were: *Dasyllirion acrotiche*, *Echinocactus platyacanthus*, *Aquila chrysaetos*, *Falco peregrinus*, *Crotalus durissus*, *Pituophis deppei*. The Simpson diversity index was calculated. The Simpson index obtained in this area was 0.09541, which means it has a high diversity, and to corroborate the above, the Shannon-Weaver index was calculated with a 5.038 value, which confirms the high diversity beforehand mentioned. Currently we are working in the management environment plan for the "La Machorra" Hill.

ACCOUNTING FOR NON-RANDOM CLEARING IN LANDSCAPE-SCALE SPECIES-AREA RELATIONSHIPS

Jeremy Simmonds

University of Queensland
Martine MARON, University of Queensland ; Berndt VAN RENSBURG, University of Queensland

Enhancing species richness is a key goal in the management of modified landscapes. Understanding how species richness relates to the amount of habitat in a landscape can guide targets for habitat protection and restoration. However, often the area of remaining habitat in a landscape is a legacy of non-random clearing practices associated with land uses such as agriculture. Thus, detecting the effect of habitat area per se is complicated by confounding factors. Indeed, abiotic attributes such as soil properties that are likely to confound habitat area in modified systems are rarely considered in studies that relate area to an ecological response like species richness. We examined species-area relationships whilst accounting for confounds of area that are associated with non-random clearing. Focussing on anthropogenically-transformed regions of Australia and South Africa, we show that the shape and functional form of the relationship between woodland bird species richness and landscape-scale habitat area varies when abiotic factors such as soil properties and topographic variability are held constant. In particular, we test for thresholds in woodland bird species-area relationships, and generalities

in the shape and form of the relationship among regions. This study provides a clearer understanding of the effect of landscape-scale habitat area on woodland bird species richness, with implications for management actions that are based on conserving or restoring habitat. More generally, this research highlights the consequences of not accounting for non-random clearing when relating an ecological response to area, and underscores the importance of considering landscape patterns when analysing human-modified systems.

PROTECTED AREA NETWORKS DESIGNED FOR GEOCONSERVATION DO NOT REPRESENT SPECIES DIVERSITY

Benno Simmons

Imperial College London

Richard GRENYER, University of Oxford

Geoconservation is rapidly becoming a major policy consideration for governments around the world. Proponents argue for the intrinsic, economic, scientific, cultural, aesthetic and functional benefits of abiotic nature, yet additionally often cite how its preservation can produce concomitant gains for biodiversity. This view likely stems from macroecology and biogeography, where studies have long-established positive spatial correlations between measures of abiotic heterogeneity and species richness. However, congruent distributions in space do not demonstrate the degree to which biodiversity conservation and geoconservation can be performed by the same network of protected areas. For this, an explicit test of the sampling of biodiversity by the set of choices made to maximize representation of geodiversity is needed. Here, for the first time, we perform such a test by modelling the outcome for biodiversity of a hypothetical geodiversity conservation policy that prioritises geodiverse landscapes in the UK. We find that, contrary to suggestions, protected area networks designed for geoconservation represent species diversity only poorly. Consequently, geoconservation and biodiversity conservation should be viewed as competing landuses that involve a spatial and resourcing tradeoff.

CONSERVATION GENETICS AND POPULATION VIABILITY OF ENDANGERED SWAMP ORCHID PHAIUS AUSTRALIS IN AUSTRALIA

Laura Simmons

University of the Sunshine Coast

Alison SHAPCOTT, University of the Sunshine Coast ; Michael MATHIESON, Queensland Herbarium, Department of Science, Innovation, Information Technology and the Arts

The Swamp Orchid *Phaius australis* occurs in disjunct populations along Australia's east coast in ecotones of coastal wetlands and springs vulnerable to climate change and fire-prone heathland. The orchids are endangered due to narrow

environmental tolerance, past illegal collection, continued habitat loss and limited connectivity between populations. We have investigated the viability and persistence of *P. australis* by combining genetic and demographic studies across a 2000km latitudinal range. We sampled for population genetics at 34 locations; undertook paired population demographic surveys over several years and a pollination experiment. Using NextGen microsatellite markers and morphology assessments, we confirmed *P. australis* population size and locations in Australia and genetic differences between two congeners. Spatial patterns of genetic diversity indicate post-colonisation divergence from the tropics southwards to current climate niche limits. Fitting with genetics theory, loss of populations and population size has resulted in lower genetic diversity in small populations. Despite small population sizes and the presence of cloned genotypes within populations, the species is not inbred. Pollination experiments support spontaneous self-fertilisation in wild populations and potential heterozygote advantage in floral output and success. Climate change vulnerability has been modelled through population viability analysis based on the climate related vital rates we observed and SIMCLIM generated climate change predictions. Fires occurred in several populations during the study allowing us to monitor recovery and undertake extinction risk analysis to different fire severity and frequency. An understanding of the genetic viability and demographic persistence of populations now and in the future will influence the likelihood of long-term survival in the context of population recovery and restoration, fire management and assisted migrations.

CONSERVATION OF FRESHWATER PEARL MUSSEL (MARGARITIFERA MARGARITIFERA) AS THE FLAGSHIP SPECIES FOR OLIGOTROPHIC CATCHMENT AREAS: ACHIEVEMENTS AND FAILURES OF 30 YEAR ACTION PLAN IN THE CZECH REPUBLIC

Ondrej Prokop Simon

T.G. Masaryk Water Research Institute[INSTITUTE]Faculty of Environmental Sciences, Czech University of Life Sciences Jan SVANYGA, Nature Conservation Agency ; Jaroslav HRUSKA, Miletínský 7 ; Karel DOUDA, Faculty of Agrobiological, Food and Natural Resources, Czech University of Life Science ; Ivana VANICKOVA, Nature Conservation Agency ; Kamila TICHÁ, T.G. Masaryk Water Research Institute ; Michal BILY, T.G. Masaryk Water Research Institute[INSTITUTE]Faculty of Environmental Sciences, Czech University of Life Sciences ; Miriam JANDAKOVA, T.G. Masaryk Water Research Institute ; Bohumil DORT, Gammarus

Freshwater invertebrates such as molluscs, gastropods and crayfish are considerably endangered by extinction. The anthropogenic eutrophication has substantial impact on the biodiversity in many countries worldwide. The Action Plan

for Freshwater Pearl mussel (FPM) was implemented in the headwaters of the Elbe/Vltava River in the Czech Republic for over 30 years. The FPM represents an umbrella species to protect the rest of a submontane oligotrophic catchment with low agricultural impact. This long-living mollusc also represents an important keystone species for these ecosystems. Throughout the action plan three large protected areas (6.9 – 59.6 km²) were founded in order to protect the FPM stream and the whole catchments. Many organisms profited from the eutrophication decline resulting from different measures. However, the other key factors limiting natural reproduction of the FPM (land use changes, drainage and soil erosion) have changed very little. The current status of natural habitat does not enable the survival of the youngest mussel stages (1 – 5 years) or natural reproduction. Although many problems persist, new semi-natural breeding helped to rejuvenate the over-aged populations. The local habitat quality was improved by new successful management methods too. The conservation of the mollusc formerly hunted for pearls, seems to be attractive both for the public and the conservation authorities. That allows long-time project funding in a politically unstable environment. The natural reproduction of FPM has not been restored yet; thus the main goal of the Action Plan was not reached. Nevertheless, many endangered water, wetland and terrestrial organisms profit from ecosystem protection. Consequently, focusing conservation on an attractive flagship animal with a wide, complex of strict habitat demands seems to be beneficial even for usually neglected invertebrate species.

POPULATION VIABILITY OF OSCILLATING POPULATIONS

Alexander Singer

Helmholtz Centre for Environmental Research - UFZ
Karin FRANK, Helmholtz Centre for Environmental Research - UFZ

Theory on the viability of small established populations is well developed. The theoretical knowledge has guided development of methods to analyze population viability. By now, population viability analysis (PVA) is a standard tool to support conservation of single species. However, more complex situations involving community dynamics or environmental change violate basic assumptions of that theory. Synthesizing concepts from population, community and conservation ecology, we enhance theory of population viability analysis to cope with cyclic populations. We find that the interplay of periodic population decline and demographic stochasticity causes varying population extinction risk and modifies the temporal structure of viability. Temporal variability in viability depends on population establishment and cycle coherence. The temporal structure in viability can be visualized and assessed. For this purpose, we develop a mathematically founded method to calculate from simulation models two

viability metrics that are known to be sensitive to temporal changes in population viability. The metrics describe how population cycles impact viability at short management relevant time scales and at long time scales that cover the general condition of a cyclic population. This improvement makes a standard PVA method applicable to populations responding to e.g. seasonality or trophic interactions. Particularly, viability analysis becomes comparable among trophic levels and therefore equips biodiversity conservation with a long missing tool.

SPECTRAL CHARACTERISTICS OF AVIAN COMMUNAL ROOSTING IN URBAN HABITATS OF DELHI, INDIA

Manoj Singh

JAWAHARLAL NEHRU UNIVERSITY
*Krishan KUMAR, JAWAHARLAL NEHRU UNIVERSITY ;
Yashmita ULMAN, NERIST ; Dinesh KUMAR, DEPARTMENT OF ENVIRONMENTAL SCIENCES, CENTRAL UNIVERSITY OF JAMMU*

Urbanization is occurring at a rapid pace resulting in restructuring of habitats and avifaunal diversity. Biotic and abiotic sound in urban areas interferes with signal detection and restricts communication range of birds. Therefore, the acoustic ambient environment of a habitat is one of the key factors influencing the effective communication system in birds. It also has high ambient noise levels, which makes vocal communication difficult for birds. The spectral characterization of chorus (bird's vocalization) provides us an insight of avian communication and their adaptation to overcome extrinsic noise levels. The present study was undertaken to understand the vocal communication of birds in urban habitat. This study compares the spectral characteristics of dusk chorus between urban and forest habitats. The sound pressure levels of birds roosting activities in ridge forest and urban habitats of Delhi were recorded during dusk for a period of one year. It was observed that the dusk chorus at urban sites were mainly dominated by two generalist species, i.e., *Corvus splendens* (House Crow) and *Acridotheres tristis* (Common Myna) while in Ridge forest the avifaunal diversity was high. Time series and spectral graphs of sound pressure levels at different 1/3rd octave frequencies were plotted. During the time of chorus a significant increase in the frequency (1-4 kHz) was observed as compare to background noise levels of the sites. Maximum SPL during the dusk chorus in urban habitats and ridge forest ranged between 68-73dB and 50-55dB levels respectively. So, it can be concluded that dusk chorus at urban sites are more intense than ridge forest sites. This might be due to lower tree densities in urban site. This study might provide evidence for acoustic dependent adaptations in birds dwelling in urban habitats.

ELEPHANTS IN A TEA CUP: UNDERSTANDING HUMAN-ELEPHANT RELATIONSHIPS AND ASSESSMENT OF THE EFFECTIVENESS OF CONFLICT MITIGATION MEASURES IN VALPARAI, TAMILNADU, INDIA

Rashmi Singh

Ambedkar University Delhi

Rishi Kumar SHARMA, WWF-India

The Annamalai hill range in Southern Western Ghats is identified as the largest potential area for the long term conservation of elephants in India. The Vaparai region of Annamalai has seen an increase in human-elephant conflict rates in last two decades. Nature Conservation Foundation (NCF), an NGO initiated a few conflict mitigation measures (CMM) to reduce the conflict. However little is understood about how people in this region view elephants and whether the conflict mitigation measures initiated by NCF have been effective. We collected qualitative and quantitative data using semi-structured interviews to understand human and elephant relations in the region and effectiveness of the CMMs. A total of 204 locals were interviewed in 17 randomly selected tea estates. The data was analyzed using a mixed methods examination using exploratory data analysis, descriptive statistics and an information-theoretic model selection approach. Majority of people (78 %) had a positive attitude towards elephants with little difference in attitudes across age, education or nativity. People showed a complex range of emotions including empathy, respect, fear and love towards elephants. Human attitudes towards elephants were best explained by gender and past experience. Negative attitudes towards elephants were primarily driven by past bad experiences, while men were likely to view elephants more positively. SMS based elephant alerts were received by 38 percent of respondents, news flash on the local channel by 89 percent in 14 estates while early warning beacon lights were working in 9 out of 17 estates. All the respondents felt that mitigations measures were important while 96 % said they had benefited and avoided accidents in the past due to these measures. Since negative attitudes are driven by past bad experiences, mitigation measures should now prioritize estates which are remote and prone to high risk of negative interactions between people and elephants.

CAN INCREASING CROP HETEROGENEITY IMPROVE SYNERGIES BETWEEN ECOSYSTEM SERVICES AND BIODIVERSITY CONSERVATION IN EUROPEAN AND NORTH-AMERICAN FARMLANDS?

Sirami C. Representing The Farmland Consortium
INRA

Agricultural landscapes occupy nearly 40% of the available land area in the world. They play an important role in providing habitat for wild species that in return contribute significantly to food production through ecosystem services such as crop pollination and pest control. Over the last half-century, intensification of agriculture has resulted in losses to biodiversity and associated ecosystem services. Landscape heterogeneity has been proposed as a key tool in conserving farmland biodiversity. Indeed, agricultural landscapes which contain higher amounts of semi-natural habitats tend to host more species. However, current policies either aim at increasing the proportion of semi-natural elements, which requires taking crop area out of production and is often not feasible, or focus on a particular group of species, which may lead to the decrease of other species or ecosystem services. It has been suggested that increasing crop heterogeneity may also increase species diversity through landscape complementation processes and improve synergies between ecosystem services. The FarmLand project tested this hypothesis on seven taxa and four services across eight regions of Europe and North America. Surveys and experiments were conducted in 453 landscapes located along two independent gradients of crop compositional and configurational heterogeneity: crop diversity and crop total border length. We compared species richness and total abundance of seven taxa as well as pollination, predation and food production potentials. Results to date suggest that crop configurational heterogeneity may have a stronger effect on biodiversity in some regions but that effects of crop heterogeneity are not consistent across taxonomic groups, ecosystem services and agricultural regions. Multi-taxa and multi-region results will be key in developing more efficient agricultural policies and identify more acceptable trade-offs between ecosystem services and biodiversity conservation.

PARTICIPATORY ANALYSIS, LANDSCAPE ASSESSMENT AND CONSERVATION IN THE GREATER GRAND CANYON REGION

Thomas Sisk

Northern Arizona University

Todd CHAUDHRY, National Park Service ; Clare ASLAN, Northern Arizona University ; Jill RUNDALL, Northern Arizona University [INSTITUTE] Northern Arizona University [INSTITUTE] Northern Arizona University ; Sasha STORTZ, Northern Arizona University

Conservation areas do not exist in isolation, and administrative boundaries seldom capture ecosystem dynamics to a degree that adequately protects biodiversity. While conservation science is increasingly able to integrate compositional and functional attributes at the landscape-level, acting on this

knowledge though transboundary management remains challenging. To address broad-scale management issues exacerbated by land use and climate change, we designed a collaborative assessment process for the Grand Canyon region. After convening stakeholders representing private landowners, state and federal agencies, Native American tribes, and other engaged citizens, we identified a 2M ha study region with the 490K ha Grand Canyon National Park at its core. Drawing on existing data from multiple sources, we applied spatial analysis and modeling to inform a multi-step deliberative process, through which stakeholders identified focal resources and processes, as well as threats and stressors. Participants mapped priority areas to guide planning and enhance stewardship. Analyses revealed priority areas and stewardship needs that unite upper watersheds with downstream resources within Grand Canyon National Park, as well as park management efforts that affect adjoining lands. Engagement engendered confidence in data and analysis, while results influenced park management and provided a scientific foundation for addressing complex problems that demand socioeconomic and cultural sensitivity, as well as environmental understanding.

BIRD FUNCTIONAL DIVERSITY DECREASES WITH TIME SINCE DISTURBANCE: DOES PATCHY PLANNED FIRE ENHANCE ECOSYSTEM FUNCTION?

Holly Sitters

University of Melbourne

Julian DI STEFANO, University of Melbourne ; Fiona CHRISTIE, University of Melbourne ; Matthew SWAN, University of Melbourne ; Alan YORK, University of Melbourne

The effects of disturbance on animal functional diversity are unknown. Functional diversity measures the trait values in a community, and links changes in species composition with the consequences for ecosystem functions, such as seed dispersal, pollination and nutrient cycling. Improved understanding of the relationship between time since fire (TSF) and functional diversity is critical to biodiversity conservation because the frequency and severity of fire are expected to increase. We examined responses of bird functional diversity to TSF and two measures of habitat variation across a 70-year chronosequence spanning four vegetation types. Six bird functional traits were used to derive measures of functional richness and evenness, and we investigated the effects of TSF, plant diversity and vegetation structure on the functional diversity indices. Functional richness was negatively associated with TSF in all vegetation types, suggesting that recent planned fire generates variable habitat and provides greater opportunities for species to partition resources. A positive relationship between functional evenness and structural heterogeneity was common to all vegetation types, suggesting that fine-scale (10s of metres) structural variation can enhance ecosystem function

and resilience. Species more common in young vegetation were primarily linked by their specialist diets, indicating that ecosystem services such as seed dispersal and insect control are enhanced in more recently burnt vegetation. Our data indicate that patchy, planned fire sustains functional diversity, and we suggest that controlled use of patchy fire to break up large expanses of mature vegetation will enhance ecosystem function and resilience, while protecting species that rely on old vegetation.

ENGAGING DIVERSE PARTNERS: THE MULTI-PARTY CONSERVATION AGREEMENT AND STRATEGY AS AN EFFECTIVE FRAMEWORK FOR ARID-LAND AQUATIC SPECIES CONSERVATION AT A LANDSCAPE SCALE

Jon Sjoberg

Nevada Department of Wildlife

Jeri KRUEGER, US Fish and Wildlife Service ; Eric MISKOW, Nevada Natural Heritage Program ; Chad MELLISON, US Fish and Wildlife Service ; Michael BURROUGHS, US Fish and Wildlife Service ; Jef JAEGER, University of Nevada Las Vegas ; Ross HALEY, National Park Service

In arid lands of the American west, rare and imperiled aquatic species often occur in isolated and geographically dispersed populations across multiple political and administrative jurisdictions, creating unique challenges to implementing conservation for those species. In Nevada, conservation providers have used the multi-party Conservation Agreement and Strategy (CAS) as an effective tool to implement proactive strategies and actions at a landscape scale across the range of included species. The CAS approach has been successfully applied to both endemic fish and amphibian species, and an agreement is currently under development to guide conservation implementation for a suite of rare gastropod species occurring in isolated habitats across the Great Basin ecosystem that share similar habitats and threats. CASs for three imperiled amphibians, Amargosa toad, relict leopard frog, and Columbia spotted frog, have guided successful implementation of more than 90 percent of conservation targets by multiple partners over 10-year timelines, and are currently being renewed for additional terms. Key to these successes is the high level of certainty for conservation through signatory commitments by participants including: Federal, State, and local governments; NGOs; academic institutions; and other private and public parties. Through a combination of successful implementation and commitment to long-term conservation efforts, CASs for two species, Virgin spinedace and Amargosa toad, have been instrumental in supporting findings that the listing of these species under the Endangered Species Act was not warranted. The CAS format provides a flexible and adaptive method for insuring that needed conservation practices are delivered effectively to at-risk species at a scale

necessary to maintain and enhance populations of these species across large landscapes, while accommodating the challenge of working with diverse partners whom often have conflicting needs and requirements.

GENETICS IN CONSERVATION ISSUES: DIFFERENT METHODS YIELD DIFFERENT RESULTS

Per Sjögren-Gulve

The Swedish Environmental Protection Agency

Methods and theories in population genetics can be very useful in both conservation policy-making and management (e.g. www.congressgenetics.eu). But different methods may also yield different answers to a conservation-management question, for example: Are these two subpopulations so much genetically interconnected that they constitute, and should be viewed as, one single population? Applying this question to the brown bear (*Ursus arctos*) in Northern Europe with different genetic methods (already done by other authors), produced two different results and answers: an FST analysis implied "Yes" while an assignment test implied "No". While population geneticists may be aware of the pitfalls in the interpretations of results from such analyses, most ecologists, conservation managers and policy-makers are not. I discuss the implications of this general problem for practical conservation management to illustrate the importance of science-policy collaborative learning in biodiversity conservation.

DEER DRIVE COMMUNITY AND EVOLUTIONARY CHANGES IN THE THREATENED GARRY OAK ECOSYSTEM

Cora Skaien

University of British Columbia

Peter ARCESE, University of British Columbia

Ungulate browsing can drastically alter species abundance or performance, or cause evolutionary change in species' traits related to fitness and survival that allow a plant to tolerate or resist ungulate browsing. In the Southern Gulf Islands of British Columbia, Canada, the threatened and heavily invaded Garry Oak and Maritime Meadow ecosystems experience deer densities as high as 100 deer/km². To experimentally assess the impact of deer browsing in these ecosystems, we erected two exclosures (c. 750 m² each) on Sidney Island, Canada in April, 2012 and assessed native species performance after three growing seasons of protection from deer. In August, 2013, 4800 seeds of the iconic *Plectritis congesta*, which originated from islands with histories of high or low deer densities, were systematically planted in and outside exclosures to determine if browsing history influenced plant survival over the subsequent growing season. In May 2014, native species cover was 2-fold greater inside exclosures than outside. Iconic *Brodiaea* species particularly benefited from deer exclusion,

with 3.7 times more cover, 2.3 times higher corm abundance and 3.4 times more volume per corm inside exclosures than outside. The survival of *P. congesta* plants was severely reduced outside exclosures regardless of browsing history, but plants originating from islands with deer had 3-fold higher survival than plants from islands without deer. Plants that originated from islands with deer grew low to the ground until mid-spring to avoid herbivory and achieved shorter final heights, whereas plants from islands without deer bolted several months earlier making them more conspicuous to deer. Together, these results suggest that removal of deer is sufficient to instigate restoration of these degraded ecosystems as manifested through increased native cover and native species performance, and that *P. congesta* populations have become locally adapted to resist herbivory on islands with deer.

BEYOND GREEN-PLANNING POLITICAL ORIENTATIONS: CONTRASTED PUBLIC POLICIES IN TWO EUROPEAN CAPITALS

Zina Skandrani

French National Museum of Natural History

Anne-Caroline PRÉVOT, French National Museum of Natural History

In the international agenda of conserving biodiversity and urban green planning, we explored how biodiversity-friendly political orientations in two European metropolises (Paris – France and Berlin – Germany) were translated in public urban park management. To do so, we used a mixed methods research strategy: we analyzed both cities' strategies for biodiversity and landscape, conducted semi-directive interviews with park managers, surveyed park design and management, and administered questionnaire to specific city dwellers. We showed that the biodiversity strategies in both cities similarly aim at increasing urban biodiversity and city dwellers' awareness; however, they are highly contrasted in their implementation, with Paris having a high level of control and top-down processes compared to Berlin. Accordingly, nature perceptions of city-dwellers differed between both capitals only in their willingness for nature-control (which was more present in Paris than in Berlin). With this example, we discuss how integrative environmental planning can encourage specific implementations of a global strategy.

ID34 REMOTELY-SENSED ESSENTIAL BIODIVERSITY VARIABLES

Andrew Skidmore

University Twente

Sander MUCHER, Alterra ; Martin WEGMANN, DLR ; Nathalie PETTORELLI, Zoological Society London ; Tiejun WANG, Universiy Twente

The original concept of Essential Climate Variables was used as a conceptual basis by the Group on Earth Observation Biodiversity Observation Network (GEOBON) to develop the concept of Essential Biodiversity Variables (EBVs). Here, we present the outcome of 2 workshops which explored the concept of EBVs from the perspective of remote sensing. Translating the conceptual biological ideas of biodiversity, as developed primarily by ecologists, into variables that can be monitored from space proved challenging. However, a framework was developed that recognizes EBVs generated from remote sensing as being global, standardized, repeatable, continuous and synoptic. These features in turn allow the EBVs, directly derived from remote sensing, to be monitored at a global scale. In this presentation, the outcome of the workshops is summarized, and the 'RS4EBV' (remote sensing for EBV) framework is presented. Some case studies based on species monitoring, primary productivity and phenology are used as examples to highlight and explain the RS4EBV framework.

REVIVING STREAMS AND WETLANDS IN ISRAEL - IN A LAND OF SEAWATER DESALINATION

Orit Skutelsky

Society for Protection of Nature Israel (SPNI)

The deep crisis in Israel's national water system is mainly expressed in deterioration in the state of natural water resources, and desiccation of natural aquatic habitats (wetlands, springs and streams). As a result, wetland biodiversity is deeply threatened. For example, over 50% of the plant and animal species that have gone extinct in the region, and over 30% of the plant species currently endangered, are wetland related species. During the second half of the 20th Century, three large-scale developmental projects desiccated the local streams and wetlands. The first was a wide-spread river drainage project that straightened the rivers' meanders, and located agricultural fields and fish ponds in close proximity to river banks – at the expense of river corridors and floodplains. The second national development project was diversion of spring water to agricultural use; and the third was large scale aquifer depletion. Pumping and over-use of groundwater has led to reduction of water levels in aquifers, consequently leading to salinization and waning of the water flow in many springs. Our research shows that 60 out of 90 springs surveyed have lost over 30% of their natural flow during the last 30 years. Processes of degradation of spring water flow raise concern over the government's "treading on the edge" policy of over-exploitation of natural water resources.

Recently the State of Israel has entered an era of large scale sea-water desalination. Currently, over 450 million cubic meters of water are desalinated annually. In the near future most of the country's urban water consumption will be supplied with desalinated water. Releasing the dependence of the urban sector on natural water resources, and increased usage of treated wastewater for agriculture, should lead to policy of rehabilitation and stabilization of aquifers and consequently to restoration of springs and wetlands.

ADVOCATING POLICY AS AN EDUCATIONAL TOOL FOR ENVIRONMENTAL STUDIES STUDENTS

Peter Smallwood

University of Richmond

Stephen NASH, University of Richmond

Undergraduate programs in Conservation Biology have developed a diversity of approaches to employ some form of experiential learning in the curriculum. They range from having the class participate in clean-up projects, create programs for their campus, to having the class work as an environmental consulting organization to help clients in the community beyond campus. Each approach has its own advantages and disadvantages, both for the students and the faculty of the courses. We co-taught the capstone course for our Environmental Studies degree, where we have used policy advocacy as the basis for experiential learning. After studying the scientific, economic and policy aspects of our chosen environmental problem, students in the course developed specific policy recommendations for officials of the Commonwealth of Virginia, and advocated for those policies. Our choices for specific problem areas to address with our recommendations have been very opportunistic. For example, in our most recent iteration of the course, we noted that the Governor of our state had appointed a commission to make recommendations for actions to help the state adapt to climate change in the coming decades. We found the structure of the committee focused on the built environment, with little attention to the natural environment. Therefore, we developed recommendations for conserving the state's biodiversity in the face of climate change, and presented them to members of the Governor's Climate Change Commission. Mechanisms of advocacy included writing and submitting opinion pieces for local newspapers, and face-to-face meetings with Virginia officials. Here, we review our approach to experiential learning for environmental studies, the advantages and disadvantages to our approach, and compare them to a selection of other approaches. We again advocate an opportunistic approach to bringing experiential learning into the classroom.

IMPACTS OF HIGHWAY 40 ON THE GREATER OCALA NATIONAL FOREST ECOSYSTEM, FLORIDA, USA

Daniel Smith

Univ of Central Florida

The greater Ocala National Forest ecosystem (2,000 km²) serves as an important conservation reserve in the heart of central Florida, USA. Highway 40 is a major two-lane road (traffic exceeds 15,000 vehicles/day) that bisects the forest. Rapid growth and development have necessitated widening the road to four lanes. A comprehensive approach that employed several methods was used to determine the current and potential impacts. Survey methods included road-kills, tracks, capture-mark-recapture, landscape genetics and radio-telemetry. Each method was used to evaluate road impacts on different taxa. The study was conducted from 2011-2014 along a 5.5 km stretch of road. Road-kills included over 63,000 individuals from 100 species, while more than 27,000 sets of tracks were recorded of 14 species. Locations of road-kills and tracks were recorded for hotspot analysis. Hair snares were used to evaluate likely road crossings by large mammals. We collected 164 samples of eight species; genetic analysis was conducted on black bear hair identifying 16 separate individuals from 39 samples. Nearly 14,000 herptiles were captured in 39 drift fence arrays. Only two lizards and one frog were recaptured crossing the road, yet herptile road-kills were relatively common. Of 1,529 small mammals captured, none were recaptured crossing the road and only 33 road-kills were documented. The road presents a significant barrier to small mammal movement. Average home range of 12 gopher tortoises was 0.88 ha; none of these were recorded crossing the road, though three road-kills of other individuals occurred. Home range of the 16 Florida box turtles monitored averaged 13.8 ha. Although the road appeared to form a home range boundary, five recorded road-kills indicate that crossings are attempted. For gopher tortoise and Florida box turtle, the road is a significant barrier. To improve habitat connectivity and eliminate road mortality several wildlife crossings and fencing are planned.

15. QUANTIFYING THE ROLE OF BIODIVERSITY AND ECOSYSTEM SERVICES IN CROP PRODUCTION AT FARM AND LANDSCAPE SCALES

Henrik G Smith

Lund University

Yann CLOUGH, Lund University; Ullrika SAHLIN, Lund University; Mark BRADY, Lund University; Ola OLSSON, Lund University;

Christoph SAHRBACHER, Leibniz-Institut für Agrarentwicklung in Transformationsökonomien (IAMO)

While demand for food and bioenergy produced on agricultural land is expected to increase substantially in the near future, agricultural intensification has been shown to negatively impact biodiversity and potentially undermine the production of supporting ecosystem services such as nutrient retention, biological control and pollination that are important for yields. An alternative to conventional intensification is to instead promote these supporting ecosystem services, resulting in increased productivity and/or reduced environmental damage. Models informed by data can be used to evaluate alternative agricultural land-use and management on ecosystem services and yield. However, modelling ecosystem services in real landscapes is challenging because consequences of management on biodiversity depend on both local and landscape-scale land-use and may also be highly context dependent. We develop mechanistic models based on ecological understanding of key processes affecting ecosystem-service providing organisms and how this translates into effects on yield of major temperate arable crops. By integrated modelling of multiple supporting ecosystem services we account for uncertainty of service generation and interactions between services. An explicit linkage with multiple empirical datasets and multiple levels of uncertainty makes the modelling and parametrisation transparent and emphasizes its evidence-based nature. We show how these models can be used to inform management of biodiversity when consequences of decisions taken by individual farmers even have consequences for neighbouring farms. In particular, by combining the modelling of ecosystem services with agent-based models driven by farmers' optimizing behaviour, we can evaluate the potential benefits of landscape scale governance of biodiversity and ecosystem services. Thus, we show how landscape-scale modelling of ecosystem services can be used to inform multi-level governance of agricultural landscapes.

TOWARDS A BLUE ECONOMY IN SEYCHELLES: MARINE SPATIAL PLANNING AND A DEBT SWAP

Joanna Smith

TNC Canada

Didier DOGLEY, Government of Seychelles; Matthew BROWN, The Nature Conservancy; Helena SIMS, The Nature Conservancy

The Seychelles is a rich, tropical marine ecosystem situated in the Western Indian Ocean. Encompassing 1.37 million km² and 115 islands, Seychelles has two UNESCO World Heritage Sites and is home to approximately 85,000 inhabitants. A recognised global biodiversity hotspot, there are high rates of endemism and 735 species on the IUCN Red List. Biodiversity is one of the countries most important assets and it supports two major

economic sectors: tourism and fisheries. The sustainability of existing and future uses is very important to Seychelles, as is meeting their biodiversity protection goals and reducing their national debt. Development and environmental pressures along the coast and at sea, including climate change and extreme ocean events, are impacting Seychelles' natural heritage, affecting livelihoods and economic prosperity. The Seychelles Marine Spatial Planning Initiative is focused on planning for, and management of, the sustainable and long-term use and health of the Seychelles Exclusive Economic Zone. The government-led process includes planning and facilitation in a partnership between The Nature Conservancy and the UNDP-GEF-PCU. The Initiative takes an integrated, multi-sector approach to addressing the challenges in Seychelles, a process with input from all major sectors such as fishing, tourism, conservation, recreation, maritime safety, infrastructure, shipping, and petroleum development. Ecological and socio-economic spatial data sets, a UNDP biodiversity analysis, participatory mapping, and Marxan are being used to develop a zoning design for the entire Exclusive Economic Zone. Management considerations are being drafted that will link the zoning to national policies and strategies, including the Blue Economy. Implementation of the plan will be made possible through a debt swap and creation of a Trust Fund that will provide a sustainable revenue stream for ocean management and climate change, and consolidate foreign debt.

EFFECTS OF HURRICANE IRIS ON RIPARIAN BIRD COMMUNITY STRUCTURE IN SOUTHERN BELIZE

Kimberly Smith

University of Arkansas

Rose Ann BARNHILL, University of Arkansas

Hurricanes are frequent and integral features in the Caribbean, but limited quantitative data exist on response of bird communities to their influence. Lack of pre-hurricane data in affected areas is the primary factor limiting those studies. We began a study of the riparian birds associated with the Bladen branch of the Monkey River in the Bladen Nature Reserve in southern Belize in February of 2000. Two transects were established, one in old secondary-growth (T1) and one in mature forest that did not appear to have been logged (T2). In October of 2001, Hurricane Iris, a category 4 hurricane with sustained winds of 225 km/hr, passed directly over our study sites, effectively destroying the tropical riparian forest along the two transects we had censused from February to June in 2000 and 2001. Although obviously different, we compared pre-hurricane vegetation data (2001, N = 80 plots) with post-hurricane vegetation data (2002), using a modified James-Shugart method for 21 variables. In 2001, 33 species of migrants and 143 permanent residents occurred on T1 and 28 migrants and 111 residents occurred on T2. After the hurricane in 2002, 34 migrants and 133 residents occurred on T1 and 26

migrant and 122 residents occurred on T2. Although numbers of species are superficially similar between years, relative abundances changed dramatically, with common species becoming rarer and rare species becoming more common. Some species disappeared post-hurricane, while some new species appeared. Significant changes also occurred based on strata a species foraged in, foraging substrate, and diet. The dramatic change from forest to early successional vegetation had an equally dramatic change in the composition of the riparian bird communities.

CLASSICAL BIOLOGICAL CONTROL FOR THE MANAGEMENT OF INVASIVE ALIEN INSECTS AND PLANTS

Lincoln Smith

USDA-ARS-EBCL

René SFORZA, USDA-ARS-EBCL ; Marie-Claude BON, USDA-ARS-EBCL ; Franck HÉRARD, USDA-ARS-EBCL ; Javid KASHEFI, USDA-ARS-EBCL ; Livy WILLIAMS, III, USDA-ARS-EBCL

Invasive alien species have become an increasing problem for the conservation of native plant communities and ecosystems worldwide. They can kill or displace desirable native species, reduce biodiversity, increase frequency of wild fires, and change ecosystem services, such as the production of timber or forage and storage of ground water. In the United States, classical biological control, the introduction of host specific natural enemies (parasitoids, herbivores or pathogens), has been used to control invasive plants in forests, grasslands and aquatic habitats, and to control invasive insects attacking desirable plants. This strategy can produce self-perpetuating reduction of the target pest with negligible nontarget impacts. Plant species successfully controlled in the United States include, musk thistle (*Carduus nutans*), diffuse knapweed (*Centaurea diffusa*), water hyacinth (*Eichhornia crassipes*), leafy spurge (*Euphorbia esula*), purple loosestrife (*Lythrum salicaria*), cajeput tree (*Melaleuca quinquenervia*), and saltcedar (*Tamarix* spp.). The European Biological Control Laboratory is conducting foreign exploration, genetic analysis and host specificity testing of prospective agents to control invasive plants, including giant reed (*Arundo donax*), yellow starthistle (*Centaurea solstitialis*), hoary cress (*Lepidium draba*), French broom (*Genista monspessulana*), medusahead rye (*Taeniatherum caput-medusae*), and North African wire grass (*Ventenata dubia*). Research is also being conducted to control invasive alien insects that attack native trees, including Asian longhorned beetle (*Anoplophora glabripennis*).

191 SPECIES, SPACES AND SCIENCE: BROADENING THE FLAGSHIP CONCEPT IN CONSERVATION MARKETING

Robert Smith

DICE, University of Kent

Douglas MACMILLAN, DICE, University of Kent ; Diogo VERÍSSIMO, David H. Smith Conservation Fellow, University of Georgia

Flagship species have been defined as “a species used as the focus of a broader conservation marketing campaign based on its possession of one or more traits that appeal to the target audience.” This concept is widely and successfully used in conservation to raise funds and awareness but the flagship species approach has been criticised for focusing on a narrow range of biodiversity, leaving many neglected species and ecosystems. Here we discuss several ways to overcome this criticism and argue that the flagship concept should be applied more broadly in conservation. First, we discuss the “Cinderella species” approach, which has been used to identify threatened species that are currently ignored by conservation fundraisers but have the potential to be effective flagships. Second, we discuss the role of “flagship fleets”, where several species are selected to appeal to different segments of the target audience. Finally we discuss how the flagship concept can be applied to conservation features other than species, using Conservation International’s biodiversity hotspots programme and the Zoological Society of London’s EDGE of Existence programme as case studies. We argue these two projects have successfully combined conservation science with marketing expertise to create flagships that cover a broader range of biodiversity.

134 USING MARXAN AND CLUZ TO GUIDE NEGOTIATIONS WITH CONSERVATION STAKEHOLDERS

Robert Smith

DICE, University of Kent

Rachel SYKES, DICE, University of Kent ; Bruno NHANCALE, Fauna and Flora International ; Kristian METCALFE, University of Exeter

Designing protected area systems and other conservation networks often involves working with a range of stakeholders representing different sectors and user groups. Systematic conservation planning was developed to make this stakeholder engagement more effective, as it defines explicit conservation goals at the beginning of the process and helps identify trade-offs and opportunities. Here we discuss four projects that illustrate the different ways in which stakeholder opinion can be incorporated into spatial conservation prioritisation. First, we introduce the Conservation Land-Use Zoning (CLUZ) plugin for QGIS that allows on-screen conservation planning so that stakeholders can investigate how modifying different options affects target attainment. Second, we discuss a case study from Southern Africa where we used Marxan to identify the broad location of a corridor between two protected areas, which was then refined using input from local farmers and fine-scale

land-use data. Third, we demonstrate a Marxan-based method for modifying the boundaries of existing protected areas to remove land that has been settled by people and replace it with land of similar conservation value elsewhere. Finally, we present a study from the Eastern English Channel that used Marxan with Zones to investigate the ecological and fisheries impacts of different combinations of no-take and limited-take marine protected areas.

LARGE-SCALE COMPLIANCE WITH SUGARCANE SUSTAINABILITY STANDARDS COULD RESULT IN MIXED CONSERVATION OUTCOMES

William K. Smith

Luc Hoffmann Institute[INSTITUTE]Institute on the Environment, University of Minnesota

Justin A. JOHNSON, Institute on the Environment, University of Minnesota ; Taro MIENO, Luc Hoffmann Institute[INSTITUTE] Institute on the Environment, University of Minnesota ; Erik NELSON, Bowdoin College ; James S. GERBER, Institute on the Environment, University of Minnesota ; Paul C. WEST, Institute on the Environment, University of Minnesota ; Steve POLASKY, Institute on the Environment, University of Minnesota ; Stefan SIEBERT, Institute of Crop Science and Resource Conservation, University of Bonn ; Eric F. LAMBIN, School of Earth Sciences and Woods Institute for the Environment, Stanford University ; Kate A. BRAUMAN, Institute on the Environment, University of Minnesota ; Kimberly M. CARLSON, Institute on the Environment, University of Minnesota ; Margaret ARBUTHNOT, World Wildlife Fund ; Derric N. PENNINGTON, World Wildlife Fund

Society faces the pressing challenge of meeting growing human demand for food, fuel, and other materials while sustaining critical environmental services and biodiversity. In an effort to address this challenge, the World Wildlife Fund and other global conservation and business entities have made significant strategic investments to develop and promote standards and certification for key agricultural commodities. However, the assumption that adoption of sustainability standards will result in conservation benefits has not been well tested at the large scale. Here, we address this knowledge gap by evaluating current sugarcane standards using spatially explicit global data on current extent, yield, and management practices. We combine these data with future scenarios of demand-driven increases in sugarcane production under various levels of compliance with standards. We find that large-scale certification has the potential to help close global yield gaps, while reducing greenhouse gas emissions, conserving biodiversity, and improving water availability and quality. Yet, we also identify critical shortcomings of current sugarcane standards, and highlight a number of potential improvements that could better conservation outcomes. This type of

global geospatial analysis serves as a general framework for evaluating and improving the potential conservation benefits of both existing and future certification programs.

OYSTER AQUACULTURE AND THE ENVIRONMENT: IS IT A WIN-WIN?

Ashley Smyth

Virginia Institute of Marine Science

Michael PIEHLER, UNC Institute of Marine Science ; Jonathan GRABOWSKI, Northeastern University ; Iris ANDERSON, Virginia Institute of Marine Science

Human activities have drastically altered the structure and function of coastal ecosystems. Increased nutrient inputs, especially nitrogen, have fueled eutrophication, with increased frequency of low oxygen events, fish kills and harmful algal blooms. Concomitantly, overharvesting has devastated fisheries. The combined effects of unsustainable fishing and pollution diminish resilience and threaten biodiversity. Moreover, the demand for a viable protein source continues to increase with global population expansion, resulting in a shift towards aquaculture. Conservation is often at odds with aquaculture, including Not-In-My-Backyard issues and specific concerns over carrying capacity, competition with natural habitats, nutrient dynamics and disease. Bivalve aquaculture provides a sustainable protein source while also having positive environmental impacts, including removing nutrients through enhanced denitrification, improving water clarity, and decreasing fishing pressure on wild stocks. However, at high bivalve densities, aquaculture can deplete resources for other species and contribute to poor sediment quality. As clear distinctions exist between the ecological role of oyster reefs and the various oyster culture methods, understanding whether and how the services provided by oyster reefs translate to culture methods is critical. Using eastern oyster (*Crassostrea virginica*) aquaculture as a case study, we will assess the matches and mismatches of maximizing aquaculture yield and environmental quality and will discuss key questions about the ecological effects of aquaculture to improve best management practices. Critical questions regarding the impact of aquaculture at the ecosystem scale require further attention to ensure practices provide a safe food source while sustaining ecosystem functions.

95 THE PROMISE AND REALITY OF USING GENETIC TECHNIQUES TO QUANTIFY THE IMPACTS OF LINEAR INFRASTRUCTURE AND EVALUATE THE EFFECTIVENESS OF MITIGATION

Kylie Soanes

Australian Research Centre for Urban Ecology

Michael A SAWAYA, Sinopah Wildlife Research Associates ; Niko BALKENHOL, Georg-August-Universität Göttingen

Roads, railways and other linear infrastructure can affect the movement and survival of wildlife, with negative consequences for gene flow and genetic diversity. Several reviews highlight the importance of these issues, yet genetic approaches are relatively underutilised in road ecology. Further, many researchers seem unaware of the power of genetic techniques to address 'non-genetic' road ecology questions. Here, we revisit the importance of conservation genetic approaches in road ecology research, discuss the latest advances in 'molecular road ecology', and introduce studies that apply these techniques to common road ecology questions. Individual-based approaches, simulation modelling, next generation sequencing and non-invasive genetic sampling have the potential to provide great insights to genetic and ecological road effects. For example, genetic approaches can be used to quantify barrier effect, identify 'unidentifiable' roadkill carcasses and estimate demographic parameters. Genetic approaches are particularly valuable when investigating the impacts of roads and wildlife crossing structures on animal movement and functional connectivity. We also discuss some of the perceived hurdles to using genetic approaches (e.g. cost, expertise, time constraints, scale) and suggest ways that they can be overcome. Finally, it is important to remember that while genetic techniques are powerful, they are not a cure-all. They are most informative when applied in the context of question-driven science, a robust study design (e.g. BACI) and sufficient replication. Further, combining genetic and non-genetic approaches will provide a more comprehensive understanding of the effects of linear infrastructure and mitigation on population viability. Our goal is to provide a realistic overview of the opportunities, challenges and requirements of genetic approaches in the hope that people will feel better prepared to include them in road ecology research.

CONFORMITY OF EUROPEAN AND NATIONAL CONSERVATION PRIORITIES: BIOGEOGRAPHIC ISSUES

Nikolay Sobolev

Institute of Geography, Russian Academy of Sciences

CBD Aichi target 11 requires establishing a coherent system of protected areas by 2020. European countries input to this target according to the Action Plan on the strategic development of the Pan-European Ecological Network (PEEN) for the period 2012-2020. The Emerald Network of Areas of Special Conservation Interest (including the Natura 2000 Network of the European Union) is considered as a set of Core Areas of the PEEN. The Calendar for the implementation of the Emerald Network of Areas of Special Conservation Interest

2011-2020 envisions the enlargement of the Network up to the expected space of the PEEN including the Far East of the Russian Federation and the Central Asia. This new challenge enhances the importance of a coherence between European and national conservation priority, especially between the list of species of European importance requiring territorial conservation measures and national and sub-national red lists of endangered and protected species. We have analysed the conformity of the mentioned European list and the red lists issued by the entities (administrative regions) of the Russian Federation. The studied index decreases from the western to the eastern part of Russia, as well as from the North to the South. Birds show the better average conformity, than other species groups, Mammals are the second, then – Amphibians and Reptiles, Pisces, Invertebrates, and Plants. We consider this to be the result of difference of a level of endemism in each groups. The endemism in its turn depends on the mobility of individuals (bionts) and on the size of the territories necessary for living population. We propose the set of biogeographic regions for developing the its-own priority list of species for the purposes of the Emerald Network and the PEEN establishment. If being correctly compiled, such a geographical based system of priority may be used for assessment of the expected level of ecosystem function by the share of really saved endangered species.

134 USING MARXAN TO AID IN MITIGATION PLANNING

Kei Sochi

The Nature Conservancy

Mike HEINER, The Nature Conservancy; Joseph KIESECKER, The Nature Conservancy

Designing protected area systems and other conservation networks often involves working with a range of stakeholders representing different sectors and user groups. Systematic conservation planning was developed to make this stakeholder engagement more effective, as it defines explicit conservation goals at the beginning of the process and helps identify trade-offs and opportunities. Here we discuss four projects that illustrate the different ways in which stakeholder opinion can be incorporated into spatial conservation prioritisation. First, we introduce the Conservation Land-Use Zoning (CLUZ) plugin for QGIS that allows on-screen conservation planning so that stakeholders can investigate how modifying different options affects target attainment. present a study from the Eastern English Channel that used Marxan with Zones to investigate the ecological and fisheries impacts of different combinations of no-take and limited-take marine protected areas.

WHAT WILL HAPPEN IF YOU DECLARE PROTECTION AND DO NOTHING? THE PAPER PARK EFFECT IN HPONKANRAZI WILDLIFE SANCTUARY, NORTH MYANMAR

Paing Soe

International Centre for Integrated Mountain Development (ICIMOD)

Rucha GHATE, International Centre for Integrated Mountain Development (ICIMOD); Pooja PATHAK, International Centre for Integrated Mountain Development (ICIMOD); Bandana SHAKYA, International Centre for Integrated Mountain Development (ICIMOD)

Many of the protected areas around the world and in Myanmar do not have adequate infrastructure or resources for management appropriate for the status of the protected area (Leverington et al. 2010; Rao et al. 2002). It is therefore important to study the realities of forest conservation in such a setting and the effect of protected areas where there is almost no actual protection despite their legal status of being a protected area. We studied the local residents' perceptions on the topic in Hponkanrazi Wildlife Sanctuary in north Myanmar as a rapid way to examine protected area effectiveness that can aid the management decision making process (Allendorf et al. 2012). We have found that local forest users, having known the declaration of protected area status for the area but not knowing when and how much they will be restricted from use of the forest, feel that they have to extract as much as they can while it is not prohibited. Villages that fall inside the protected area boundary also feel resentment towards people from outside of the area coming in for extraction because of the restrictions perceived to be unfairly placed on their land use, which villages outside the protected area do not have to abide by. Residents living inside the protected area boundary however, have expectations to be afforded forest use rights even after active management would begin. These perceptions, although they can be subjective, are important and of substantial relevance as they come from the people who use the forest themselves. Therefore, we contend from the findings that gazettement alone without following up with management action is likely to be counter-productive, and that giving forest use rights to local residents can foster protection activities by the local people to protect the forest areas under their management when the protected area management is under-staffed and under-resourced.

TRADE IN WILD ANIMALS (MOLLUSCAN, REPTILIAN AND AVIAN SPECIES) FOR TRADITIONAL AFRICAN MEDICINE IN OGUN STATE, NIGERIA

Durojaye Soewu

Osun State University

Opeyemi SOEWU, Osun State University; Bolanle AKINLEYE, Nigerian Conservation Foundation; Adams YUSUF, Osun State University

A steady rise in the patronage for Traditional African Medicine (TAM) has caused a corresponding increase in the demand for the ingredients used in the preparation of the trado-medicines. These ingredients are the various wild animals and plants parts, cropped from the wild. The attendant rise in demand for ingredients calls for a need to document the extent of utilisation of these natural resources as a measure of the impact of such trade on biodiversity conservation. This paper examined diversity of molluscan, reptilian and avian species traded for use in TAM; the quantity of each species traded over a period of time, and, seasonal fluctuations in abundance and utilisation of these species. A multi-stage stratified random sampling technique was employed. An open-ended questionnaire was administered on vendors in selected market stalls for six consecutive markets days in each of dry and rainy seasons. The study identified twenty-three species, 8 were listed in CITES and Nigerian Decree 11(1985). A total of 3196 (molluscan), 2527 (reptilian), 2894 (avian) carcasses were traded over an average period of twenty days. The mean number of carcasses traded per dealer per month in the two seasons were: Molluscs (24.0 ± 1.6); Reptiles (19.0 ± 1.9) and Aves (21.7 ± 2.3). Trade in, and utilisation of wild animal species in TAM had no consideration for conservation status, hence it involved species under various degree of conservation threats. There seems to be no implementation of regulation of trade in wild animal species, including those purportedly protected by Decree 11 (1985). A twin approach of increase in yield and decrease in demand is required to stem the negative impact of trade and utilisation on biodiversity. Massive conservation education and extension services for the entire populace, capacity building and involvement of indigenous communities in conservation projects are also urgently required.

WOOD DENSITY FOR FOREST CONSERVATION: TOWARDS IMPROVEMENT OF BIOMASS AND CARBON STOCKS IN TROPICAL REGIONS

Gaël Sola

Food and Agriculture Organization of the United Nations
Emily DONEGAN, Food and Agriculture Organization of the United Nations; Javier Garcia Perez GAMARRA, Food and Agriculture Organization of the United Nations; Luca BIRIGAZZI, Food and Agriculture Organization of the United Nations; Nicolas PICARD, COMIFAC; Laurent SAINT-ANDRÉ,

CIRAD, UMR Eco&Sols[INSTITUTE]INRA, UR BEF - Biogéochimie des Ecosystèmes Forestiers; Ghislain VIEILLEDENT, CIRAD, UPR BSEF; Tommaso CHITI, DIBAF, Università della Tuscia; Julian MURILLO, Food and Agriculture Organization of the United Nations; Matieu HENRY, Food and Agriculture Organization of the United Nations

The assessment of forest biomass has important consequences for climate-related policies, including conservation and activities related to deforestation and forest degradation. Tree and forest biomass are most efficiently assessed by a combination of remote-sensing, ground-based measurements and allometric models to predict tree and forest characteristics such as tree volume and biomass. The accuracy of these allometric models and therefore of biomass estimates can be improved greatly if wood density is used as an input variable. It is the most commonly used species functional trait in multispecies biomass models, which are frequently used in tropical ecosystems. However, wood density is difficult to measure accurately and thus is not included in large-scale forest inventories. This issue can be bypassed by using species average values, but often wood density values are only available at coarse taxonomic and/or spatial scales. Applying regional multi-species averages reintroduces to the models the potential bias originally removed by the use of wood density values. Therefore more wood density data is needed to cover the diversity of species and environments. This paper presents the work carried out to complement current initiatives aiming to collect, harmonize and share existing wood density data stored in national research institutes across the tropics. The database compiles raw data and calculated averages, with 70 information fields including GPS coordinates, measurement methods and sample size, when available, for a wide range of taxonomic and environmental values. Where precision in both taxonomic and environmental scales remains difficult to meet, the trade-off between the two can be better understood as the database includes both very accurate data and coarse averages. This database will improve forest biomass estimates, towards increasing the potential of climate change mitigation initiatives in the forestry sector.

HOW PERVASIVE IS BIOTIC HOMOGENIZATION IN HUMAN-MODIFIED TROPICAL FORESTS?

Ricardo Solar

Universidade Federal de Vicosa

Land-cover change and forest degradation in the tropics is leading to large-scale biotic homogenization (BH), or the simplification of regional biotas to a subset of generalist and resilient taxa. However, we still have poor understanding of how patterns of BH play out across different land-cover types, taxa and spatial scales. Here we analyse a multi-taxa tropical forest data set from the Brazilian Amazon, with 335 samples from 36 landscapes to assess how the species diversity of five taxonomic groups (plants, birds, ants, dung beetles and orchid bees) responds to land-cover changes at site, landscape and regional scales. We used multiplicative diversity partitioning and generalized linear models to examine how patterns of species loss at both site (α diversity) and landscape (γ diversity) scales change as a function of land-cover change; as well as how differences in species composition (β diversity) respond to land-cover changes at both scales. We also assess the contribution of nestedness and turnover in determining changes in assemblage composition within different land-cover types. While α diversity exhibited a steady decline with increasing land-cover intensification as expected, γ diversity was found to only decline in production areas. β diversity patterns were highly scale and land-cover dependent, with greater differences between species assemblages among forest vs. non-forest sites, while β diversity between landscapes remained high irrespective of land-cover type. At both site and landscape scales, the contribution of nestedness to β diversity, and hence the degree of biotic homogenization, increased with land-use intensification. Our finding highlights the importance of underlying environmental heterogeneity, spatially heterogeneous pressures, and stochastic processes in driving divergence in species composition across landscapes that have already been widely modified by humans. We discuss the role of effective conservation strategies on private land.

ENVIRONMENTAL AND BIODIVERSITY IMPACTS OF VARIABLE RETENTION FORESTRY IN TIERRA DEL FUEGO (ARGENTINA)

Rosina M. Soler

Centro Austral de Investigaciones Científicas (CADIC-CONICET).

Stefan Schindler, Environment Agency Austria ; Maria V. LENCINAS, Centro Austral de Investigaciones Científicas (CADIC-CONICET). ; Guillermo MARTÍNEZ PASTUR, Centro

Austral de Investigaciones Científicas (CADIC-CONICET). ; Pablo L. PERI, UNPA-INTA-CONICET

Variable retention (VR) harvesting was suggested to maintain postharvest continuity of structural and compositional diversity, and a series of studies for *Nothofagus pumilio* forests in Tierra del Fuego (Argentina) seem to confirm this suggestion. VR applied in *Nothofagus* forests combines two types of retention: aggregates of original forest (AR) and dispersed single trees (DR). This study assesses the assumption that VR maintains mature forest conditions after harvesting by synthesizing 605 individual results from two regions of Tierra del Fuego with permanent monitoring. VR effects on (i) microenvironment, (ii) forest structure, (iii) forest reproduction, and (iv) biodiversity were investigated. AR had no effect on microenvironmental variables and forest structure, but increased the values of forest reproduction. DR did not affect microclimate and forest reproduction, but negatively affected forest structure. Species richness and abundance of native plants were significantly increased in AR; in DR richness of native plants was increased while their abundance was slightly decreased. Alien plants significantly increased in both treatments, with particularly strong effects in DR. Insect richness and abundance were hardly affected by the treatments, whereas for birds, these indicators were significantly increased in AR and in DR. Species of *N. pumilio* forests maintained their populations only in AR, whereas species of neighboring environments were positively affected by DR. We conclude that the ecological conditions of *N. pumilio* forests are influenced by VR, but direction and magnitude of the effect depend on the treatment and the kind of variable. Inside aggregates several primary forest components and conditions were maintained. Due to the considerable increase of alien species and of such from associated environments, particularly in DR, VR has still significant ecological impact over the original forest characteristics.

156 - MODELING FRAMEWORKS FOR IDNA DATA ANALYSES

Rahel Sollmann

Zoo and Wildlife Research ; Thomas P. GILBERT, Natural History

Museum of Denmark

Invertebrate-parasite-derived, iDNA, has recently emerged as a powerful tool to detect vertebrate species, and has been discussed as a new non-invasive method to survey wildlife populations. But so far little attention has been given to whether and how iDNA-derived data can be combined

with state-of-the-art analytical tools to estimate wildlife demographic parameters and distributions. We discuss the challenges that face the application of existing analytical methods such as site-occupancy and spatial capture-recapture (SCR) models to iDNA, in particular, possible violations of key assumptions arising from factors intrinsic to invertebrate parasite biology. We focus on terrestrial leeches as a model iDNA source and their utility for occupancy and spatial capture-recapture modeling. The main source of uncertainty regarding target species detections from leech gut contents stems from uncertainty about the spatio-temporal sampling frame, since leeches retain host-blood for months and can move after feeding. This influences the spatial resolution of species detection data and consequently, the resolution of explanatory habitat covariates. It further complicates approximating a closed population (i.e., no losses or additions during the study) in spatial capture-recapture surveys. Lack of knowledge about leech feeding and habitat preferences, the inability to target a particular species with leech surveys, and the current lack of field experience to guide allocation of sampling effort can all complicate the implementation of efficient leech surveys. However, we conclude that with careful planning and under certain assumptions about leech movement, iDNA from leeches should be appropriate for occupancy models. On the other hand, the uncertainties associated with this method currently make SCR surveys unlikely. Future research should focus on resolving questions of leech feeding and movement ecology and blood retention, to try and resolve these outstanding uncertainties.

INFECTIOUS AGENTS SURVEY IN PIED TAMARINS SUBPOPULATIONS IN MANAUS, AMAZONAS STATE, BRAZIL.

Monica Solorio

Department of Preventive Veterinary Medicine and Animal Health, University of São Paulo

Marcelo GORDO, Federal University of Amazonas ; Wilson Roberto SPIRONELLO, National Institute of Amazonian Research (INPA) ; Luiz Edison DURIGON, Institute of Biomedical Sciences, University of São Paulo ; Angelica CAMPOS, Institute of Biomedical Sciences, University of São Paulo ; Luiz Gustavo GOES, Institute of Biomedical Sciences, University of São Paulo ; Simon ANTHONY, The Center for Infection and Immunity, Columbia University [INSTITUTE] EcoHealth Alliance ; Karin KIRCHGATTER, Institute of Tropical Medicine of São Paulo, University of São Paulo ; Lilian GUIMARÃES, Institute of Tropical Medicine of São Paulo, University of São Paulo ; Paulo BRANDÃO, Department of Preventive Veterinary Medicine and Animal Health, University of São Paulo ; Fernando FERREIRA,

Department of Preventive Veterinary Medicine and Animal Health, University of São Paulo

In past decades, numerous studies have highlighted how urban expansion, habitat fragmentation, deforestation, and superposition of human and wildlife population areas contribute to surges in emergent and reemergent diseases. As a result of continuing anthropogenic disturbance in the Amazon, wildlife populations find themselves increasingly exposed to human populations and their domestic animals, bringing higher risks of transmission of a variety of infectious agents. Manaus, located in the Brazilian Amazon, represents a potentially useful model to understand the mechanisms of disease transmission. The city has undergone a disorganized and precipitous growth with ongoing industrial development, causing constant landscape alteration. Because non-human primates are closely evolutionary related to humans they share a diversity of infectious agents. The present study proposes to use subpopulations of critically endangered Pied tamarins (*Saguinus bicolor*) occupying urban forest fragments in Manaus as a flagship species to evaluate the presence of infectious agents at the human-nonhuman primate interface. It will also assess whether anthropogenic perturbation at sites favors transmission of agents within this human dominated matrix. During the period of 2011-2014 a total of 49 pied tamarins in 9 urban forest fragments and 2 control areas. Molecular analyses were performed for the detection of Rotavirus, Hantavirus, Coronavirus, Flavivirus, Enterovirus, Influenza A, Adenovirus, Human Metapneumovirus, Human Respiratory Syncytial Virus, Parainfluenza Virus 1, 2, 3, 4, West Nile Virus and Plasmodium spp. The results indicate prevalence for Hantavirus (n =4), Rotavirus (n =9), and Plasmodium brasilianum (n =1). This is the first record of Hantavirus in neotropical primates. Data indicate that smaller fragments have proportionally higher prevalence rates, however small sample sizes did not allow formal statistical testing.

PARASITIC FLIES IN ARTIFICIAL RED-FOOTED FALCON'S NEST BOXES

Zoltán Soltész

MTA Centre for Ecological Research

The Red-footed Falcon (*Falco vespertinus* Linnaeus, 1766) is listed in the Red List of IUCN and is a strictly protected raptor species in Hungary. Followed by the eradication campaign in the 1980s against Rook (*Corvus frugilegus* Linnaeus, 1758), and consequent reduction in rook nest number, Red-footed Falcon population collapsed. Ornithologists installed more than 3000 artificial nest boxes in Hungary in order to increase the breeding populations. Actually there are more than 1000 breeding pairs in Hungary. Red-footed Falcon primarily uses crow or magpie nests for breeding, in nature these nests are

rebuilt in every year. The aim was to ascertain whether the material in the artificial nests accumulated over the years increase the number of parasitic, blood sucking flies. The study was performed in Northern Hungarian colonies during 2009 and 2010. Prior to 2009 the nest boxes were not cleaned for 3 years. After the youngsters left the artificial nest boxes the remaining nest material was collected. Nest material has been collected from 42 nest boxes in 2009 and from 17 nest boxes in 2010. The material has been stored in linen bags, and overwintered in a cellar. The hatching flies have been collected and preserved. Altogether 23,406 flies have been identified. 83% of the material (19,524 specimens) belonged to *Carnus hemapterus* Nitzsch, 1818. However, this fly was described from other *Falco* spp. hosts earlier, this is the first record from *F. vespertinus*. The number of *C. hemapterus* was one order of magnitude lower in 2010 than in 2009. These flies (the imagoes) suck the blood of especially the chicks. Therefore we suggest that artificial nest boxes are important in order to protect the species, but their annual cleaning is important. While the natural nests are rebuilt (consequently cleaned) in every year, without cleaning the number of the parasitic species increases during the accumulation of materials in the artificial nest boxes.

OCCUPANCY AND ABUNDANCE ESTIMATION IN THE PRESENCE OF DETECTION ERROR: WHAT CAN WE DO WITH A SINGLE SURVEY?

Peter Solymos

University of Alberta

Subhash R LELE, University of Alberta

Detection error is present in almost all ecological surveys. The method of replicate surveys, where one visits the same survey location multiple times, is one of the most commonly used methods to correct for detection error. Multiple-visits based methods to estimate occupancy and abundance suffer from various shortcomings: (1) the assumption of closed population is hard to satisfy in practice, (2) multiple-visits can be costly and logistically unfeasible, and (3) historical data often lack temporal replication. We show that if information on habitat covariates that affect occupancy/abundance and detection is collected, then one can estimate detection probability as well as occupancy/abundance parameters. This removes the need for replicate surveys. We discuss abundance estimation in N-mixture models and their extension to distance sampling situations where data might have been collected under many different survey protocols.

COMPARISON OF BUTTERFLY ASSEMBLAGES ON OLD-FIELDS AND NATURAL HABITATS IN KISKUNSAĞ REGION, CENTRAL HUNGARY

László Somay

Hungarian Academy of Sciences Centre for Ecological Research[INSTITUTE]Szent István University

Réka ÁDÁM, Hungarian Academy of Sciences Centre for Ecological Research[INSTITUTE]Eötvös Loránd University

Abandoned agricultural lands become more important in biodiversity conservation because of decrease of natural habitats. In our study we assessed the difference of butterfly assemblages between abandoned old-fields and natural habitat types. The study was carried out on KISKUN LTER field site network in Kiskunság sand forest-steppe region, Central Hungary. Old-fields were compared to locally most important butterfly habitats: sandy grasslands, forest edges and meadows. We studied 3 stands of 4 habitat types in 6 different landscape areas. Butterflies were counted and the amount of flowering nectar source plant species were estimated along 500 m long fixed transects at each sampling plot. The relationships between habitat types, flowering plant species and butterfly assemblages were explored by redundancy analysis (RDA). A total of 4418 individuals belonging to 44 species were observed in 4 visits between June and September. Butterfly species numbers were similar at each habitat types. The butterfly abundance was significantly higher on meadows, while in case of butterfly diversity only sandy grasslands had significantly lower value. Abundance of butterflies was strongly positively correlated with flower abundance, while butterfly species number with flowering plant species number. The butterfly assemblage of meadows differed from other habitat types which had similar species composition to each other. Using flowering plant species as explanatory variables, not only meadows, but old-fields and dry natural habitats (sandy grasslands and forest edges) had different species composition. On old-fields typically wide ranging, larger sized, bi- or multivoltine species occurred (e.g. *Vanessa cardui*, *Pontia daplidice edusa*, *Pieris rapae*, *Colias* spp., *Issoria lathonia*). Summarizing the results we can conclude that, although simple assemblage characteristics of old-fields did not differ from natural habitat types but their butterfly species composition was different.

126 BIODIVERSITY, GLOBAL CHANGE, AND SUSTAINABLE LAND MANAGEMENT: EXAMPLES FROM WESTERN AND CONTINENTAL AFRICA

Jan Henning Sommer

Center for Development Research (ZEF), University of Bonn
Lisa BIBER-FREUDENBERGER, Center for Development Research (ZEF), University of Bonn ; Siè Sylvestre DA, West African Science Service Center for Climate Change and Adapted Landuse (WASCAL) ; Nicholas MORET, Center for Development Research (ZEF), University of Bonn ; Katharina SABELLEK, TU Dresden,

European Project Center ; Wilhelm BARTHLOTT, Nees Institute for Biodiversity of Plants, University of Bonn

The maintenance of ecosystem functionality and ecosystem services is essential for human development. Hence, human wellbeing is closely connected to the wellbeing of ecosystems. Biodiversity facilitates provisioning, regulating and supporting ecosystem services at genetic, species-, and ecosystem level. Even though climate change represents a major challenge to the maintenance of global biodiversity and to human development, little is known about the magnitude and direction of its future impacts. This is a challenge for the set-up of appropriate mitigation and adaptation strategies. Given the comparatively high dependence of many agricultural production systems on climatic and environmental conditions in tropical and subtropical Africa, comprehensive land management strategies need to consider the status and dynamics of the biodiversity matrix in which they are embedded. This presentation spotlights distribution patterns of biodiversity across Africa, the actual status of habitats and their potential threat in order to derive vulnerability indicators and to identify trade-offs between biodiversity conservation and human land use claims. This is mandatory for the analysis of scale-crossing linkages of human-environment interactions and to evaluate the resilience of social-ecological systems under different development scenarios and under future climate change projections.

PARTICIPATORY MONITORING OF REINTRODUCED PRZEWALSKI'S HORSES IN KALAMAILI NATURE RESERVE, XINJIANG, CHINA

Melissa Songer

Smithsonian Conservation Biology Institute
Xeerxiati NULAZHI, Xinjiang Forestry Department ; Daniel RUBENSTEIN, Princeton University ; Peter LEIMGRUBER, Smithsonian Conservation Biology Institute ; Qing CAO, Smithsonian Conservation Biology Institute

Przewalski's horses (*Equus ferus przewalskii*) went extinct in the wild during the 1960s but have made a comeback through reintroduction projects in Mongolia and China. Based on these efforts, the species has recently been upgraded from Critically Endangered to Endangered on the IUCN Red List. Xinjiang Forestry Department initiated a project in 2001 to release captive horses to Kalamaili Nature Reserve (KNR) in Xinjiang, China. Currently there are approximately 100 individuals are released, but due to difficult winters and presence of livestock for winter grazing, most horses are enclosed and fed through winter. We are working together to find solutions through research and working with local Kazakh families to improve management and monitoring, with the goal of moving the population towards into year-round release and self-sufficiency. In 2012-13, SCBI conducted workshops among nearby Kazakh

communities to exchange ideas for a winter release, discuss means for involving the community, and find solutions that won't negatively impact people or wildlife. Partners agreed to a full winter release for several harem groups in 2013-14 at a new site, with a plan to establish a community scout program to train and hire local Kazakh herdsman to monitor horses through winter. We met with families to discuss concerns and identified 3 herdsman interested in becoming scouts. We collected data to evaluate the scout program along with socioeconomic interviews with over 70 households. We had mixed results but were able to identify methods for improving the scouting program. Results showed community involvement had positive impacts on the reintroduction project and that local conservation awareness was raised. We also gained insights for improving our overall management strategy for the reintroduction.

DESIGNING FOREST RESERVES NETWORKS USING SYSTEMATIC CONSERVATION PLANNING

Vincent Sonnay

N+p wildlife ecology

Jerome Pellet, N+p wildlife ecology

Public policies promote the designation of forest reserve networks that are set-aside from conventional forestry. Designing a network of old-growth woodland is a challenging task for forest managers trying to balance ecological benefits and economical/social costs over large spatial and temporal scales. We applied the systematic conservation planning (SCP) framework to the largest uninterrupted stand of forest on the Swiss Plateau in order to identify forest stands maximizing the biological potential for old-growth reserves, while minimizing the surface to 10% of the total area under scrutiny. Each planning unit was characterized by seven conservation features describing forest structure, composition, and function. The product of this approach is an irreplaceability value that is attributed to each planning unit, and reflects how important a given hectare is to achieving the conservation goals. Because identified hotspots are relatively small and disjoint, they do not allow for the emergence of large scale ecological processes. Larger high-value woodlands patches were selected, concentrated on core areas while expanding towards areas of lower irreplaceability, but allowing the appearance of large-scale ecological processes. The use of systematic conservation planning allowed for the emergence of a general spatial pattern (a heat map of irreplaceability values) and proved an efficient communication tool for community-wide workshops on the design of a forest reserve network.

STRUCTURE OF COCOA AGROFOREST IN WEST AND CENTRAL AFRICA: OVERVIEW

Denis Jean Sonwa

CIFOR (Center for International Forestry Research)
F. Weise WEISE, Bioversity International ; Go ¨tz SCHROTH, Rain Forest Alliance ; J. J. Janssen JANSSEN, Institute of Crop Science and Ressource Conservation (INRES: Institut fr Nutzpflanzenwissenschaften und Ressourcenschutz), Unit of Tropical Crops, University of Bonn ; Howard-Yana SHAPIRO, Mars, Incorporated

Cocoa agroforest had been gradually recognized as a space for forest biodiversity management and conservation. This recognition affects expectations from cocoa landscapes. While farmers see forest species associated with cocoa a way to diversify the list of farm products from their farms, conservation agencies see cocoa agroforests as a way to increase the network of biodiversity conservation areas. At the same time, the chocolate industry considers cocoa farms as an opportunity to free the acquisition of cocoa beans from deforestation. Several companies have expressed their will to be "deforestation" certified in one/two decades. The characteristic of a cocoa farm is one of the main parameters illustrating its sustainability. Research efforts have been more focused on identifying plant species that can be grown in association with cocoa but few studies have investigated the horizontal and vertical arrangement of cocoa and non-cocoa plants (mostly forest trees) that are grown together in the same field. The spatial organization of cocoa and non-cocoa is expected to improve the productivity of the cocoa farms as well as ecological services expected from cocoa orchard/agroforest. This paper reviews the: (a) the density of cocoa, (b) the density of associated plants, (c) the basal area, and (d) the space between components and stratification in 4 of the main cocoa producing countries of West and Central Africa (Cameroon, Nigeria, Ghana and Cote d'Ivoire) with the perspective of improving the product and services within cocoa landscapes.

COMPARING RESULTS FROM DUNG COUNTS AND CAMERA-TRAPPING TO ASSESS RED DEER POPULATION IN HYRCANIAN MOUNTAIN FORESTS, IRAN

Mahmood Soofi

August University Gttingen ; Matthias WALTERT, Workgroup on Endangered Species, J.F. Blumenbach Institute of Zoology and Anthropology, Georg-August University Gttingen

The elusive Caspian red deer (*Cervus elaphus maral*) lives at low densities in rugged forest habitats of the Caucasus and the South Caspian region and its declining population requires urgent attention. In order to establish a population monitoring plan, we applied dung counts (Fecal Standing Crop, FSC) from 18 two-km transects and accumulated 1,585 trap days of camera-trapping (Random Encounter Model, REM) to estimate deer numbers in the mountain forests (421.77 km²) of Golestan National Park, Iran. Decay rates were not habitat-specific; time to decay was $141.81 \pm SE 15.07$ days, being much shorter than in northern Europe. Estimated deer population size and density from FSC was lower (105 ± 15 individuals, 0.25 ± 0.07 ind/km²) than from REM (240 ± 25 individuals, 0.57 ± 0.19 ind/km²), but this difference was not statistically significant. Density estimates reached a stable level and were most precise at a sampling effort of 12 transects (FSC) and 300 camera trap-days (REM). Costs for both methods were almost identical when not taking into account the initial investment for camera traps. With regard to reliability, we discuss necessary improvements in assessments of the following variables: dung count (FSC method: line vs. strip approach, season), animal daily range and group size (REM method).

SPECIES PATTERNS IN SMALL FRESHWATER BODIES GUIDES TOWARDS FOCAL SPECIES APPROACH IN AQUATIC HABITAT RESTORATION

Elin Soomets

University of Tartu
Riinu RANNAP, University of Tartu

Small, isolated freshwater bodies are essential habitats supporting high regional biodiversity. In metapopulation conception, isolated waters as a part of sink-source systems are unique habitats for many species of amphibian and water macro-invertebrates. However, this type of waters are highly vulnerable by a number of human activities. To avoid habitat change from source to sink, habitat restoration and construction should be considered. Our aim was to detect species patterns in various types of restored and unrestored water-bodies to find out whether the habitat restoration targeted to focal species could support other species in conservation concern. We linked focal species approach, nestedness (NODF, PN) and co-occurrence (C-score) analysis and set of different type of water bodies with pond-breeding amphibians and threatened aquatic macro-invertebrates. *Triturus cristatus* and *Pelobates fuscus* were chosen as focal species, being among the most threatened amphibians in Estonia. We compared species co-occurrence patterns inter and intra: natural, man-made, and restored/constructed water

bodies. Nestedness pattern occurred in all studied water-body types. In natural and man-made waters it depended on site's area, while in constructed waters sun exposure and the age of water body raised the level of nestedness. In natural and constructed waters *T. cristatus* has obvious niche overlap with *Lissotriton vulgaris*, *Pelophylax lessonae*, *Rana arvalis*, *R. temporaria*, *Leucorrhinia albifrons* and *L. caudalis*, in constructed waters it co-occurred also with *P. fuscus* and *Leucorrhinia rubicunda*. In all types of waters *P. fuscus* shared the niche with *Pelophylax lessonae* and *Lissotriton vulgaris*. However, in constructed waters also *Triturus cristatus*, *Rana temporaria*, *Leucorrhinia pectoralis*, *L. caudalis*, *L. dubia* and *L. rubicunda* co-occurred. Our study demonstrated that habitat restoration targeted to focal species may offer quality habitats also for other co-occurring species.

99 - BOOSTING BIODIVERSITY AND CONTACT WITH NATURE THROUGH SOWN MEADOWS IN URBAN GREEN SPACES

Georgina Southon

The University of Sheffield

Nigel DUNNETT, The University of Sheffield ; Karl EVANS, The University of Sheffield ; Samuel GRICE, Cranfield University ; Helen HOYLE, The University of Sheffield ; Anna JORGENSEN, The University of Sheffield ; Briony NORTON, The University of Sheffield ; Paul RICHARDS, The University of Sheffield ; Philip WARREN, The University of Sheffield

Urban green space provides numerous and essential environmental benefits and is a vital resource for the promotion and awareness of biodiversity. However, the potential for urban green spaces to deliver these benefits is often under exploited, as many such green spaces are characterised by large expanses of mown amenity grass that fail to optimise biodiversity potential as well as being resource intensive. Our research aims to address this through a large scale biodiversity manipulation experiment in which we investigate how variations in the structural and species diversity of a sequence of sown meadow plots influences ecosystem services that include increased biodiversity, water infiltration, carbon sequestration and human wellbeing via perceptions of visual and aesthetic quality. Using a factorial design across two axes of variation we measure how manipulations to vegetation height and floristic diversity influences key soil processes and plant and invertebrate richness in addition to public responses to a range of aesthetic and biodiversity parameters including perceptions of beauty, attractiveness and naturalness. Given that standard nature conservation practice pays little regard to aesthetic considerations, this research is crucial in understanding how methods to increase biodiversity can be integrated into the urban system in a way that is acceptable and enjoyable to urban residents.

COST AND FEASIBILITY OF A BARRIER ZONE TO CONTAIN THE SPREAD OF CANE TOADS IN NORTH-WESTERN AUSTRALIA

Darren Southwell

University of Melbourne

Reid TINGLEY, University of Melbourne ; Michael BODE, University of Queensland ; Emily NICHOLSON, University of Melbourne ; Ben PHILLIPS, University of Melbourne

Cane toads (*Rhinella marina*) have spread rapidly throughout more than 1 million km² of Australia, causing population declines of many species of frog-eating predators. In arid Australia, cane toad spread depends critically on the arrangement of artificial water bodies (AWB) that have been created for pastoralism. One approach to containing the spread of cane toads is to create a 'waterless' barrier zone in the landscape by managing AWB's. However, an effective barrier zone requires a number of decisions regarding its location, size and shape in the landscape. In this study, we developed a predictive model of cane toad spread across arid regions of Australia to identify the most cost-effective location for a barrier zone. While developing our model, we actively engaged potential end-users to improve trust in its capabilities and increase the likelihood that it is adopted by decision-makers. Our modelling suggests that toads can be contained by managing less than 100 AWB's in an arid corridor of pastoral land between the Pilbara and Kimberly regions of north-western Australia. The optimal location for a barrier zone was sensitive to alternative management objectives, management actions, and assumptions about cane toad biology. Few conservation actions have successfully halted or slowed the spread of an invasive species at a comparable spatial scale. We demonstrate that a relatively small conservation investment could prevent toads from spreading into approximately 268,000 km² of their potential range, which would help secure numerous endemic and endangered predators that are vulnerable to the toads toxin.

MAIN FEATURES OF ILLEGAL TRADE IN ENDANGERED SPECIES WORLDWIDE

Lucrecia Souviron-Priego

Universidad de Malaga

Miguel Angel FARFÁN, Universidad de Malaga ; John. E FA, Imperial College London ; Juan Mario VARGAS, Universidad de Malaga

The illegal wildlife trade is one of the main threats to biodiversity, and monitoring this at a global level presents severe challenges. Therefore, any information that countries can offer is of great value to obtain a more accurate vision of the species and volume traded. In the present study, we collected data from the largest seizures occurring between

1996 and 2012, reported by 79 countries worldwide. We recorded species, type of merchandise, amount seized and conservation status of the species. We first determined the characteristics of illegal wildlife trade during the study period. Results show that there is no significant relationship between the number of countries reporting seizures and the number of species seized, which leads us to conclude that illegal trade of species is primarily linked to a few countries. More than half of the species seized (63%) are birds and reptiles, followed by mammals (22%). The remaining 15% consists of species from other groups. A total of 56% of live animals seized were reptiles, followed in descending order by fish (27%), birds (7%), other animal groups (7%) and mammals (3%). During the study period, we observed a significant increase in seizures of mammals, molluscs and fish. For birds the trend was descending. In the case of reptiles, no significant variations were found. During the period analyzed there was an increase in seizures of species classified in the three IUCN red list higher threat categories (vulnerable, endangered and critically endangered). This increase was significant in the case of mammals, for the three categories analyzed jointly and separately, reptiles, for the endangered category, and fish and shellfish, for the three categories together and for the endangered category.

4.03 PRIORITY AREAS FOR CONSERVATION OF ATLANTIC FOREST ENDEMIC BIRDS UNDER CLIMATE CHANGE SCENARIOS

Thiago Souza

Federal University of Rio de Janeiro

Renato CROUZEILLES, Federal University of Rio de Janeiro ;

Mariana Vale, Federal University of Rio de Janeiro

A key strategy in biodiversity conservation is the establishment of protected areas. Efficient protected areas are those able to, at least, represent the biodiversity of the region of interest. In the future, however, the redistribution of species due to global climate change is likely to affect species' representativeness in protected area networks. Here we assess the effectiveness of protected areas in representing 155 endemic birds of the Brazilian Atlantic Forest, a major biodiversity hotspot, both today and under climate change scenarios for 2050. The study combined species distribution modeling and systematic conservation planning. Species distribution models used the consensus between several algorithms and global circulation models, weighted by True Skill Statistics. The systematic conservation planning used municipalities as planning units, fixing those that currently have $\geq 50\%$ of its area covered by forest and/or within a protected area, and weighting species according to their IUCN conservation status. For the vast majority of the species, we predicted range reduction and southward shifts. We estimated an average range reduction of 29,500 km², with future ranges that were 53% of the original

range size. As a consequence, the regions of the Atlantic Forest that today have the highest species' richness were greatly reduced in future scenarios, except for small areas in the south. The systematic conservation planning created final solutions that included all species, selecting 321 municipalities today and 309 under climate change scenarios. Of these, 207 were selected both in the present and in the future. Very few of the selected municipalities, however, has protected areas. We conclude that the Atlantic Forest current protected areas network does not adequately protect its endemic birds, neither today nor in the future, and recommend some selected municipalities to be prioritized for the establishment of new protected areas.

BOTANICAL GARDEN OF SALVADOR: CONSERVING THE URBAN PLANT DIVERSITY

Luciano Souza Dos Santos

Jardim Botânico de Salvador

Maria Zélia Alencar OLIVEIRA, EBDA-CLA[INSTITUTE]Nea-Trilhas ; Eivaldo Pereira QUEIROZ, Prefeitura Municipal de Salvador - CMVS ; Lucineide Jesus TEIXEIRA, Jardim Botânico de Salvador

The conservation of urban forests is increasingly threatened by rapidly growth of Latin America cities, due to demand for housing, transportation and real estate overvaluation. Their environmental benefits are incontestable, especially for maintaining the forest genetic resources. In Salvador, a forest fragment located in the Botanical Garden of Salvador (BGS) has been resisting to serious threats. Even thus, this singular urban forest fragment presents good conservation state, sheltering endemic and endangered species, some rare and indicators of preserved areas. Being the biodiversity conservation one of its missions, BGS develops and supports projects focusing species conservation, particularly from the Bahia State's flora (Brazilian Atlantic Rainforest and Restinga vegetation). BGS seeks to integrate researchers from various institutions, university students and NGOs in order to participate in projects with the objective of knowing, mapping and analyzing the biodiversity, proposing alternatives and public policies to conservation. The priority tasks are focused on in situ conservation of forest species and ex situ conservation of Brazilian native species used by Afro-Brazilian population, besides controlling plant health and invasive species. Having a Research Section, the conservation investigation is addressed to the Plant Diversity Conservation Program (PDCP), aiming at conducting research to preserve the native species from the local flora, promoting the knowledge of regional plant resources and protecting the endangered species for maintenance and restoration of ecosystems. PDCP also includes the Floristic Survey of BGS Forest, restructuring of Seedling Nursery of Atlantic Rainforest Native Species, Conservation Education, as well as, study projects to be carried out such as: propagation of native tree

species; substrate assessment for development of native plant species; germination and growth of BGS forest's seedlings and recovery of degraded areas.

LARGE MAMMAL DIVERSITY IN THE PROVINCE OF KASTAMONU, TURKEY: CAMERA-TRAPPING FOR AN INTACT ASSEMBLAGE

Anil Soyumert

KASTAMONU UNIVERSITY, GAME AND WILDLIFE PROGRAM
Alper ERTURK, KASTAMONU UNIVERSITY, GAME AND WILDLIFE PROGRAM

Province of Kastamonu is situated at the central part of Black Sea Region of northern Anatolia and it is one of the largest provinces in Turkey with 13108 km² land area, stretching between coast line and mountains with a peak at 2565 m. The mountainous and forest habitats cover 74.6% of Kastamonu including old-growth forest habitat types, and there are four wildlife reserves and one national park in the province. This diversity in habitat types leads to high biodiversity and the region hosts an intact large mammal community. Camera-trapping studies are being conducted since 2009 in Kastamonu in eight different study areas including protected and unprotected areas with 105 systematic cam-trap stations in total; and large carnivores and herbivores such as brown bear (*Ursus arctos*), grey wolf (*Canis lupus*), Eurasian lynx (*Lynx lynx*), wild cat (*Felis silvestris*), golden jackal (*Canis aureus*), red deer (*Cervus elaphus*), wild boar (*Sus scrofa*) and European roe deer (*Capreolus capreolus*) are being monitored. The distribution, relative abundance and activity patterns of the target species are determined with concrete data based on camera-trap records and assessments on protected areas were evaluated in accordance with the results of the study to lead more effective conservation efforts in the region. The study reveals the importance of the province of Kastamonu for the large mammals but the high rate of poaching in the region is detected as a major threat especially on brown bear, grey wolf, red deer and roe deer.

ACCESSING THE EFFECTIVENESS OF LANDSCAPE MANAGEMENT PRACTICES FOR A LANDSCAPE SPECIES: ARE CORE AREAS WORKING TO PROTECT SAGE-GROUSE?

Emma Spence

Bowling Green State University
Jeffrey BECK, University of Wyoming ; Andrew GREGORY, Bowling Green State University

Greater sage-grouse (*Centrocercus urophasianus*) are a species of conservation concern in 11 western states and 2 Canadian provinces, and have been in decline for 50 years. Sage-grouse have been petitioned for listing under the Endangered

Species Act 7 times; the 8th listing is currently being reviewed. Wyoming contains ~40% of the extant sage-grouse population, and is located at the center of the distribution of this species. These factors and concern for ESA listing of sage-grouse, the state of Wyoming designated and limited human disturbance in "core areas" in 2008. Using Wyoming Game and Fish Department male sage-grouse lek count data and oil and gas development data from the Wyoming Oil and Gas Conservation Commission, we investigated the effectiveness of core areas on sage-grouse persistence. In 2013, core areas contained 77% of the Wyoming sage-grouse male population and 64% of active leks. Using a Bayesian binomial probability analysis, we analyzed the conditional probability of leks going extinct in and out of core areas pre and post core area development. We observed a 10.9% probability of a lek going extinct in core areas and a 20.4% probability going extinct outside core areas. When we regressed the difference in conditional probability of non-core and core lek extinction versus oil and gas development density within 1.6 and 4.8 km of the core area boundary we found the difference in extinction probabilities was correlated to oil and gas development density within 1.6 km of the core area ($R^2 = 0.83, p = 0.01$). Development density inside the core areas was not related to the probability of extinction in core areas ($R^2 = 0.04, p = 0.82$). Collectively these data show that the core area strategy is likely working; however, development outside of core areas effects populations inside core areas. Consequently, additional guidelines to limit development densities in regions adjacent to core areas may also be necessary to effectively protect core area populations.

68 RESPONSE OF FOREST BIODIVERSITY TO PARTIAL RETENTION HARVEST IN A BOREAL MIXEDWOOD FOREST: HOW TO MANAGE IT?

John Spence

University of Alberta
Jaime PINZON, University of Alberta ; Colin BERGERON, University of Alberta ; Sonya ODSSEN, University of Alberta ; Linhao WU, University of Alberta ; David LANGOR, Natural Resources Canada (CFS)

Results of the large-scale (1000 ha) EMEND experiment in northwestern Alberta show that forest biodiversity is recovering more quickly toward pre-harvest condition after partial retention harvest than after traditional clear-cuts in four commercially exploited mixedwood cover-types. Both initial impact on and recovery of plant, invertebrate and songbird communities varies with harvest intensity in a way consistent with the view that partial harvest approaches better meet the sustainability criterion of conserving biodiversity than do traditional clear-cuts. Interestingly, assemblages of songbirds and epigeic invertebrates appear to recover more rapidly than do those of understory plants. The current approach to

'extensive forest management' in Alberta that incorporates consideration of ecosystem criteria in addition to those focused on sustained yield promises improved conservation of stand-level biodiversity. Effective forest management will link stand-level treatments in a way that promotes fully integrated landscapes. An understanding of relationships between forest ecosites and biodiversity that is rooted in knowledge about historical forest development can assist in up-scaling biodiversity conservation from stands to forests and establishing landscape level conservation goals.

SYM ID 88: MOVING BEYOND CURVE-FITTING: USING COMPLEMENTARY DATA TO ASSESS ALTERNATIVE EXPLANATIONS FOR LONG MOVEMENTS

Orr Spiegel

University of California Davis

Roi HAREL, The Hebrew University of Jerusalem ; Alejandro CENTENO-CUADROS, The Hebrew University of Jerusalem ; Ohad HATZOFE, The Israeli nature protection authority ; Wayne M. GETZ, University of California, Berkeley ; Ran NATHAN, The Hebrew University of Jerusalem

Management often includes supplementary release of captive-raised (naïve) individuals. In contrast to re-introduction of a (locally) extinct species, this scenario facilitates the establishment of naïve individuals through their ability to interact or follow wild individuals. Hence, the movements of wild individuals during releases inform managers on the population's space-use and provide a template for comparing with introduced individuals' movements. The Eurasian Griffon vulture (*Gyps fulvus*) is declining in the eastern Mediterranean despite intensive management efforts. Here we describe the movement of wild-individuals and explore possible explanations for a distinct pattern of long-range movements that may shed light on lack of management success in this region. We tracked adult vultures caught in southern Israel using high-resolution GPS/accelerometer tags accompanied by behavioral, genetic and morphological data. Curve fitting of mixed models suggests vultures combined distinct movement modes operating at three different scales. The larger spatial scale was partly a result of long-range forays – rare, short-term, large-scale circular journeys that greatly exceed the typical foraging range of this species. We rejected optimal foraging as an explanation for these forays and found no support for preferred weather conditions or population genetic structure as alternative explanations. The hypothesis that these forays represent failed breeding dispersal attempts to find mates remains our most plausible explanation. We conclude that 1) inference about the mechanisms underlying animal movement should be confronted with complementary data, and suggest that mixed behavioral-modes likely explain commonly

observed fat-tailed movement distributions. 2) Conservation of species with large home-ranges should consider the suitability of local management and strive to obtain international collaborations for achieving the relevant spatial scale for these species

ARE THEY FRIENDS OR JUST NEIGHBORS? A BETTER USE OF SOCIAL NETWORKS IN CONSERVATION THROUGH SEPARATION OF SOCIAL PREFERENCE FROM ENVIRONMENTAL CONSTRAINTS

Orr Spiegel

University of California Davis

Stephan, T. LEU, Flinders University ; C. Michael BULL, Flinders University ; Andrew SIH, University of California Davis

Understanding how animals interact with their natural and social environment is a major question in behavioral ecology with implications for conservation. Social networks (SNs) are commonly used to study sociality and disease spread in free-ranging animals. However, observed proximity-based SNs may also reflect constraints imposed by environmental heterogeneity. For instance, two individuals can co-occur due to conspecific attraction or simply since they share clumped/ephemeral resources. Despite recent advances in SNs randomization procedures, less attention has been devoted to teasing apart these two effects. Here we suggest a new method that takes environmental constraints into account, and show how this can modify previous conclusions on sociability of free ranging animals. We constructed SN for a population of Sleepy lizards (*Tiliqua rugosa*), a large-bodied pair-living Australian skink. Simultaneous GPS-tracking of 60 individuals (30 males) at 10 min interval for the entire activity season allows identification of almost all social interactions in this population. We compared observed SN-properties (e.g. lizard's degrees or strength) with those obtained from SNs generated from randomized paths. By using existing movement data to generate a more realistic null model we could identify the distinct contributions of sociability and spatial environmental constraints. In contrast to previous finding using null models that ignore such constraints (e.g., ideal gas), our results shows that male lizards interact more than expected by chance. Our results suggest that better consideration of environmental constraints is important when testing ecological hypotheses about sociability. Building a better mechanistic understanding of animal behavior will help to inform species-conservation plans. The proposed method can be broadly applied to proximity-based SN studies (e.g., from GPS tracking) in various species.

THE SWISS BREEDING BIRD ATLAS 2013-2016

Martin Spiess

Swiss Ornithological Institute

Peter KNAUS, *Swiss Ornithological Institute*; Hans SCHMID, *Swiss Ornithological Institute*; Sylvain ANTONIAZZA, *Swiss Ornithological Institute*; Samuel WECHSLER, *Swiss Ornithological Institute*; Jérôme GUÉLAT, *Swiss Ornithological Institute*; Marc KÉRY, *Swiss Ornithological Institute*; Thomas SATTLER, *Swiss Ornithological Institute*

In Switzerland, two national breeding bird atlases have been published. The first one covered the period 1972–1976 (Schifferli et al. 1980), the second one the period 1993–1996 (Schmid et al. 1998). Fieldwork for the new, third atlas started in 2013 and will last up to 2016. Because many species had suffered massive declines already before the 1970s, a historic atlas additionally documents the distribution of the breeding birds in the 1950s (Knaus et al. 2011). The bird census methods for the new atlas are in general similar to the last atlas 1993–1996. The grid is the same (467 atlas squares of 10 × 10 km), and simplified territory mapping in 5 squares of 1 × 1 km per atlas square delivers the data set for density calculations. The voluntary collaborators are instructed with extensive information available online. The online portal www.ornitho.ch plays a key role in data transmission. Also the analyses of the simplified territory mapping are carried out online. The final data will allow comparisons with the two previous atlases and for 100 species also with the Historic Breeding Bird Atlas. First results show dramatic changes in both the distribution and density of some species. While many species in the agricultural zone or long-distance migrants got extinct or experienced serious declines, other species appeared newly in Switzerland or have increased, especially water birds. Differences in the altitudinal distribution since 1993–1996 allow the estimation of the effects of climate and habitat change. Finally, the new atlas will allow improved estimates of the population size of all breeding birds in Switzerland. The data of the Swiss Breeding Bird Atlas 2013–2016 will of course also be available for the new European Breeding Bird Atlas.

DIFFERENTIAL EFFECTS OF FOREST PROXIMITY ON FRUIT SET OF TROPICAL TREE CROPS DEPENDS ON POLLINATION GUILDS

Tuanjit Sritongchuay

Prince of Songkla University

Claire KREMEN, *University of California*; Sara BUMRUNGSRI, *Prince of Songkla University*

Deforestation and forest fragmentation are leading to declines in crop pollinators. To date, studies have focused on the reproductive success and pollination ecology of single crop species in given locations. However, comparing the effect of distance to forest on multiple crop species is important because this distance may have different impacts on different group of pollinators, such as for example, insects versus bats, differentially affecting pollination services. We

evaluated flower-visiting animal diversity, visitation frequency and number of fruits set in three species of economic crops: rambutan, durian, and mango, near (<1 km.) and far (>7 km.) from forest edge. The number of fruits set in rambutan was significantly affected by distance to forest, while distance to forest played no role for number of fruits set in durian and mango. The main flower visitors of rambutan were stingless bees. The dominant flower visitor to durian and mango were fruit bats and flies, respectively. The effect of proximity to forest on pollination success varied between plant species which depend on the visiting animal group. This study provides empirical evidence that not only forest but also caves can act as a source of flower-visiting agents that provide pollination services to agricultural crops, and underscore the importance of tropical rainforest and cave conservation for maintaining such services.

DUNG ENCOUNTERS AND PHOTO-CAPTURES SHOW SIMILAR SPACE-USE PATTERNS BY MOUNTAIN UNGULATES IN THE HIMALAYA

Tanushree Srivastava

National Centre for Biological Sciences and Centre for Wildlife Studies

Ajith KUMAR, *National Centre for Biological Sciences and Centre for Wildlife Studies*

The use of dung encounters as an indicator of space use by ungulates has been highly debatable due to differences in species-specific defecation rates and dung decay rates. In this study we used dung encounter rates and camera trap photo-capture rates to examine variation in the use of four elevation zones by three mountain ungulates: Himalayan musk deer (*Moschus chrysogaster*), Himalayan goral (*Naemorhedus goral*) and Himalayan serow (*Capricornis thar*). The study was carried out in Kyongnosla Alpine Sanctuary situated in East district of Sikkim, India. We laid 16 permanent trails, each 600 m long, between 3000 m and 4200 m elevation to estimate dung encounter rates. One camera station was established at each of these trails. Each trail was monitored once every month, thus generating continuous data for winter when temperature went down to -15°C and post winter when temperature went up to 19°C. We walked a total distance of 108.00 km and camera trapped for 2219 nights in all. Goral had the highest mean dung encounter rate (dung groups/km) (1.27±0.28) followed by musk deer (1.07±0.19) and serow (0.13±0.06). Mean photo-capture rate (number of photographs/100 days) was the highest for musk deer (5.60 ± 0.90) followed by goral (1.96 ± 0.44) and serow (1.45 ± 0.59). Both dung encounter rates and photo-capture rates were significantly different at different elevation zones. Though the mean values for the dung encounter rates were lower than that of photo-capture rates of the three ungulates at different elevation zones, the overall patterns exhibited by the two indices along the elevation

gradient were almost similar. The space-use patterns from the two indices were similar in two different seasons. Our study, therefore suggests that camera trap and dung encounter surveys can be reliably used to assess space use of ungulates inhabiting such mid-elevation gradients.

HABITAT USE BY MOUNTAIN UNGULATES IN A SUBALPINE HABITAT IN SIKKIM HIMALAYA, INDIA

Tanushree Srivastava

National Centre for Biological Sciences and Centre for Wildlife Studies

Ajith KUMAR, National Centre for Biological Sciences and Centre for Wildlife Studies

Habitat use and factors affecting the same were studied in three mountain ungulates viz. Himalayan musk deer (*Moschus chrysogaster*), Himalayan goral (*Naemorhedus goral*) and Himalayan serow (*Capricornis thar*) inhabiting a subalpine habitat of Sikkim Himalaya, India between April 2011 and March 2012. Permanent trails (16) between 3000 m and 4200 m elevation were repeatedly sampled to estimate dung encounter rates and photo-capture rates as indicators of habitat use. The trails were sampled in winter when temperature went down to - 15°C and post winter when temperature went up to 19°C. Both photo-capture and dung encounter rates showed musk deer and serow to be distributed all along the elevation gradient with goral mostly restricted till 3600 m. Both dung encounter and photo-capture rates increased for musk deer and decreased for goral and serow along the elevation gradient, thus authenticating unimodal distribution patterns of the species. Zero-inflated Poisson regression was used to identify key factors affecting the habitat use patterns of the ungulates. Elevation was found to be the most important factor in determining the habitat use patterns of both musk deer (positively) and goral (negatively) with season having significant effects on habitat use of serow. Musk deer showed strong associations with steeper south-east and south-west facing slopes. However, habitat use of goral and serow was not affected by slope and aspect. Quantile regression showed goral photo-capture rates to be negatively affected by dogs at their highest abundances. The study further authenticates elevation, slope and aspect to be critical in determining ungulate habitat use patterns inhabiting these subalpine habitats. Moreover, the study suggests that these mid-elevation ungulates may not be affected by season to the extent as reported in species occupying much higher elevation areas, which are known to exhibit strong seasonal shifts.

TOLERATING TIGERS: UNDERSTANDING HUMAN BEHAVIOUR TOWARDS TIGERS AND OTHER WILDLIFE IN SUMATRA

Freya St John

DICE, University of Kent

Jeanne MCKAY, Fauna & Flora International ; Matthew LINKIE, Fauna & Flora International ; Erlinda KARTIKA, Fauna & Flora International ; Ika AGUSTIN, Fauna & Flora International ; Betty MILLYANAWATI, Fauna & Flora International ; Yulian ANGGRIAWAN, Fauna & Flora International ; Matthew STRUEBIG, DICE, University of Kent

People come into greater contact with wildlife as rural populations grow. At worst, where animals are perceived to threaten human lives or livelihoods, they may be killed. Such a response poses a threat to wide-ranging species such as large and potentially dangerous carnivores. However, local opinions and behaviour towards carnivores can vary radically within and across human societies and landscapes. Further, behaviour towards different types of wildlife also varies. Tigers have undergone abrupt declines across much of their former range as a result of retribution killings and an unsustainable increase in poaching driven largely by demand for body parts. Increased persecution is frequently observed where local tolerance for carnivores has declined, a situation exploited by poachers. However, whilst poaching has caused dramatic declines of tigers elsewhere in Asia, against a backdrop of ongoing encounters, Sumatran people continue to coexist with tigers. In order to understand an apparent tolerance for living with tigers, we draw on theories of human behaviour to investigate underlying social psychological characteristics associated with tolerance (no intention to kill), or intolerance (intention to kill), for tigers and other species found within the Kerinci Seblat landscape, Indonesia. We estimate the prevalence of illegal hunting using multiple configurations of the randomized response technique, a method developed specifically for investigating sensitive topics. Preliminary analysis reveals the importance of exploring the role of attitudes, injunctive and descriptive norms, and affect/emotion in determining people's behaviour towards wildlife. Moreover, behavioural beliefs and intentions are not homogenous across species. This study highlights the interacting effects of internal and external factors influencing human decision making.

AN ALLELOPATHIC STUDY OF THE HAYSCENTED FERN

Madison Stahr

Clarion University of Pennsylvania

Suzanne BOYDEN, Clarion University of Pennsylvania

In Pennsylvania, forest ecosystems can be found in any direction. These areas are a wealth of nature; they provide habitat for local wildlife, serve as natural air and water filtration systems, and are a great source of timber. However, the forests are suffering from the over herbivory of deer, and the aftermath it has caused. As deer are selective browsers, they are capable of picking and choosing their food source. Many young tree

seedlings are eaten until almost all individuals of the younger cohorts are gone, while plant species that the deer do not eat, particularly the hayscented fern or *Dennstaedtia punctilobula*, remain to flourish and can even begin to act as native invasive species. As the hayscented fern has been shown to be allelopathic towards other fern species, the question remains as to whether or not the fern is allelopathic towards tree species. Allelopathy works in one of three ways; exuding chemicals through the roots, exuding chemicals through decaying leaf litter, and exuding chemical vapors during photosynthesis. One of the main goals of this study is to determine whether the hayscented fern uses allelopathy to suppress its competitors, and if so by which of the three ways. The second goal is to determine if the fern is simply preventing seed germination or is actually inhibiting growth of established plants, both leading to the mortality of the plant. To test this, seeds and seedlings of up to four different tree species will be divided into groups, and each group given a treatment to replicate a different form of allelopathy. Seed germination and the seedling growth will be measured over a maximum of a 3 month period to determine if any of the fern treatments have a negative effect. It is my hypothesis that the fern will only use one mode of allelopathy that effects either the seeds or the seedlings, but not both.

EMERGING THREATS TO URBAN ECOSYSTEMS

Margaret Stanley

University of Auckland

Jacqueline BEGGS, University of Auckland ; Imogen BASSETT, Auckland Council ; Bruce BURNS, University of Auckland ; Kim DIRKS, University of Auckland ; Darryl JONES, Griffith University ; Wayne LINKLATER, Victoria University ; Cate MACINNIS-NG, University of Auckland ; Robyn SIMCOCK, Landcare Research ; Gayle SOUTER-BROWN, Greenstone Design Ltd ; Sam TROWSDALE, University of Auckland ; Kevin GASTON, University of Exeter

Urbanisation is rapidly increasing, with more than half the world's population living in towns and cities. The UN predicts that by 2050, 86% of the developed world will be urbanised, resulting in increasing pressures on urban ecosystems and biodiversity. Far from being depauperate, the unique diversity of habitat structures in cities supports a wide variety of biodiversity, often the only connection with nature experienced by much of the world's population. While existing threats to urban ecosystems (e.g. building intensification) are being exacerbated by globalisation and climate change, there are a number of emerging threats that are likely to be drivers of change in urban ecosystems. A multidisciplinary team of scientists, encompassing ecology, ecophysiology, soil science, hydrology, landscape design, environmental physics and human epidemiology, undertook a horizon scan of emerging issues (not well known or well understood) in urban environments. Early identification of such issues is important

in order to commence research that can inform policy and management. We consulted widely (scientists, government, NGOs) to encompass a range of views and ideas in a long list, before ranking and reducing the list in an iterative process during a 3-day workshop. Ten emerging threats were identified and they were most commonly associated with rapid advances in technology (e.g. solar panels, LED light, self-healing concrete) or with the demands of people on urban nature (e.g. green prescriptions). We anticipate this horizon scan will be of interest to policy makers and researchers looking to mitigate threats to urban ecosystems.

159 THE NEW NATURE IN EUROPE: WHAT IS IT?

Mark Stanley Price

WildCRU

Considering landscapes, 'wilderness' and 'wild' in Europe, it is easy to be trapped in the tension between perception and reality. Our perception is that green landscapes are natural and wildlife habitats. The reality is that very few of Europe's landscapes are not highly modified by human activities, and intensely farmed areas are green deserts for wildlife. Species have demonstrably shifted their ranges since the end of the Ice Age, and we can now observe species on the move. Climate change is only starting, with the prospect of new species' ranges, new communities of species assemblages, and even novel ecosystems. Conservation needs to respond with clarity on what it wants for Nature, and what is acceptable. Redford et al (2011) define six attributes of successfully conserved vertebrate species and five stages of their conservation, ranging from captivity to self-sustaining without specifying where such successful conservation takes place. IUCN (2013) permits conservation introductions outside indigenous range provided there is a conservation benefit. On the other hand, the Red List definition of Extinct in Wild uses the term historic range, and populations outside this range are not considered as contributing to a Red List assessment. Given the realities of more species either naturally extending their range, shifting them or even jumping into new areas, with the further appearance of hitherto non-native species, we must accept the reality, the consequences and risks inherent in such situations. So, we have to decide what we want for Nature in Europe: do we prefer to see species go extinct in their ranges as we knew them, or would we prefer to see them persist, albeit in different ranges, probably managed with only some attributes of 'wild' and self-sustaining? Should our position be 'pragmatic but prudent'?

PROTECT YOUR LOCAL SPECIES: THE POTENTIAL OF ZOOS IN THE CONSERVATION OF EUROPE'S THREATENED SPECIES

Johanna Stärk

Max-Planck Odense Center on the Biodemography of Aging, University of Southern Denmark

Dalia CONDE, Max-Planck Odense Center on the Biodemography of Aging, University of Southern Denmark

Zoos play an important role in species conservation, mainly through public education and by providing funding to protect species in their natural habitat and in captivity. However, given that most threatened species are located along the equator, European threatened species might not be a major priority for conservation programs in European zoos. The conservation of European species is important though, in raising public awareness that extinction is not only an abstract global process but can be observed on a very local scale. In this sense, it is important to know to what extent local threatened species are already represented in European zoos. Therefore, we accounted the number of European threatened species represented in European zoos using data from the International Species Information System (ISIS), the European IUCN Red List of threatened species and other risk indices. Our results show that 23% of European threatened vertebrates are represented in European zoos (birds excluded). Most European species held in captivity are mammals (35%), with lower numbers for reptiles and amphibians (15% and 9%). Most species listed at highest-risk are not represented in any zoo. With this study we aim to raise awareness on the conservation of local species and the role that zoos can play protecting these species. The results can be used to inform future prioritization efforts in zoo collection planning and European conservation programs.

UNDERSTANDING PARTNERSHIPS FOR DELIVERING CONSERVATION OUTCOMES: HOW AND WHY DO CORPORATIONS AND NGOS COLLABORATE?

Janna Elizabeth Steadman

Durrell Institute of Conservation and Ecology, University of Kent

Paul, R. ARMSWORTH, Department of Ecology and Evolution, University of Tennessee ; Martin DALLIMER, School of Earth and Environment, University of Leeds ; Sue HORNIBROOK, Kent Business School, University of Kent ; Freya, A, V ST JOHN, Durrell Institute of Conservation and Ecology, University of Kent ; Zoe, G. DAVIES, Durrell Institute of Conservation and Ecology, University of Kent

Environmental issues are typically too large for a single organisation to tackle independently, thus partnerships between different sector organisations, such as conservation NGOs and corporations, are beginning to proliferate. Little

research has been conducted on this topic from a conservation perspective, with many assumptions about partnerships being based on anecdotal rather than empirical evidence. This research therefore aimed to provide valuable baseline information on the prevalence of conservation NGO-corporate interactions, as well as highlighting the key motivations which underpin partnership initiation. These objectives were assessed using two structured quantitative questionnaires, one being administered to UK-based conservation NGOs and the other to FTSE350 listed corporations. The results illustrate that while philanthropic donations are a prominent form of interaction, other types of activities are regularly engaged in such as terrestrial ecosystem restoration, educational activities and stakeholder outreach programmes. For corporations, drivers of partnership initiation are centred on reputational benefits by association, whereas conservation NGOs are motivated by access to financial resources. Our findings represent a first step in providing a basis for informing more effective relationships between NGOs and corporations in the future which should, in turn, deliver better conservation outcomes. This is important, as these types of interactions are currently not standardised, unmonitored and poorly understood.

ENERGETICS AND THE LIMITS OF RARITY

Philip Andrew Stephens

Durham University

Marcus V. VIEIRA, Universidade Federal do Rio de Janeiro ; Chris CARBONE, Institute of Zoology

The limits to population viability have long been of interest to conservation biologists. Two particular areas of research, Allee effects and Minimum Viable Populations, might have been expected to cast light on the subject; however, they have yet to expose generally applicable explanations for where the limits to viability might lie. An alternative approach to the problem is via macroecology, where considerable attention has been given to documenting relationships between population density and body mass. Typically, density-mass relationships appear to exhibit a reasonably clear lower bound. At present, however, we have "only the haziest notion" (Lawton 1990) about the lower limits to abundance, how they are determined and how they scale with body size. Here, we ask whether simple energetic models can shed light on this question. We focus on terrestrial Carnivora, using published allometries for energetic expenditure and resource acquisition to predict the scaling of minimum viable resource densities. We discuss how to infer carnivore population densities that might be supported at these limits to resource availability. With reference to extensive data on carnivore densities, our results suggest that carnivore populations might often persist at levels of resource availability close to their energetic limits. This has implications for our understanding of time and energy budgets in wild animals, and major drivers of extinction.

CONSERVING ASIAN ELEPHANT'S POST-MORTEM - A REVIEW OF AGE DETERMINANT TECHNIQUES ASSESSING THE USE OF DENTITION, SKULL MORPHOLOGY AND CRANIAL SUTURE SCHEDULING.

Eloise Stephenson

Royal Veterinary College of London

*Ayona SILVA-FLETCHER, Royal Veterinary College of London ;
Michael WATERS, Royal Veterinary College of London*

Modelling mortality events for endangered species can be a useful tool to assess and direct conservation initiatives. The ability to model such events is limited by methods to age skeletal remains. Despite a lack of validation Laws Scale, reliant on categorising teeth in wear, is the primary method used for Asian elephants. Originally developed for African elephants, Laws Scale is not reliable for Asian elephants. This study aimed to apply Laws Scale to 24 Asian elephant skulls of unknown age, to identify areas of discrepancy and review the use of two additional techniques, skull morphology and cranial suture scheduling. Skull morphology was assessed through 36 cranial and 19 mandibular measurements. Cranial suture scheduling was tested by identifying five sutures as 'open' or 'closed' for each specimen. During this study it became evident that Laws Scale focussed on age as a number of years, whilst modelling mortality is reliant on age as a physiological class. For Asian elephants however, a consensus on well-defined physiological classes do not exist. Based on an extensive collation of available literature sources, this study therefore proposes six age classes; 'Calf', 'Juvenile', 'Sub-adult', 'Adult', 'Mature-adult' and 'Geriatric'. Using Laws Scale, age classes 'Sub-Adult' and 'Adult' were indistinguishable. The skull morphology results correlated with age, however they did not provide further refinement of Laws Scale. The results of the cranial suture assessment found four of the five sutures correlated positively with age. Furthermore, the naso-frontal suture directly addressed discrepancies between 'Sub-adult' and 'Adult'. From current understandings and these results, an age determinant protocol was developed. This novel protocol and the refined age classes await validation in specimens of known age but this does not reduce its potential as a practical tool for gathering information on mortality events to assess and direct current conservation initiatives.

129- USING EVIDENCE BASED SCIENCE TO ASSESS WWF'S GLOBAL CONSERVATION PROGRAMME WITH REFERENCE TO THE VALUE OF THE OPEN STANDARDS IN CONSERVATION PROJECTS

P. J. Stephenson

WWF

Sheila O'Connor, WWF ; Tom MCSHANE, Arizona State University, Global Institute of Sustainability ; Lydia GASKELL, WWF

WWF has a presence in over 90+ countries with offices managing over 4000 projects and more than 70 large scale programmes with the aim of conserving nature and reducing humanity's footprint for One Planet Living. WWF is a network of independent offices and hundreds of partnerships at local, national, regional and international scales. Ten years ago WWF had a myriad of approaches to design, implement, and monitor projects and programmes due to the breadth of its network. Working with other conservation organisations to develop the Open Standards helped WWF focus on the most important elements for adaptive management. A recent review of WWF's 70+ priority programmes has provided evidence to the value of the Open Standards in improving effectiveness and impact. However our decade long experience with the OS has also indicated where improvements can be made, and the challenges associated with organisation-wide adoption. ÅÅ During the review, scores for each programme were allocated to an assessment framework [based loosely on the OS] after which a series of correlations were analysed showing support for the theory that better design and ÅÇ'management' is related to improved effectiveness and impact. We will share the assessment framework and methodology, evidence and recommendations from the review as well as some specific case studies of projects that have benefitted from the application of the Open Standards.

OVERCOMING THE CHALLENGES TO CONSERVATION MONITORING: INTEGRATING DATA FROM IN SITU REPORTING AND GLOBAL DATASETS TO MEASURE IMPACT AND PERFORMANCE

Pj Stephenson

WWF International

Neil BURGESS, UNEP-WCMC ; Laura JUNGSMANN, WWF Market Transformation Initiative ; Jonathan LOH, Zoological Society of London ; Sheila O'CONNOR, WWF International ; Thomasina OLDFIELD, TRAFFIC International ; William REIDHEAD, WWF International ; Aurelie SHAPIRO, WWF-Germany Remote Sensing Centre

If Parties to the Convention on Biological Diversity (CBD) and their partners are to report effectively on progress against national, regional and global biodiversity conservation goals, data will need to be collected at multiple levels. Global datasets, many fuelled by remote sensing techniques, offer partial solutions but need to be complemented by field-level observations to provide the resolution necessary to track key conservation measures in a meaningful way. This paper summarizes efforts made by the conservation organization WWF, working with several partner organizations, to integrate

global datasets with data collected by its field programmes to determine progress against multi-level organizational goals and to assess conservation impacts and programme performance. We assessed the quality and usefulness of data collated on ten indicators of relevance to CBD Parties, as well as a conservation achievement key performance indicator tracking annual results of WWF programmes. Integration of in situ and ex situ data into reporting dashboards allowed some degree of assessment of progress and adaptive management of the programme portfolio. However key challenges remain to be overcome if global and local monitoring objectives are to be attained, including increased collection of data by field projects, improved harmonization of indicators, and greater sharing of data in formats of use to practitioners.

SYMPOSIUM ID_181_ IDENTIFYING BIOCULTURAL INDICATORS THAT INTEGRATE LOCAL AND GLOBAL CONSERVATION OUTCOMES

Eleanor Sterling

American Museum of Natural History
Sophie CAILLON, National Center for Scientific Research (CNRS), UMR5175 Centre d'Ecologie Fonctionnelle et Evolutive, France ; Chris FILARDI, American Museum of Natural History ; Erin BETLEY, American Museum of Natural History ; Stacy JUPITER, Wildlife Conservation Society, Melanesia Program ; Simon ALBERT, The University of Queensland ; Georgina CULLMAN, American Museum of Natural History ; Joachim CLAUDET, CNRS, CRILOBE & Laboratoire d'Excellence CORAIL ; Pascale DE ROBERT, IRD, UMR 208 PALOC Patrimoines Locaux et Gouvernance ; Marie ROUÉ, CNRS, UMR 7206 Eco-anthropologie et Ethnobiologie ; Patrick PIKACHA, Solomon Islands Community Conservation Partnership ; Senoveva MAULI, Solomon Islands Community Conservation Partnership ; Mary BLAIR, American Museum of Natural History ; Hara WOLTZ, American Museum of Natural History ; Myknee SIRIKOLO, Solomon Islands Community Conservation Partnership ; Joe MCCARTER, American Museum of Natural History

Biocultural approaches to resource management emphasize actions to sustain dynamic, interdependent social-ecological systems. These approaches implicitly seek to overcome perceptions of human activities and ecological systems as separate or independent of one another. They are founded on local perspectives, perceptions and knowledge. Implementation of these approaches entails multiple types of evidence in decision-making and requires sets of indicators capable of reflecting local as well as global influences and perspectives. This presentation will define and explain the need for biocultural approaches to local management partnerships with an emphasis on developing new kinds of indicators and indices. The talk will outline current efforts to

define and implement biocultural indicators and also explore specific challenges and opportunities in setting targets in biocultural land and seascapes. Challenges include: identifying robust social-ecological resilience metrics across mosaics of land and seascapes; integrating qualitative with quantitative information; integrating across diverse groups with differing values and perspectives; adopting valuation and measurement techniques that make sense to local community members; identifying methods for bringing local voices to national and international arenas; and translating relevant international principles to local settings. The opportunities, however, are significant. Biocultural approaches have the ability to identify underlying value differences that may be confounding conservation activities, to achieve conservation goals through eliciting broad support from multiple stakeholders, and to increase the long-term sustainability of initiatives. Local interactions with land and seascapes are critical to global conservation strategies and local strategies may well help to overcome global threats. Thus biocultural approaches will be integral to biodiversity conservation and natural resource management into the future.

MARINE SPATIAL PLANNING MAKES ROOM FOR OFFSHORE AQUACULTURE IN CROWDED WATERS

Joel Stevens

California Polytechnic State University
Rebecca GENTRY, University of California ; Thomas BELL, University of California ; Carrie KAPPEL, University of California ; Sarah LESTER, University of California ; Dean WENDT, California Polytechnic State University ; Crow WHITE, California Polytechnic State University

Offshore aquaculture is an emerging industry predicted to contribute significantly to global seafood production and food security. However, aquaculture farms can generate conflicts by displacing existing ocean user groups and impacting ecosystems. Further, there are multiple farm types with different seafood species, productivity levels and impacts. Thus, it is important to strategically and simultaneously plan farm type and location in relation to the seascape in order to most effectively maximize aquaculture value while also minimizing conflicts and environmental impacts. We address this problem and demonstrate the value of multi-objective planning with a case study that integrates bioeconomic modeling with ecosystem service tradeoff analysis to inform the marine spatial planning (MSP) of mussel, finfish and kelp aquaculture farms in the already-crowded Southern California Bight (SCB) ecosystem. We considered four user groups predicted to conflict with or be impacted by the three types of aquaculture: wild-capture fisheries, ocean viewshed from coastal properties, marine benthic habitat protection, and risk of disease outbreak between farms. Results indicate that significant conflicts and impacts, expected under conventional planning, can be

reduced substantially by strategic planning. For example, 28% of potential mussel farm sites overlap with wild-capture halibut fishery grounds, yet MSP can enable mussel aquaculture to generate up to a third of its total potential industry value without impacting halibut fishery yield. This study comprehensively informs aquaculture farm design in the SCB, and demonstrates the value of multi-objective planning as a key component in MSP.

129-THE OPEN STANDARDS FOR THE PRACTICE OF CONSERVATION AS A TRANSFORMATIVE TOOL IN MANAGING THE BUSINESS OF CONSERVATION

Annette Stewart

Bush Heritage Australia

Bush Heritage Australia manages a million hectares of land for conservation, and assists partner Aboriginal organisations in managing a further 4 million hectares. Several years ago we faced many challenges with the range and complexity of projects that these responsibilities entail. We scanned the market for processes and tools to help us manage our work and decided to adopt the Open Standards for the Practice of Conservation, along with its supporting software, Miradi. We have since applied these tools to all of our projects, including a variation known as Healthy Country Planning which we use with Aboriginal partners. The result has been a step-change in the quality of our conservation plans, the efficiency of our project implementations, and our ability to report results to donors and other stakeholders. Application of the Open Standards assists conservation practitioners to be more effective - guiding them in choosing the right targets, involving stakeholders, planning projects, monitoring outcomes, and adapting their plans in light of the evidence resulting from their actions. We have built upon this approach by adding a focus on efficiency, developing tools that create linkages to the broader business processes that support conservation activities. We will show examples of how we apply the Open Standards, the outcomes achieved, and the steps we went through to get to where we are today.

CONSERVATION OF OCEANIC MANTA RAYS: DOES THE HIGHLY MIGRATORY PARADIGM HOLD UP?

Joshua David Stewart

UC San Diego

Calvin Beale, Misool Eco Resort Conservation Center ; Daniel Fernando, Linneaus University ; Octavio Aburto-Oropeza, UC San Diego ; Ronald S Burton, UC San Diego ; Brice X Semmens, UC San Diego

Decades of research on the spatial ecology of large marine vertebrates have shown that these species almost invariably exhibit migratory behavior on a regular basis. As a result, large

marine vertebrates often have extensive home ranges that may straddle the exclusive economic zones of multiple countries or extend into international waters. The ubiquity of these spatial patterns in large marine vertebrates has created a paradigm of highly migratory species that are notoriously challenging to manage effectively. The oceanic manta ray (*Manta birostris*) is an example of a large marine vertebrate that has been heavily impacted by fisheries over the last decade. Oceanic manta rays, along with closely related mobula rays, are caught frequently as bycatch in pelagic fisheries, and have been increasingly targeted in direct fisheries as demand for manta and mobula gill plates has increased in traditional Asian medicine. Low fecundity and small population sizes make mantas highly susceptible to fisheries-driven population decline. Due to their large size and pelagic lifestyle, mantas have long been assumed to be highly migratory, an assumption reinforced by low resighting rates in photo identification databases. Using a combination of satellite telemetry, stable isotope analysis, and next-generation genetic methods, we have studied the population dynamics and spatial ecology of four oceanic manta populations separated by 600km to 18,000km. Our results indicate that oceanic manta ray populations have very limited connectivity, and highlight the susceptibility of manta populations to local fisheries. We comment on previous observations of fisheries impacts in the context of our findings, and present notable conservation management action that has been implemented in response to an improved understanding of oceanic manta ray spatial ecology. We provide recommendations for effective management to prevent population decline in light of these findings.

ECOSYSTEM CONTEXT AND HISTORICAL CONTINGENCY IN APEX PREDATOR RECOVERIES

Adrian Stier

National center for Ecological Analysis and Synthesis
Jameal SAMHOURI, National Marine Fisheries Service ; Mark NOVAK, Oregon State University ; Kristin MARSHALL, National Marine Fisheries Service ; Eric WARD, National Marine Fisheries Service ; Philip LEVIN, National Marine Fisheries Service

Habitat loss, overexploitation, and numerous other stressors have caused global declines in apex predators. This “trophic downgrading” has generated widespread concern because of the fundamental role apex predators play in ecosystem functioning, disease regulation, and biodiversity maintenance. In attempts to combat declines, managers have conducted reintroductions, imposed stricter harvest regulations, and implemented protected areas. Here we suggest that full recovery of viable apex predator populations is currently the exception rather than the rule. We argue that, in addition to well-known considerations such as continued exploitation and slow life histories, there are several underappreciated factors that complicate predator recoveries. These factors

include the challenges of: (i) identifying the suite of trophic interactions that will influence recovery a priori, (ii) defining and accomplishing predator recovery in the context of a dynamic ecosystem, and (iii) designing adaptive sequences of management strategies that embrace key interactions. Consideration of recent research on food web modules, alternative stable states, and community assembly offer important insights for predator recovery efforts, and restoration ecology more generally. Foremost among these is the importance of a social-ecological perspective in facilitating a long-lasting predator restoration while avoiding unintended consequences

THE CURRENT STATUS OF BIRD CONSERVATION IN THE SOUTH PACIFIC

Rebecca Stirnemann

Samoan conservation Society

Bird populations in the South Pacific are declining and the need for conservation actions to address threats is increasingly acknowledged. Effective conservation requires a robust knowledge base on which decisions over appropriate actions can be made, yet at present there is no current and accessible synthesis of the status of populations, the threats they face and knowledge gaps. In this study we begin to address this disparity for red listed bird species in the South Pacific region. We review the current status of conservation of birds in the South Pacific, identify areas where critical knowledge is lacking and highlight opportunities to address them. We emphasize the degree to which even knowledge of basic biology is missing for many red listed species in this area and discuss contributing factors. This review aims to provide a base line upon which progress towards an improved understanding of the conservation needs of threatened and endangered birds in the South Pacific can be made while highlighting the critical need for further research and conservation efforts. This technique could be applied to other species groups as a method of assessing conservation progress over a shorter period than is currently possible using red listing processes.

INTERACTION OF LANDSCAPE STRUCTURE, LIGHT, AND PREDATORS ON RISK PERCEIVED BY BEACH MICE: IMPLICATIONS FOR CURRENT AND FUTURE HABITAT UNDER A CHANGING CLIMATE

Margo Stoddard

University of Florida

Lyn BRANCH, University of Florida ; Debbie MILLER, West Florida Research & Education Center, University of Florida

Weather- and development-related habitat fragmentation on barrier islands can interact with factors that elevate perceived risk of predation to affect the amount of habitat available

for use by dune-dependent species, such as beach mice (*Peromyscus polionotus* spp). On two barrier islands along the Florida Gulf Coast (USA), we used foraging trays to relate the amount of food eaten (surrogate for perceived risk) to microhabitat and landscape structure (e.g., vegetation cover, patch size, and connectedness) under ambient and heightened (light or predator cues present) risk conditions. Using occurrence data and results from these behavioral studies, we created habitat suitability maps and combined them with results from sea level rise and storm surge models to estimate how habitat would change over the next century. Finally, we used tracking tubes to examine use of natural, open sand, and planted linear dune restoration plots to assess how habitat connectivity might be increased to facilitate movement of beach mice in areas affected by large storms. Our findings confirm ambient and artificial light, owl (predator) cues, and distance to vegetation can increase risk perceived—and thus decrease activity—by beach mice. We found some factors measured at intermediate and broader spatial scales, such as distance to vegetation and presence of a vegetated corridor, be scale- and season-dependent. At the broadest spatial and temporal scales, sea level rise reduced the amount of habitat usable by beach mice in all scenarios examined (0.64, 1.0 or 2.0 m increase by 2100), with most drastic changes observed when effects of large storms were considered along with sea level rise. If conservation of beach mice and other coastal species remains a concern over the next century, management activities that facilitate movement by mice, e.g., reducing artificial light near dunes and restoring vegetation in overwashed areas—should be implemented.

SYMPOSIUM #20 FIELD SENSOR TECHNOLOGY FOR IMPROVING CONSERVATION EFFECTIVENESS: OPPORTUNITIES, LIMITATIONS AND FUTURE HORIZONS

Emma Stokes

Wildlife Conservation Society

Biodiversity is currently facing unprecedented human pressures and conservation efforts are rightly coming under increasing scrutiny in achieving effective outcomes. Scientists, conservation practitioners and the private sector alike are increasingly looking to harness technology in meeting biodiversity conservation goals. Technology has much to offer in the way of innovative solutions to intractable conservation problems; perhaps none more so than the global illegal trade in wildlife. I discuss here the different objectives for technology support in combatting wildlife crime specifically, including surveillance and detection, tactical and operational support, communications and logistics, and investigative and analytical support. I assess a number of existing and emerging technologies, with a focus on remote field sensors, including,

but not limited to, cameras and UAVs. Using a series of global field case studies I provide an overview of the efficacy of these technologies with respect to their reactivity, accuracy, endurance, scalability, capacity needs and cost-efficiency. This review emphasizes the importance of a needs-based approach rather than one that is technology development-led, and identifies a suite of key human and operational capacity criteria for consideration in the implementation effectiveness of any field-based technology. The role of 'technology competitions and challenges' in promoting innovative solutions is discussed. Looking forward, conservation technology needs to excite and inspire new solutions and directions, yet remain grounded to its user base in order to achieve tangible conservation outcomes. We highlight some proof of concept cases where technology has directly contributed to improved conservation effectiveness.

THE IMPACTS OF NEW STREET LIGHT TECHNOLOGIES: EXPERIMENTALLY TESTING THE EFFECTS ON BATS OF CHANGING FROM LOW PRESSURE SODIUM TO WHITE METAL HALIDE

Emma Stone

University of Bristol / African Bat Conservation

Andrew WAKEFIELD, University of Bristol ; Harris STEPHEN, University of Bristol ; Jones GARETH, University of Bristol

Artificial light at night is a major feature of anthropogenic global change, and is increasingly recognized as affecting biodiversity, often negatively. Increasingly, on a global scale, newer technology white lights are replacing orange sodium lights to reduce energy waste. In 2009 Cornwall County Council (UK) commenced replacement of existing low pressure sodium (LPS) high intensity discharge (HID) street lights with new Phillips CosmoPolis white ceramic metal halide street lights to reduce energy wastage. This changeover provided a unique collaborative opportunity to implement a before-after-control-impact field experiment to investigate the ecological effects of newly installed broad spectrum light technologies. Activity of the bat species *Pipistrellus pipistrellus*, *P. pygmaeus* and *Nyctalus/Eptesicus* spp. was significantly higher at metal halide than LPS lights, as found in other studies of bat activity at old technology (i.e. mercury vapor) white light types. No significant difference was found in feeding attempts per bat pass between light types, though more passes overall were recorded at metal halide lights. Species-specific attraction of bats to the metal halide lights could have cascading effects at lower trophic levels. We highlight the need for further research on possible ecosystem-level effects of light technologies before they are installed on a wide scale.

RESOLVING WOLF AND SHEEP CONFLICTS WITH NONLETHAL METHODS AND COMMUNITY COLLABORATION

Suzanne Stone

Defenders of Wildlife

Jesse TIMBERLAKE, Defenders of Wildlife ; Peter HASWELL, Bangor University ; Fernando NAJERA, University of Madrid ; Stewart BRECK, USDA National Wildlife Research Center ; Lawrence SCHOEN, Blaine County Commission ; Brian BEAN, Lava Lake Lamb and Livestock ; Daniel THORNHILL, Defenders of Wildlife

Worldwide, lethal control of predators to manage conflict with livestock is commonly employed and can inhibit wildlife conservation efforts. Our study focuses on developing non-lethal solutions that reduce conflict and the need for lethal management of carnivores. Wolf restoration to the USA northern Rockies is heralded as a biological success but with the re-establishment of wolves, conflict in the form of livestock depredation is an important driver for current policies setting hunting quotas and lethal control actions to protect agricultural interests. We present results from a seven year study where we employed animal husbandry techniques to manage livestock and nonlethal techniques to manage wolves in place of lethal control measures. Our paper discusses the range of nonlethal adaptive mitigation methods we used to protect sheep and compares rates of depredation to other areas in the state that employed lethal control strategies. Data was collected on wolf activity, sheep-herder activity, sheep losses to predators, and nonlethal tools used for keep wolves from attacking sheep. We employed a variety of nonlethal tools including corralling sheep at night with fladry, light and noise devices, and human activity but did so judiciously when threats from wolves were believed to be elevated. Preliminary results indicate that over the seven year period sheep predation rate was lowest in the state (0.03 percent of the total sheep present in the area) with fewer than 30 sheep killed by wolves out of total of 110,000 sheep animal units present. A cost-benefit analysis also demonstrates that our methods are economically competitive with traditional lethal wolf control methods. Critical to our success was working with local stakeholders to construct a community model for peacefully addressing conflicts and implementing solutions.

THE ROLE OF FIRE DISTURBANCES ON THE DISTRIBUTION OF STRUCTURAL RESOURCES FOR THE EASTERN BRISTLEBIRD

Zoe Stone

The University of Queensland

Martine MARON, The University of Queensland ; Elizabeth TASKER, Office of Environment and Heritage, NSW Government

Many ecosystems are experiencing changing disturbance regimes. In Queensland, Australia, many species rely on frequent disturbance patterns for the maintenance of habitat in grassy eucalypt forests. In particular, ground dwelling species that rely on structural resources provided by the grassy layer, such as the Eastern Bristlebird (*Dasyornis brachypterus*), are sensitive to disrupted fire regimes. The Northern population of the Eastern Bristlebird (NEBB) is rapidly declining, with an estimated population of less than 30 individuals. As a small bird with limited flight ability, it relies heavily on local resources provided by the grassy layer within its habitat. This research looks at how fire has affected the spatiotemporal distribution of structural resources within grassy eucalypt forests of Southern Queensland and Northern New South Wales, Australia. Current and historic distribution of suitable grassy habitat was mapped across the known range of the NEBB and assessed against bristlebird distribution. At a more local scale, grass structure was measured across all known currently occupied and historical bristlebird sites. Grass height, thickness, and diversity were measured within bristlebird territories, along with shrub and canopy cover. Preliminary results suggest decreased fire has led to a significant reduction in grassy habitat available to NEBB across its range, as a result of shrub encroachment. In addition, the quality of structural resources that are provided by the grassy layer for the NEBB has degraded with decreasing disturbance. Inappropriate burning practises have led to decreased structural resources for these ground dwelling birds, which require a dense and complex grass layer for breeding, protection and foraging. Understanding how these resources have been influenced by changing disturbance patterns will assist in the preservation of grassy eucalypt forest types, and therefore the conservation of threatened species associated with them.

VALUES SHAPE THE WAY ECOLOGICAL INFORMATION INFLUENCES PEOPLE'S ATTITUDES TOWARDS URBAN WETLANDS

Tanja Straka

Australian Research Centre for Urban Ecology (ARCUE)
Dave KENDAL, Australian Research Centre for Urban Ecology (ARCUE) ; Rodney VAN DER REE, Australian Research Centre for Urban Ecology (ARCUE)

Urban wetlands are important for wildlife conservation and valued by people. However, wetlands that are beneficial for wildlife are not necessarily aesthetically pleasing to people. This is important in human-dominated areas where people's preferences influence the design and management of wildlife habitats. We investigated people's preferences towards urban wetlands that benefit insectivorous bats, the effect of

ecological information on people's preferences, and the role of underlying values for wildlife in mediating this process. Residents ($n = 1,200$) living around wetlands in Melbourne, Australia were posted a photo-booklet containing images of 27 wetlands and a questionnaire which was used to rate their preferences and their wildlife value orientations. To test the effect of ecological information, half the participants also received information about insectivorous bats and the ecological quality of each wetland for these cryptic mammals. We hypothesized that this information would change people's preferences for some types of wetlands, and that this effect would be mediated by their wildlife values. People generally preferred urban wetlands that were beneficial for insectivorous bats. Somewhat surprisingly, people who received ecological information did not have higher preferences for wetlands that provided good habitat for bats; instead, their preferences were lower for wetlands that were less beneficial for insectivorous bats. This effect was mediated by high wildlife value orientations. Results of this study suggest that wetlands with high quality habitat for bats can be enjoyed in an Australian urban context. More importantly, our results show that preferences for landscapes can be influenced by the provision of ecological information when that information is consistent with people's value orientations.

PARKS IN HUMAN-DOMINATED LANDSCAPES: RELATIVE VULNERABILITY TO CLIMATE AND LAND USE CHANGES

Esther Stroh

US Geological Survey

Matthew STRUCKHOFF, US Geological Survey ; David SHAVER, US Geological Survey ; Krista KARSTENSEN, US Geological Survey

Many national parks in the American Midwest are islands of natural vegetation surrounded by agricultural or urban land uses or are in highly fragmented or rapidly changing landscapes. Climate change is just one of many stressors on park natural resources. Understanding the relative vulnerability of these parks to climate and land use changes is important for region-wide planning. We conducted a relative vulnerability assessment of 60 units in the (US) National Park Service Midwestern administrative region to climate and land use change using data from multiple sources. We assessed individual parks' exposure (5 metrics), sensitivity (5 metrics), and adaptive constraints (8 metrics) under two climate change scenarios (A1B and A2). The metrics from these three components were combined into an overall vulnerability score. Metrics were measures of existing or projected conditions within park boundaries, within 10 km buffers surrounding parks, and within ecoregions that contain or intersect the parks. Data were normalized within the range of values for all assessed parks, resulting in relative scores for exposure,

sensitivity, adaptive capacity, and overall vulnerability within the 13-state area. Results are consistent with recent assessments regarding patterns and rates of climate change nation-wide, but provide greater detail and relative risk for Midwestern park units. Overall relative vulnerability ranking of parks did not differ much between climate scenarios. Scores for the vulnerability components of exposure, sensitivity, and adaptive constraints varied geographically and indicate mitigation opportunities and constraints. Output will allow individual parks to understand which metrics weigh most heavily in their overall vulnerability and can be used for region-wide responses and resource allocation for mitigation efforts.

HOW WELL DO WE KNOW OUR BIODIVERSITY? A CASE STUDY OF MAMMALS OF COLOMBIA

Andrés Felipe Suárez-Castro

University of Queensland

Héctor E RAMÍREZ-CHAVES, University of Queensland

Species checklists provide basic information for taxonomic and geographic studies, and usually, are the first tool for those involved in wildlife management and conservation. However, their use is constrained by the completeness and accuracy of updated information. Here, we reviewed changes in the number of species of native mammals from Colombia over the last fifteen years (2000-2015). Based on data from natural history collections and online databases, we analysed diversity and distributional patterns in order to identify research efforts in different regions of the country. Forty seven species were added since 2000, increasing the diversity of mammals in the country to 503 species and 208 genera. Most of the additions (17) correspond to bats (order Chiroptera), one of the most studied groups in the country. Nevertheless, the increasing number of mammal diversity is not restricted to small mammals. This is reflected by the discovery of new species of primates (2), carnivores (1), and perissodactyls (1) in the last decade. We also highlight some groups that require urgent taxonomic and systematic reviews. Although Colombia is one of the global hotspots for mammalian diversity, our results show that little or nothing is known about diversity or distributional patterns of certain species, especially the endemic taxa. The presence of the main cities and roads in the Andes have allowed for higher levels of sampling effort in this region. In contrast, the Amazonia is the least studied region. Therefore, many conservation decision and quantification tools have a limited ability to determine impacts of anthropic changes on biodiversity. Given this sampling bias, we suggest fieldwork efforts based on the updated distribution data of the species. Finally, we propose new approaches to update the checklist of Colombian mammals in order to identify advances and information gaps in a more accurate way.

AMPHIBIAN DISTRIBUTION AND CONSERVATION IN THE EASTERN HIMALAYA

Barkha Subba

Ashoka Trust for Research in Ecology and Environment (ATREE)

The Eastern Himalaya (EH) Hotspot offers a unique and vast altitudinal and environmental gradient for studying species turnover and species adaptation in a rapidly changing landscape. The amphibians of EH are the least studied group among vertebrates. Their cryptic nature, inconspicuousness, highly seasonal activity and inaccessibility due to difficult terrain have resulted in limited studies on this fauna. My study area is Sikkim Himalaya and my work seeks to understand the role of multiple factors on species richness and distribution pattern of amphibians along an elevation gradient and mapping the distribution of amphibians in the entire EH region. I used Ecological Niche Modeling to predict the present and future distributions of amphibians in the EH and possible conservation issues and mitigation with regard to these high altitude species in the light of climate change. In addition to the ecological aspects, I also used participatory tools, like, focus group discussion, questionnaire surveys among the communities inhabiting the fringe villages to understand the local practices with respect to the use of amphibians. In rural settlements, especially the buffer villages, people had knowledge about the ecological role of the anurans but unfortunately they were also preyed upon by these people for various reasons, like medicine, meat and culture of hunting. Furthermore, the Indian Wildlife Protection Act (WPA), 1972 has added greater pressure towards the anuran population. Before the WPA, the ethnic people hunted for larger preys in addition to hunting for frogs but now it seems the whole focus has shifted towards hunting of frogs for keeping their hunting-tradition alive, sustenance for some and also for sports. As frogs are small and inconspicuous, their hunting usually goes unnoticed. These ecological and social surveys have helped identify various threats to the high altitude amphibian population and initiated development of a comprehensive conservation protocol.

SIZE DOES NOT ALWAYS MATTER. POLLINATION OF A SPECIALIST PLANT TROLLIUS EUROPAEUS IN A FRAGMENTED HABITAT.

Tomasz Suchan

University of Lausanne

Nadir ALVAREZ, University of Lausanne

Many plant species are experiencing negative consequences of habitat fragmentation, a process resulting, for instance, in a decrease of population sizes and an increase of the isolation between remnant populations. Moreover, such changes can

potentially affect biotic interactions within communities, such as pollination success, further disturbing the reproduction and survival of the remaining populations. It is speculated that specialized plant-pollinator interactions should be particularly sensitive to such processes. In this study we focused on the European globeflower *Trollius europaeus*, a specialist plant, pollinated mostly by *Chiastocheta* flies. This well studied interaction can be used as a model plant-pollinator interaction, as the interacting partners are well defined - one plant interacting with one genus of main pollinators. We measured pollination efficiency, defined as the proportion of fertilized ovules, in natural *T. europaeus* populations of varying size, isolation, and plant density on a local, within-population scale. Contrary to our expectations, *T. europaeus* population size and isolation did not have negative effect on pollination efficiency. Instead, the fine-scale plant population density was the determining factor for pollination success. Our findings highlight the fact the plant population size is not always the main factor determining the processes occurring in fragmented populations. Other factors, such as local plant density can also play an important role in attracting pollinators and may thus affect plant reproduction.

SPECIES DISTRIBUTION AND ABUNDANCE OF AMPHIBIANS USING GEOGRAPHIC INFORMATION SYSTEM MAP IN TWO VEGETATION TYPES OF AGUSAN MARSH, PHILIPPINES

Rainer Sularte

Caraga State University

Agusan Marsh is the 1009th RAMSAR site, a wildlife sanctuary which harbour unique and pristine faunal species. It is considered one of the most ecologically significant wetland ecosystems in the Philippines. The study assessed species distribution and abundance using Geographic Information System Map in Agusan Marsh between Sago Palm and Terminalia Forest. Results showed a total of 322 individuals, 11 species and 6 families of amphibians documented. Of the eleven (11) species of amphibians documented in Sago Palm and Terminalia Forest, six (6) were Philippine endemics, three (3) were invasive species in the area. Terminalia forest had the highest number of individuals documented during the conduct of the study. Sago Palm and Terminalia Forest have almost the same type of vegetation where amphibian species thrive most. Furthermore, ecological and environmental threats (conversion of Terminalia Forest to agricultural land, run-off of environmental pollutants such as pesticides and Kaingin or Slash and Burns) being identified in the two habitat types, posed immediate attention. Agusan Marsh is home of 6 Philippine endemic amphibian species and should therefore be better managed and protected. Key words: Abundance,

Agusan Marsh, Biodiversity, Distribution, Frogs, Sago Palm, Terminalia Forest

MODELING THE IMPACT OF HYDROLOGICAL ALTERATIONS: SHIFTS IN EURASIAN SPOONBILL HABITAT IN POYANG LAKE, CHINA

Benjamin Sullender

University of Wisconsin-Madison

Janet SILBERNAGEL, University of Wisconsin-Madison ; Jeb BARZEN, International Crane Foundation

Poyang Lake, the largest freshwater lake in China, provides critical wintering refuge for over 300 species of migratory waterbirds. Suitable habitat for these birds, including an available and abundant food supply, is driven by a seasonal flood-pulse system fed by the Yangtze River. To protect livelihoods such as agriculture and fishing, people have manipulated local hydrology to a great extent. Future alterations – namely, a proposed Yangtze-Poyang outlet dam – could have a much larger ecological impact, although little is currently known about this relationship. To quantify the role of hydrology in habitat suitability, I used a hybrid approach integrating behavioral observations with long-term monitoring in Poyang Lake National Nature Reserve. I selected the Eurasian spoonbill (*Platalea leucorodia*) as an indicator for co-occurring waterbirds of concern such as the endangered Oriental stork (*Ciconia boyciana*). In winter 2014-2015, I conducted a series of focal and scan samples to examine preferred habitat and flock activity budget. These observations indicate that water level is the main driver of habitat suitability due to its role in both spoonbill behavior and foraging success rates. 64% of bird activity occurred in 35-55cm of water, and birds foraging at these depths acquired 3.1 food items per 5-minute bout compared to 1.2 items at other depths. I used these findings to inform a spatially explicit logistic regression model of spoonbill habitat based on surveys from 1999-2015. After determining the baseline relationship, I adjusted parameters based on potential hydrological changes and found that reducing water levels would have a disproportionate impact on habitat: 10% and 15% reductions in winter water level would decrease optimal foraging habitat by 15.2% and 42.9% respectively. Although altering hydrology may benefit human livelihoods, changes exceeding the narrow range of suitable water depth would displace, reduce, or entirely eliminate available habitat.

PUBLIC-PRIVATE PARTNERSHIPS AS A FINANCIAL MECHANISM FOR BIODIVERSITY CONSERVATION AT THE LANDSCAPE SCALE: THE ALTO MAYO CASE IN THE NORTHEASTERN PERUVIAN AMAZON

Percy Summers

Conservation International

Claudio SCHNEIDER, Conservation International [INSTITUTE] Conservation International ; Agustin SILVANI, Conservation International HQ ; Ivo ENCOMENDEROS, Conservation International ; Fabiano GODOY, Conservation International HQ ; Annie WALLACE, USAID ; Dora SAMANIEGO, Conservation International

A sustainable landscape integrates good governance, sustainable production and natural capital conservation to improve health, human well-being and social equity. However, in practice, the changes required for managing the landscape sustainably are daunting. The private sector can be a key component for driving change of land use and land cover processes that can spur economic growth and biodiversity conservation. This session explores the ways in which the public sector and NGOs are attracting private sector investment compatible with the vision of a sustainable landscape. We take as an example the demonstration project being developed jointly with the Peruvian Ministry of Environment, the Regional Government of San Martin, USAID and various private sector entities. By bringing together real-world experiences we will explore the hurdles preventing the public and private sector from cooperating more closely, how non-government actors such as NGOs can facilitate this exchange, and spark a discussion on what is needed to break from the business as usual and move towards sustainable investment models that spur economic growth and maintain a country's natural capital. How can we effectively tie investments to a decision making process based on science to maximize economic, environmental and social outcomes? How can we guide investments for multiple benefits? How can we integrate information and stakeholder expectations for optimum outcomes? Other lessons include the design and implementation of a landscape accounting system to track how investments and other project activities are reducing emissions on the ground, as well as increasing production, while maintaining natural capital and biodiversity, and improving human well-being.

INTEGRATING AQUACULTURE, AGRICULTURE AND VETERINARY COMPONENTS IN POND AQUAPONICS FOR FOOD SECURITY AND INCOME OF FARMING HOUSEHOLDS IN COASTAL BANGLADESH

Atiqur Rahman Sunny
Sylhet Agricultural University

Aquaponics is an agricultural technology of integrated culture of fish and vegetables that is emerging with global popularity. The present study was designed for integrated culture of fish and vegetables with pigeons in pond aquaponics in the Barisal region of Bangladesh. Using cheaper, locally available inputs and farmers' skills and labor, 3 square meter

(1.52m x 2.12m) aquaponics cage structure was introduced in pond; made by bamboo-spilt within the costing range from 1200 to 2000 BDT. In the three sides of the cages, there were sunshades like structures to support vegetables like basil, green pepper, tomato, brinjal, ornamental flowers, medicinal plants etc. Above the cage; a trellis supported spreading plants like bean, bitter gourd, long bean etc. Three treatments of aquaculture were introduced; monoculture of Tilapia (*Oreochromis niloticus*), monoculture of Koi (*Anabas testudineus*), polyculture of Koi and Tilapia. After 80 days of stock, Tilapia becomes 178.5g and 174g in monoculture and polyculture with 19cm and 17 cm in size respectively from 24g and 22g initial weight respectively with 4cm of initial size. Whereas Koi become 70g weight in monoculture and 57.6g in polyculture from 0.5g initial weight. Farmers' acceptance of the modified aquaponics is encouraging and they are constructing aquaponics by their own effort since the production and profit of vegetables was comparatively higher than other traditional aquaponics. Considering the adaptability of this culture system in relation to tidal surges, flood, this culture system could increase resilience of the farming households in relation to environmental changes in the coastal region of Bangladesh.

ASSESSING TROPICAL BIRD DIVERSITY WITH THE DYNAMIC HABITAT INDEX

Naparar Suttidate

University of Wisconsin-Madison

Nicholas C. COOPS, University of British Columbia ; Anna M. PIDGEON, University of Wisconsin-Madison ; Nicholas S. KEULER, University of Wisconsin-Madison ; David P. HELMERS, University of Wisconsin-Madison ; Volker C. RADELOFF, University of Wisconsin-Madison

Biodiversity loss is a global crisis. Predicting how species will respond to a changing environment requires assessments of biodiversity at relevant temporal and spatial scales. Inconsistent and incomplete biodiversity assessments hamper conservation efforts in many tropical regions. Our goal was to assess the strength of the relationship between the Dynamic Habitat Index (DHI), derived from satellite data, and tropical breeding bird species richness in Thailand. The DHI summarizes three measures of annual vegetation productivity that characterize the capacity of a given habitat to support a number of species: a) cumulative productivity, as sites with more available energy are generally more biodiverse; b) minimum productivity, as sites that never exhibit extreme lows are more biodiverse; and c) seasonality in productivity, as sites with less intra-annual variability are more biodiverse. We calculated the DHI for Thailand at 8-km resolution for 2002-2009 from NASA's MODIS FPAR data, and breeding bird richness from IUCN species range maps. We modeled richness of all breeding bird species and for different functional guilds as explained by the DHI, climate, topography, latitudinal

gradients, habitat heterogeneity and area, with best-subsets and hierarchical partitioning regressions. Species richness was highest where the DHI had high cumulative productivity, high minimum productivity, and low seasonality. Cumulative productivity best explained species richness (up to 63%). Together, DHI and environmental factors explained up to 87% of variation in richness overall and among guilds, with DHI being the most important factor. The DHI is a promising tool for biodiversity assessments and conservation because it quantifies those aspects of the dynamics of vegetation productivity that strongly correlate to diversity.

SPATIAL ECOLOGY OF FEMALE TRIMERESURUS MACROPS IN NATURAL AND HUMAN-DISTURBED FOREST OF SAKAERAT BIOSPHERE RESERVE, THAILAND

Pongthep Suwanwaree

Suranaree University of Technology

Colin T. STRINE, Suranaree University of Technology ; Inês SILVA, Sakaerat Environmental Research Station ; Curt BARNES, Sakaerat Environmental Research Station ; Jacques HILL, University of Arkansas ; Taksin ARTCHAWAKOM, Sakaerat Environmental Research Station

The Big-eyed green pit viper (*Trimeresurus macrops*) is a venomous snake species, endemic to Southeast Asia. Although we have some knowledge of the systematics and toxicology of *T. macrops*, little is known about the spatial ecology of this species. Considering the increase in habitat fragmentation and isolation, it is important to study the impact of human presence and expansion on snake species. During 2013–2014, we used radio-telemetry to determine home-range sizes of 13 adult female *T. macrops* inhabiting Sakaerat Biosphere Reserve, a patchy landscape of undisturbed and disturbed habitats. We found that individual home ranges for *T. macrops* averaged 0.175 ha, with activity areas ranging from 0.112–0.303 ha and core areas ranging from 0.023–0.052 ha. There was little overlap between conspecific tracked females, especially for the most used areas of their home ranges. We did not detect significant differences in home ranges, movement patterns, or behavior between individuals living in forested areas and near the research station. Our study suggests that *T. macrops* are not significantly affected by human disturbance, likely due to their cryptic behavior and limited movement patterns.

It is proposed that metacommunity and phylogenetic structure encompasses assemblages of hosts and non-hosts that interact and influence pathogen spread and transmission in time and space but empirical data is lacking. Here we investigate the metacommunity structures and substructures of 4 zoonotic systems, across taxa and geographical areas. These include: (1) vectors (fleas) in rodent communities at local scales, (2) hosts and non-hosts rodents at local scales, (3) rodents (hosts and non-hosts) at continental scales, and 4) viral diversity in bat communities at regional scale. Our results show different structures including random, nested, and anti-nested with several substructures. Although no idealized structure is identified to describe host-non host and host-non host-parasite distributions across taxa or scales. We identify indeed that metacommunity and phylogenetic structure relates with both, the distribution and prevalence of parasites, and the distribution and abundances of host and non-host in different scales. Our results suggest that patterns observed at different scales relates to the ecological and phylogenetic assemblages involved in each system. Using a metacommunity approach, public health scientists may better evaluate the factors that predispose certain times and places for the origin and emergence of infectious diseases, and will provide important information for conservation biologists to identify emerging patterns that compromise diversity or ecosystem services.

88: THE BIG MOVE: HABITAT SELECTION, DISPERSAL AND REINTRODUCTION

Ronald Swaisgood

San Diego Zoo Institute for Conservation Research

Behavioral ecology has yet to be fully integrated into conservation biology, yet many behavioral processes are likely to influence the success of conservation programs. Habitat selection, particularly how dispersing animals choose where to settle, provides a rich theoretical framework generating testable hypotheses that can guide many conservation actions. Here I review how some of these ideas may be incorporated into conservation programs, with a focus on reintroduction biology. Perceptual and decision-making mechanisms in dispersers determine the distribution of members of a species on the landscape. Decisions made by dispersers sometimes run counter to goals set by conservation managers; for example, suitable habitat may be set aside but target species fail to settle there. Reintroduction and translocation programs suffer from high post-release mortality and long-distance, unpredictable dispersal behavior that exacerbates risks. These programs are essentially exercises in “forced dispersal” and thus lessons learned from dispersal ecology are informative. Several mechanisms are known to influence dispersal and settlement, including conspecific cueing and natal habitat preference induction (NHPI). The conspecific cueing hypothesis posits that dispersers rely on the presence of conspecifics to assess habitat suitability. Similar to the concept of habitat imprinting, NHPI occurs when an animal’s experience with its natal habitat shapes its post-dispersal preference for habitat settlement. Dispersers may not settle until they find “someplace like home” or “someone like me,” exposing themselves to the cumulative risks associated with long-distance movements. I explore the possibility that these and other mechanisms can be manipulated in pre- or post-release contexts to encourage animals to settle, quickly and safely, in appropriate protected habitat.

CITIZEN SCIENCE ONLINE: PRODUCING HIGH-QUALITY DATA FROM CAMERA TRAP IMAGES

Alexandra Swanson

University of Oxford

Margaret KOSMALA, University of Harvard

Remote monitoring networks, such as camera trap surveys, are revolutionizing wildlife conservation and research by providing large-scale monitoring in remote areas. However, these surveys often produce overwhelming amounts of imagery that create data-processing bottlenecks. Citizen science holds enormous potential to quickly process overwhelming numbers of images produced by remote camera surveys, but requires careful attention to data quality. Snapshot Serengeti, a project on the citizen science platform The Zooniverse (www.zooniverse.org) engages members of the general public to help process photographs produced by a large-scale camera survey operating in Serengeti National Park, Tanzania. Here I will present generalizable techniques utilized by Snapshot

Serengeti to rapidly and accurately classify 1.51 million images. On Snapshot Serengeti, volunteers classify species, number of individuals, and behaviors captured in each image. By circulating each image to multiple users, and then applying straightforward algorithms to aggregate answers, we produced expert-quality “consensus” data that has directly contributed to Serengeti monitoring. Since 2012, over 28,000 volunteers have contributed 13 million classifications on the 1.55 million images processed to date. Applying a “plurality” algorithm to raw classifications yielded a “consensus dataset” that was 97% accurate when compared to a gold-standard dataset of 4,149 expert-classified images. In this talk, I will explore 1) how the performance of this algorithm varies across species of varying difficulty and rarity, 2) how we can use measures of agreement among raw classifications to predict when consensus answers are likely to be correct, and 3) how many citizen-scientist classifications are required to produce reliable data with this algorithm. These analyses will help other science teams optimize similar citizen science projects for their specific data needs.

GREENING - BEST PRACTICE AND WORSE

Stanisław Świtek

Poznan University of Life Science

Victoria TAKACS, Poznan University of Life Science

One of the main thing New Common Agricultural Policy is Greening. Farmers have to follow new environmental rules to take payment. Pro ecological farm management should improve biodiversity, landscape quality and sustainable agriculture. In this case ecosystem services play also important role. One of the point of greening is EFA- Ecological Focus Area. This minimum 5% of total land area each farm have to be used ecologically friendly. The general aim of this paper is to contrast several ways of understanding this in practice on the example of Wielkopolska region, Western Poland. In Poland there were several ways of “green agricultural practice” in the past. In 2001 1,3mln ha of the agricultural land was characterized as a fallow land. Following EU accession the agro – environmental schemes made it possible to get subsidies for so called “Green agriculture”. In practice however there are several ways of understanding these ideas – all are sound legally, however the ecological, cultural and scenic value of them is different. Several types of “green agricultural practice” as field margins, grassland, forest belts are characterized using ortophotomaps and via contrasting them to old maps from the same area – supplementing this to statistical data on land cover at certain areas we can show trends. As a part of LIBERATION project we collected data on faunal and weed diversity from a long term experimental management (over 50 years non sown area – experimental station in Brody). Using these data we can show a clear evidence for the value of these green areas in increasing biodiversity. We argue that the scenic and biodiversity value

of traditionally managed “greening” is high – thus we should advocate this type of management.

EUROPE’S FRESHWATER BIODIVERSITY: PRIORITIES, PATTERNS AND GAPS IN CURRENT CONSERVATION

Marton Szabolcs

Hungarian Academy of Sciences, Centre for Ecological Research

Felicia KAPUSI, University of Debrecen, Department of Ecology ; Savrina CARRIZO, International Union for the Conservation of Nature, Freshwater Biodiversity Unit ; Danijela MARKOVIC, Leibniz-Institute of Freshwater Ecology and Inland Fisheries ; Jorg FREYHOF, German Center for Integrative Biodiversity Research ; Nuria CID, European Commission, Institute for Environment and Sustainability ; Ana-Cristina CARDOSO, European Commission, Institute for Environment and Sustainability ; Mathias SCHOLZ, Helmholtz Centre for Environmental Research, Department of Conservation Biology ; Hans D KASPERIDUS, Helmholtz Centre for Environmental Research, Department of Conservation Biology ; William R T DARWALL, International Union for the Conservation of Nature, Freshwater Biodiversity Unit ; Szabolcs LENGYEL, Hungarian Academy of Sciences, Centre for Ecological Research

Freshwater ecosystems host disproportionately high numbers of species relative to their surface area and are more threatened than marine or terrestrial ecosystems. Yet freshwater biodiversity is poorly protected globally, which necessitates scientifically sound prioritisation and evaluation of conservation effort. Our aim was to determine conservation priorities for 18,816 river and lake catchments of Europe (over 10 million km²) using data on the distribution of 1631 species of freshwater fishes, molluscs, odonates and aquatic plants while also considering their IUCN Red List category, range restriction and level of endemism. We used the MARXAN systematic conservation planning software to estimate the irreplaceability of catchments as a proxy for conservation priority. We found that catchments with high irreplaceability were mostly in the Balkan, Iberian and Italian peninsulas or in the Danube and Volga river systems. Starting the prioritisation with the inclusion of well-protected catchments resulted in clearer priorities and better coverage of threatened species. The correspondence between irreplaceability and proportion of protected areas was as expected in central and N Europe, whereas we found underprotection (high irreplaceability, low protection) in the Balkans and E Europe and overprotection (low irreplaceability, high protection) in NW Europe. Finally, starting the prioritisation with the exclusion of well-protected catchments further increased the priority of some S European catchments, which can thus be recommended for increased protection, management or restoration. Our study presents continental-scale conservation priorities based on a large

database of freshwater biodiversity by focusing on species conservation status, range-restriction and uniqueness of species assemblages and it contributes to a higher efficiency of the protection of freshwater biodiversity by providing relevant input for conservation policy and action.

STAKEHOLDER ATTITUDES AND OPINIONS REGARDING THE MANAGEMENT OF LARGE MAMMALS IN THE CARPATHIANS

László Szemethy

Szent István University, Institute for Wildlife Conservation
Zsolt BIRÓ, Szent István University, Institute for Wildlife Conservation ; Imre KOVÁCS, Szent István University, Institute for Wildlife Conservation ; Krisztián KATONA, Szent István University, Institute for Wildlife Conservation ; Patkó László, Szent István University

The Carpathians are one of the strongholds of the large carnivore and herbivore populations in Europe and form a cross-border bioregion. In the framework of the BioREGIO Carpathians SEE Project we collected Common Integrated Management Measure ideas, that should be implemented by the stakeholder groups and directly contribute to the long-term conservation of brown bear (*Ursus arctos*), grey wolf (*Canis lupus*), Eurasian lynx (*Lynx lynx*), red deer (*Cervus elaphus*), roe deer (*Capreolus capreolus*) and chamois (*Rupicapra rupicapra*). Based on the demand-driven concept of conservation we organized four stakeholder meetings in Hungary, Romania, Slovakia and Serbia, with 42, 50, 72 and 54 participants. Representatives of National Parks, universities, forestries, game managers, farmers, water management, nature conservation and tourism experts, as well as researchers, took part on these meetings. The ecological and socio-economic importance/impact, ecological and socio-economic conservation conflicts and threats, data requirement, accessible databases, problem solving system, integration of different interests were discussed. The ecological importance of the large mammals was generally not questioned. According to the stakeholders they increase the biodiversity, maintain the balance of the ecosystem and play an important role in the trophic web. The opinions about the problems of target species are different among the countries. The carnivores cause the most problems in Romania, while the herbivores are considered as problematic species mostly in Hungary. The main conflicts are based on the economic damages in case of both groups. The stakeholders generally agree with that, the accessible databases are quite poor and more realistic population data are needed in the conservation and planning. According to a frequent opinion, the stakeholders are often not involved enough in planning and management.

BROWN HARE AS AN INDICATOR SPECIES FOR AGRI-ENVIRONMENTAL PROGRAMS IN HUNGARY

László Szemethy

Institute for Wildlife Conservation

Norbert KELLER, Institute for Wildlife Conservation ; Sándor

CSÁNYI, Institute for Wildlife Conservation ; Imre KOVÁCS,

Institute for Wildlife Conservation ; Bálint TÓTH, Institute for

Wildlife Conservation ; Gergely SCHALLY, Institute for Wildlife

Conservation ; Zsolt BIRÓ, Institute for Wildlife Conservation;

Patkó László, Szent István University

Agri-environment schemes (AES) exist to enhance agricultural landscape's biodiversity all across Europe. Brown hare (*Lepus europaeus*) is one among the few useful AES mammal indicator species. Previous researches showed controversial data on the indicator effect of hares. Based on the population estimation and harvest data of 482 game management units (Hungarian National Game Management Database {NGMD}) we have analysed the effect of the Hungarian AEP (2007-2014) and red fox culling on brown hare population and harvest density. According to our hypothesis red fox culling and increasing AEP proportions will have beneficial effects on the hare population. Based on all the game managements units compiled data we have found that higher AEP proportion did not influence hare numbers, but it has a small negative effect on harvest density (linear regression). Cull index has a slightly positive impact of harvest density in every year. With natural breaks of the AEP proportions, we got significantly lower hare harvest density in the higher AEP category (Kruskall-Wallis with Dunn's test). Based on fox cull intensity we could separate three categories and found that larger culling index means more brown hares can be harvested (Kruskall-Wallis with Dunn's test). It seems that large AEP grasslands can affect brown hare population negatively, while arable lands have no detectable effect on large-scale in Hungary. We believe that AES protocols might not be well targeted on brown hares. More local fox control results in more obvious hare population increase. Yet, on a small-scale these effects might change, thus our future goal is to develop a theoretical model on how small-scale agri-environmental improvements can be beneficial for hares, and we also want to verify our models on a practical way at the fields.

SEX-SPECIFIC ADRENOCORTICAL RESPONSES IN BIRDS DEPEND ON THE PERIOD OF THE YEAR

Zulima Tablado

Swiss ornithological institute

In face of threatening situations, vertebrates activate an adrenocortical stress response aimed to help animals to escape

and promote survival. This response, however, is modulated according to factors such as sex or life history stage. In birds, it has been shown that during breeding stages the sex providing more parental care tends to dampen their stress response to favour brood success. However, little is known about non-breeding stages. That is why the aim of this study was to investigate how adrenocortical reactivity varies across periods of the year depending on sex. For this, we performed a comprehensive literature review and compiled information about sex-specific levels of baseline and stress corticosterone for numerous bird species in different life history stages (e.g. moult, wintering, and breeding). Then, we carried out a meta-analysis to examine the interaction between sex and season of the year on the adrenocortical response. We observed that, as shown in previous studies, females tended to have a lower reactivity than males during breeding season, although it depended on the parental care allocation of each species and the exact phase within the breeding season. However, in other periods of the year, there were no differences among sexes or even in some cases; we found the opposite trend with females having higher reactivity than males. Our results suggest that variation in stress responses not only depend on sex and period of the year, but also on the interaction between them. These findings could have important implications for interpreting and predicting the physiological response of animals to environmental stressors, such human disturbance and habitat degradation.

LINKING WOODLARK ABUNDANCE TO FOREST MANAGEMENT PRACTICE

Viktoria Takacs

University of Life Sciences

Tadeusz MIZERA, University of Life Sciences ; Dariusz KUJAWA,

Komitet Ochrony Orlow

Woodlark is a protected species included in Birds Directive - though in many areas still can be considered as common. This species adopted to the contemporary forest management practice - occupying clearings and young stands (<10 years), therefore to successful species conservation eventual The study site is one of the largest NATURA 2000 sites - Notec Forest (Western Poland). This is a large forest complex mostly consisting of planted scotch pine. As a part of N2k monitoring in 2010 we started a systematic woodlark survey in 20 randomly selected plots of 4 km². Within these plots all potential habitats for woodlark were controlled, minimum 3 times within the breeding season. The habitat was considered as occupied if a singing male occurred twice at the site. Our goal is to show the population trend of this species and face its habitat occupancy pattern to habitat characteristics (elevation, forest stand type and age habitat size and shape, presence of left-over trees) and forest management clues (these two are strongly correlated at the study sites). We used

QGIS and "Statistica" program packages for the data analysis. Altogether 320 woodlark pairs were found in the monitored area. The suitable habitat varied from The suitable habitats in the monitored plots were 539 to 397 Ha (varying among the years) within 234 to 252 habitats in a year within the monitored area. Within the study period a 40 % decrease occurred between 2010 and 2014, this cannot be explained by any of the factors. There was a strong correlation with the habitat size, also with the abundance of remaining tree spots on a clearing / young tree stands. Habitat shape, elevation and forest management activities did not influence the abundance patterns of woodlarks. The observed decline during the study period cannot be explained by the checked. Woodlark is still numerous in the Notec forest however, the observed trends call for special attention.

FACTORS INFLUENCING THE OCCURRENCE AND DISTRIBUTION OF THE ADMIRALTY ISLAND CUSCUS (*SPILOCUSCUS KRAEMERI*), MANUS ISLAND, PAPUA NEW GUINEA

Wallace Takendu

Wildlife Conservation Society Papua New Guinea

The Admiralty Island Cuscus *Spilocuscus kraemeri* is a cryptic and elusive cat-sized member of the Phalangeridae family which is endemic to the Admiralty group of Islands, Papua New Guinea. Despite the importance of the animal in the local diet as the primary source of terrestrial protein and widespread concerns over the sustainability of the harvest, little is known of the ecology of the species. In this study we investigated the factors affecting the occurrence, relative density and distribution of *S.kraemeri* on Manus Island through a network of camera traps (13 May – 14 June 2013). Our study focused on three traditional villages on the north coast of Manus Island: Tulu 1, Tulu 2, and Lahapau. Camera traps were placed on arboreal crossings (tree branches which allowed cuscus to cross village tracks in the forest without descending to the ground). Count data from photo capture events together with environmental data were modelled through generalised linear models in program R while presence-absence data was modelled through a variable detection probability occupancy method in program MARK. We used a model selection framework to analyse a suite of candidate models to identify the factors had the greatest influence. The occupancy analysis revealed two distinct clusters amongst the villages: Lahapau had the highest occupancy and detection probability ($\hat{N} \pm = 1$, $p=0.40$) while Tulu 1 and Tulu 2 formed a single cluster with lower occupancy and detection probability ($\hat{N} \pm = 0.50$, $p=0.25$). Both the generalised linear modelling and occupancy analyses highlighted the importance of vegetation type (a preference for secondary forest) and to lesser a role for canopy cover and tree height. On this basis we recommend the development of

community driven land-use plans for Tulu 1 and Tulu 2 in order to help sustain the local cuscus populations.

ONLINE LEARNING: HOW CAN WE BEST USE IT TO STRENGTHEN CAPACITY FOR CONSERVATION?

Lucy Tallents

University of Oxford

Rajan AMIN, Zoological Society of London ; David MACDONALD, University of Oxford

Online learning offers a new path to cost-efficient capacity-building. It has the potential to overcome challenges of traditional face-to-face teaching such as the diversity and geographic dispersion of training needs, fitting classroom study around the demands of field schedules, and the limited availability of trainers. However, the new paradigm poses many questions. How does the quality of learning compare with face-to-face workshops? How do participants experience and value online learning in comparison to classroom training? How do we teach practical conservation skills in a virtual environment? How likely are people to complete the course, and how confident are they in applying their new skills? Online learning promises exciting possibilities for greater flexibility in the pace and breadth of learning, and better support and engagement of non-native speakers. By connecting practitioners across the globe, it highlights how conservation problems and their solutions aren't constrained by geographic boundaries. Conversely, barriers include differing cultural expectations, the reliability of internet access, and the difficulty of motivating people to study in physical isolation and with competing demands on their attention. Based on our experience creating and teaching online courses, we describe different approaches and explore the strengths and weaknesses of online versus face-to-face teaching for conservation. We summarise what to consider when commissioning, creating or teaching online courses, and address how online training can complement and extend existing efforts to strengthen conservation capacity globally.

EXTINCTION AND INVASION RISK ARE NOT TWO SIDES OF THE SAME COIN, AT LEAST NOT FOR REPTILES

Aimee Tallian

Utah State University

Reid TINGLEY, The University of Melbourne ; Peter MAHONEY, Utah State University ; Andrew DURSO, Utah State University ; Alejandra MORÁN-ORDÓÑEZ, The University of Melbourne ; Karen BEARD, Utah State University

Anthropogenic activities homogenize biodiversity by increasing extinction risk, while simultaneously facilitating the transition of species through each stage of the invasion pathway. It is often assumed that trait values that predispose

species to become either threatened or invasive (i.e., those associated with population growth rates) lie on opposite ends of a continuum (i.e., the ‘two sides of the same coin’ hypothesis). In contrast, we might assume that anthropogenic threats will have analogous effects on threatened and invasive species. To test these hypotheses, we compared 1) extinction risk of 765 threatened and least concerned reptile species, and 2) 302 introduced established and non-established reptile species around the globe using a Bayesian generalized linear mixed model with a binomial response that accounted for confounding effects. Comparing predictors of threat status and invasion success in reptiles revealed little support for the two sides of the same coin hypothesis. Only 50% of model coefficients describing 12 aspects of a species’ life-history, ecology, geographic origin, and environmental niche breadth were opposite in sign between the two groups. The variables showing strong and opposing relationships were body size, insularity, and parthenogenesis. Larger-bodied, non-parthenogenetic species that exclusively occupied islands were more likely to be threatened, whereas small-bodied, parthenogenetic species that were not island endemics were more likely to become invasive. Variables relating to anthropogenic threats showed the opposite pattern. The strongest variable was mean human population density across a species’ native geographic range, which had a strong positive effect on both threat and invasion probability. Our results support the notion that threat status and establishment success can be predicted using a combination of species traits and anthropogenic threats, but that not all variables will follow the two coins hypothesis.

177 - PAWS : RANDOMIZED PATROLS FOR WILDLIFE SECURITY

Milind Tambe

University of Southern California

Optimizing the use of limited security resources, e.g., patrols, is a critical concern in protected areas where organizations are focused on wildlife security. Limited security resources must be scheduled efficiently, simultaneously taking into account how actors engage in illegal activities in protected areas may respond to security coverage, and any past available data about previous patrols and adversary actions. This talk will present PAWS, Protection Assistant for Wildlife Security, a decision aid for security resource optimization that builds on our previous work. Specifically, to help in generating efficient and randomized patrols and security resource allocation more generally, we build on past research in “security games”. Security games is a novel area of research that is founded on computational and behavioral game theory and machine learning. Research in security games has allowed us to build decision-aids for a number of security agencies in the United

States. These decision aids have been deployed for security of ports and ferry traffic with the US coast guard (in the ports of New York, Boston, Los Angeles/Long Beach, Houston and others), deployed for security of airports and air traffic with the Federal Air Marshals (FAMS) and evaluated for assisting police in deployment against urban crime in the Los Angeles area. While building on this past work in security games, PAWS leads the way in “green security games”, focused on protection of forests, fish and wildlife. PAWS complements current tools available to security organizations such as MIST and SMART; it uses data collected by these tools in planning for the future using the predictive model it learns of adversary behavior. PAWS was earlier tested at various sites, e.g., Queen Elizabeth National Park in Uganda, providing us feedback on its efficiency. This presentation will discuss PAWS and the interdisciplinary research issues it raises.

15 POTENTIAL INTERACTIONS BETWEEN BIODIVERSITY-BASED ECOSYSTEM SERVICES SUPPORTING MAJOR EUROPEAN CROPPING SYSTEMS

Giovanni Tamburini

University of Padova

Riccardo BOMMARCO, Swedish University of Agricultural Sciences ; Lorenzo Marini, University of Padova

Yield formation is sustained and regulated by bundles of ecosystem services delivered by above- and belowground biodiversity. Ignoring potential interactions occurring between different ecosystem services may lead to unwanted tradeoffs and synergies, resulting in unexpected outcomes when turned into management practices. Although pollination is an important service to agriculture that has recently received great attention, it has been usually studied in isolation. Using several manipulative experiments, we studied potential interactions between soil services and pollination for two important European crops, oilseed rape and sunflower. In both crops, pollination benefits to yield formation were strongly influenced by soil services, although the response was crop-dependent. In sunflower, benefits to crop yield from insect pollination were observable only under good soil fertility conditions whereas they were canceled in highly deteriorated soils. In oilseed rape, decreased nitrogen inputs enhanced pollination benefits to yield, indicating that nitrogen use efficiency increased with optimal insect pollination. Hence, fertilizer applications can partly compensate degraded pollination service whereas optimal pollination can compensate for low nitrogen inputs. Management practices that aim to augment insect pollination should include not only measures to enhance pollinator abundance and diversity but also measures to improve soil fertility together with accurate application of inorganic fertilizers. Currently, economic evaluation of multiple ecosystem services is primarily based on land-cover mapping

assuming an additive effect of the different services. Expanding our knowledge about service interactions and making them explicit in the available predictive models will improve our ability to define sustainable management strategies both at the local and regional scale.

CONSERVATION TILLAGE MITIGATES THE NEGATIVE EFFECT OF LANDSCAPE SIMPLIFICATION ON BIOLOGICAL CONTROL

Giovanni Tamburini

University of Padova

Serena DE SIMONE, University of Udine ; Maurizia SIGURA, University of Udine ; Francesco BOSCUCCI, University of Udine ; Lorenzo MARINI, University of Padova

Pest biological control (BC) is a key ecosystem service and it depends on multiple factors acting from the local to the landscape scale. However, the effects of soil management on BC and its potential interaction with landscape are still poorly understood. In a field exclusion experiment, we explored the relative effect of tillage system (conservation vs. conventional tillage) on aphid BC in 15 pairs of winter cereal fields (barley and wheat) selected along a gradient of landscape complexity. We sampled the abundance of the main natural enemy guilds and we evaluated their relative contribution to aphid predation and parasitism. Conservation tillage was found to support more abundant predator communities and higher predation (16% higher than in the fields managed under conventional tillage). In particular, both the abundance and the predation of vegetation- and ground-dwelling arthropods were considerably increased under conservation tillage conditions. Conservation tillage also increased parasitism. High proportion of semi-natural habitats in the landscape enhanced both aphid parasitism and predation by vegetation-dwelling organisms but only in the fields managed under conventional tillage showing that the better local habitat quality provided by conservation tillage may compensate for a low-quality landscape. Our study stresses the importance of considering both soil management and landscape composition when planning strategies for maximize BC service in agro-ecosystems, highlighting the role played by conservation tillage in supporting natural enemy communities. The benefits obtained by introducing conservation tillage will, however, depend on landscape composition. In simple landscapes, the adoption of conservation tillage will locally improve the BC provided by both predators and parasitoids mitigating the negative effects of landscape simplification.

INSPIRING FUTURE GENERATIONS OF CONSERVATION LEADERS AND STEWARDS IN PRIMATE RANGE COUNTRIES

Chia Luen Tan

San Diego Zoo Institute for Conservation Research

Most nonhuman primate species are distributed in tropical and subtropical regions, and many countries in these regions, particularly Asia and Africa (Madagascar included), are densely populated by humans often living in impoverished conditions. As approximately 40% of nonhuman primate taxa in these geographic areas are threatened by human activities, we need more than hope to ensure a future for our closest relatives. Investing in in-country conservation talents and improving children's education are two important ways that can lead to meaningful, long-term conservation solutions. This presentation will feature two programs I created in Asia using a global partnership approach to cultivate range country conservation leaders and foster local conservation stewards. The Training in Primatology Series (TIPS) is a no-fee, professional development program with practical workshops and mentoring support tailored toward early career conservation practitioners for the purpose of elevating their core, leadership and professional competencies. The Little Green Guards (LGG) is an education program that fosters appreciation and understanding of wildlife in children, especially those living in and around critical habitats with threatened primate populations. As many TIPS alumni now serve as role models or "conservation heroes" for local children and lead in-country LGG initiatives, the synergistic effect created by these two programs cannot be overstated. Examples of both programs have been adopted in other geographic regions where primate species and habitat conservation are a top priority.

IMPROVING CAMERA TRAP PERFORMANCE ENHANCES LONG-TERM ECOLOGICAL STUDIES

Chia Luen Tan

San Diego Zoo Institute for Conservation Research
Rose Marie RANDRIANARISON, Groupe d'Etude et de Recherche sur les Primates de Madagascar ; Cristina GIACOMA, University of Turin ; John Andrew PHILLIPS, LVDI International

Scientific field studies aimed at remotely monitoring natural animal populations frequently employ camera trap technology. The reliability of data derived from such studies is often dependent upon continuous operation of commercially available trail cameras originally designed for short-term use by hunters. Limited battery life and camera malfunction caused by moisture accumulation inside the camera housing are common issues reported. To overcome these technical problems, we tested if simple, inexpensive modifications to a commercially available model would allow cameras to operate continuously and untended for periods of over 12 months, even in high humidity, low temperature environments. First, under controlled but variable conditions, we examined the

effects of ambient temperature on battery life and length of operation of cameras, as well as how moisture infiltrates the camera housing. We then devised solutions that eliminate moisture incursion in the camera housing, and designed an inexpensive subterranean external battery pack that increases battery performance by relying on the nominal annual fluctuations in ambient ground temperature. We subsequently tested 5 camera traps incorporating these modifications in a 12-month study in a rainforest in Madagascar. All cameras operated continuously throughout the study period with no degradation in image quality when powered by our specially designed external battery pack (LVDI-4F). Also, the external battery setup extended the lifespan of the cameras while simultaneously minimizing human disturbance at each camera trap location. Accordingly, our camera trap data have identified long-term ecological trends among potentially competing species, as well as captured glimpses of elusive species and rare predation events. Our technical improvements are applicable to most brands of camera traps and should lead to successful long-term, continuous research and monitoring of wildlife under varied field conditions.

REPRESENTATION OF THE PROTECTED AREA SYSTEMS IN THE INDO-BURMA HOTSPOT: INCREASING COMPLETENESS

Naruemon Tantipisanuh

KMUTT

Tommaso SAVINI, KMUTT; George GALE, KMUTT

The designation of protected areas in the past has been clearly biased toward specific habitat types, resulting in insufficient representation of several habitats and their associated species. This study identified gaps in current protected area systems of the Indo-Burma Hotspot, proposed additional areas which could be included in such systems to increase their overall representation, and identified high priority areas. Representations of habitat types and 199 threatened species were assessed using gap analysis. Areas which could be potentially added to improve the current protected area system were identified using MARXAN software, while high priority areas were selected based on irreplaceability and vulnerability. From the gap analysis, the representations of biodiversity in the Indo-Burma Hotspot were notably skewed for both habitats and species. To achieve the representation targets for all conservation features, 21% of the hotspot's entire land area would need to be included in a protected area system. Approximately two-third of the proposed additional areas were smaller than 10 sq.km., while most of the large (>1,000 sq.km.) proposed areas were located in Myanmar and Cambodia. Many of the suggested additional areas are located along the borders between multiple countries. Four of the five largest high priority areas are located in Thailand. In conclusion, protected areas in the Indo-Burma Hotspot can be significantly

improved by focusing on maintaining as well as restoring linkages between smaller patches to create and sustain larger protected area networks. As part of this, transboundary collaboration among countries within this hotspot will be particularly important.

BUILDING CAPACITY FOR BIODIVERSITY CONSERVATION IN UKRAINE: NETWORK AND TRAINING SUPPORT

Olena Tarasova-Krasiieva

National University of Kyiv-Mohyla Academy

Natalia GUDKOVA, State Environmental Academy of Postgraduate Education and Management at the Ministry of Ecology; Natalia GOZAK, National University of Kyiv-Mohyla Academy

The project was implemented co-financed by MAVA FONDATION POUR LA NATURE and MATRA Programme Embassy of the Netherlands in cooperation with the Centre of Biodiversity and Conservation at the American Museum of Natural History in New York (09.2012 - 09.2014). The overall goal of the project was to assist Ukraine in fulfillment of its obligations under the Convention on Biodiversity, especially Articles 12 and 13 on setting educational programmes. The target group included students, conservation practitioners, managers and educators who represent both governmental and non-governmental sectors (protected areas, universities, NGOs, business and local authorities in charge of coordination of conservation activities). A core set of 24 modular educational resources on key topics in biodiversity conservation were developed, adapted, and disseminated among academic institutions (78 universities), protected areas (148 representatives), business companies (80 members of Global Compact), and local relevant authorities. A case study competition was held, and 3 Ukrainian case studies on biodiversity conservation were included into the educational modules as examples of good practices. As a result of project Ukrainian Network of Conservation Educators and Practitioners was established. As project activities were highly evaluated by Ministry of Ecology and Natural Resources in Ukraine, a training on biodiversity conservation will be conducted in the State Environmental Academy of Postgraduate Education and Management at the Ministry of Ecology. The course was also recommended by National University of Kyiv-Mohyla Academy, Department of Ecology for Master level.

ORAL PRESENTATION

Kanuma Nathan Taremwa

University of Rwanda

Thimmayiah RANGANATHAN, Gandhigram Rural University (GRU); Jean Lambert SEBAREZE, World Vision Rwanda

Protected Areas in Rwanda have continued to face serious problems and are at the risk of declining despite efforts made to conserve them. Currently, 79 percent of Rwanda's land is classified as agricultural; 11 percent of total land is permanent cropland, of which only 0.6 percent is irrigated. Six percent of the land is marshland, and about 20 percent of total land is classified as forests and only 8 percent of total land area is in PAs. Akagera National Park (ANP), one of the major Protected Areas in Rwanda is threatened by human pressure following the high demand for grazing together with conflicts between wildlife and agriculture. The objectives of the study were to: (i) to assess the impact of household behavior on the conservation of protected areas; (ii) to determine the nature and extent of the current relationship or dependence of the adjacent community to ANP. Data was collected from 66 households around ANP from the communities within 5 Km from the park boundaries. Research instruments applied in data collection mainly included questionnaire, interview schedules and Focus Group Discussions (FGDs). Descriptive statistics and logistic regression were run for data analysis. Findings indicated that the adjacent communities to ANP highly depend on park mainly through livestock grazing which consequently have a negative impact on conservation of biodiversity within the park. Impact has been observed through habitat alteration, erosion, disease transmission and wildlife extinction. Crop raiding, lack of compensation policy to crop damage and lack of effective law enforcement policy were the major challenges affecting the adjacent communities. Due to competing claims for resources from ANP, the conservation objectives and community livelihood improvement requires concerted efforts from various stakeholders in Rwanda. Market based mechanisms are very essential to mitigate the impact of community behavior on the national parks of Rwanda.

FIRE MANAGEMENT FOR CONSERVATION IN A MEGA-DIVERSE AND HIGHLY FLAMMABLE WORLD HERITAGE AREA: A COLLABORATIVE PARTNERSHIP BETWEEN SCIENTISTS AND LAND MANAGERS IN THE BLUE MOUNTAINS, AUSTRALIA

Elizabeth Tasker

Office of Environment & Heritage NSW

Kathryn HAMMILL, Office of Environment & Heritage NSW

The Greater Blue Mountains is a UNESCO-listed World Heritage Area of international conservation significance. More than a million hectares of native vegetation on the western fringes of Sydney, its wild and rugged landscapes are home to a high biodiversity with more than 400 species of vertebrate animals, 484 genera of plants, of which 114 species are endemic, including the very rare Wollemi Pine. It is also one

of the most flammable landscapes on earth. Fires occur every year, and once or twice per decade massive bushfires burn a large proportion of the region and can result in significant property losses. Climate change predictions suggest that the frequency and severity of fires may increase. The paradox is that a large proportion of the plants and ecosystems of the region need fire (e.g. more than 1,000 species depend on fire to break the dormancy of their seeds). Thus managers have a complex challenge. In this collaborative science-management project we have compiled a fire history of unprecedented spatial (1 million hectares) and temporal (40+ years) coverage. We have combined this with life history information for more than a thousand plant species, and with vegetation surveys, to better understand the patterns and causes of fire in the landscape, and the impacts on biodiversity. Over the past four decades more than 80% of the World Heritage Area has burnt, with up to 25% in a single year. While successive fires mostly burn different areas, we have identified a series of hotspots of conservation concern where repeated high intensity and/or too-frequent fires have occurred. Our floristic surveys in these areas suggest that the biggest effect of adverse fire regimes is on vegetation structure, with a surprising resilience of the floral diversity, even for many rainforest plants. The results are now being used in conservation and fire management planning of this iconic World Heritage Area.

EVIDENCE FOR THE DISTURBANCE OF BATS BY SMALL SCALE TURBINES IN THE UK

Cerian Tatchley

University of Stirling

Kirsty PARK, University of Stirling; Jeroen MINDERMAN, University of St Andrews

Wind power is an increasingly important method of electricity generation employed worldwide. While much of the focus in wind energy technology to date has been on wind farms, a relatively recent development is the expansion of the micro-wind sector (turbines generating < 50 kW), and there are now over 800,000 small wind turbines (SWTs) installed globally. There are a range of potential negative effects wind power can exert on wildlife and quantification of the potential wildlife impacts is necessary to inform planning guidance. Yet to date, there has been little research into the wildlife impacts of SWTs. We present the results of a field experiment investigating the impact of SWTs on bat activity with particular focus on the role of distance from known favoured bat foraging habitat (e.g. hedgerows, treelines). *Pipistrellus pygmaeus* activity declined near to operating turbines installed close to hedgerows (5m distance), while *Pipistrellus pipistrellus* activity declined only marginally after SWT installation, both at the turbine and at a control site 30m away. Activity of both species declined rapidly with distance from the hedgerow. This highlights the importance of installing SWTs away from linear habitat features

to reduce their disturbance impact on bats. These results will contribute to quantifying a minimum installation distance from linear habitat features needed to minimise any disturbance impact on bats.

INBREEDING DEPRESSION IN TRANSLOCATED POPULATIONS OF A RECOVERING RATITE: THE LITTLE SPOTTED KIWI (APTERYX OWENII)

Helen Ruth Taylor

Allan Wilson Centre, University of Otago
Nicola J NELSON, Allan Wilson Centre, Victoria University of Wellington ; Hugh A ROBERTSON, Department of Conservation ; Fred W ALLENDORF, University of Montana ; Kristina M RAMSTAD, Allan Wilson Centre, Victoria University of Wellington

Translocations are a necessary and popular conservation tool, but often involve populations being founded with small numbers of individuals. This creates population bottlenecks that can lead to a loss of genetic diversity relative to the source population, inbreeding, and inbreeding depression. However, few studies have investigated these effects in wild populations founded via translocation. We studied genetic erosion and inbreeding depression in New Zealand's little spotted kiwi (*Apteryx owenii*) (LSK), a species that experienced a bottleneck of, at most, five individuals ~100 years ago and has been managed solely via translocations ever since. Our work focused on two seemingly healthy (i.e., growing) translocated populations of LSK; one founded with 40 individuals and the other with just 2 birds, all from the same source population. Using a suite of 21 microsatellite markers developed for this species, we show that i) the 40 founder population has retained all the allelic diversity of the source population, but the population founded with 2 individuals exhibits severely reduced allelic diversity, (ii) both populations show continued erosion of heterozygosity over generations, indicating an on-going bottleneck in each site, (iii) the recorded growth in the population with 2 founders is mainly driven by first generation individuals (i.e., the offspring of the 2 founders) with only 26% of the population comprised of subsequent generation inbred individuals and (iv) this inbreeding depression particularly affects females. Our findings highlight the importance of selecting sufficient numbers of founders for translocations, the potential for on-going genetic erosion following bottlenecks and the impact that inbreeding depression can have on a population's demography. We also stress the need for genetic monitoring in order to avoid the failure of conservation translocations.

SEEDS OF DESTRUCTION? MEASURING SPERM HEALTH IN BIRD SPECIES WITH RECENT POPULATION BOTTLENECKS

Helen Ruth Taylor

Allan Wilson Centre, University of Otago
James V BRISKIE, University of Canterbury ; Neil J GEMMELL, Allan Wilson Centre, University of Otago

In the midst of the current extinction crisis, severe population bottlenecks have become increasingly common. These bottlenecks can lead to loss of genetic diversity, and increased inbreeding and inbreeding depression. Although the negative impacts of low genetic diversity and inbreeding are clear, the underlying mechanisms driving loss of fitness are not yet fully understood. One neglected area in which inbreeding depression often manifests is male reproductive fitness. Sperm quality (sperm count, motility and percentage of abnormal sperm) has been shown to be related to fertility in a variety of species and is known to be negatively associated with inbreeding. However sperm health (in particular motility) can be challenging to measure in wild populations. We are conducting the first ever assessment of bird sperm health in New Zealand, a country where the majority of native species have experienced recent population bottlenecks. We have developed a new "mobile lab" facility that can be taken to remote sites and used to assess bird sperm motility in situ, almost immediately on collection of semen samples. Here, we focus on the South Island robin (*Petroica australis australis*), which has experienced a number of translocation-induced bottlenecks in the past few decades. By comparing males from populations founded by translocation with those in the original source population, we are able to illustrate the negative effects of population bottlenecks on sperm motility and, thus, fertility. Inbred robins are known to exhibit higher nest failure than less inbred individuals and our sperm data suggests that at least some of these failures are due to infertility as a result of reduced genetic diversity and increased inbreeding. We will discuss the implications of this for species management (in particular conservation translocations) as well as explaining how the techniques implemented here could be extended to provide data for a wide range of bird species.

RAD-SEQUENCING AND SNP GENOTYPING TO EXAMINE ADAPTATION IN GLOBALLY INVASIVE PARAKEETS

James Taylor

DICE
Jim GROOMBRIDGE, DICE

The ringneck parakeet *Psittacula krameri*, native to the African and Indian continents, is now a globally introduced species with the current UK population now numbering over 30,000

birds. Evidence from the native range suggests that the species may become invasive in introduced regions, impacting upon native biodiversity and agriculture. The spread of invasive species is considered one of the greatest ecological and economical threats to our planet and the need to further understand how species adapt to and succeed in, their new environments is essential. European ringneck parakeet populations have conquered a substantial temperature gradient in expanding from their native range, adapting to environmental change and subsequently provide an ideal scientific framework to examine how species evolve in response to environmental change and to identify the potential genetic basis for such adaptability and invasion success. By identifying single nucleotide polymorphisms (SNP's) within ringneck parakeets and using these genetic markers to compare the level and type of genetic diversity between their native and introduced ranges we can potentially capture signatures of adaptation to the extremes of the climatic gradient across which the species has spread RAD sequencing is a reduced-representation technique, employing next generation DNA sequencing. The technique allows for comprehensive identification of genetic markers (RAD markers) across the genome for population analysis, without having to sequence the entire genome itself. This allows us to identify areas of the ringneck parakeet genome that may be responsible for the behavioural flexibility seen in the species that have resulted in successful adaptation. Such a framework may also be applicable to other species and represent a step forward in our understanding of how species may respond to future climate change.

ASSESSING THE QUALITY OF THE GREAT BARRIER REEF'S CURRENT PROTECTED AREAS IN TERMS OF CONNECTIVITY AND HABITAT QUALITY

Matthieu Taymans

Université Catholique de Louvain

Christopher THOMAS, Université Catholique de Louvain ; Jolan WOLTER, Université Catholique de Louvain ; Jérôme MALLEFET, Université Catholique de Louvain ; Alana GRECH, Macquarie University ; Emmanuel HANERT, Université Catholique de Louvain

Over the last 30 years, the Great Barrier Reef (GBR) has lost about half of its coral cover due to key ecosystem-level pressures such as industrial development in coastal areas, overfishing and climate change. In the past decades considerable efforts have progressively been made in order to improve the protection of this outstanding natural icon. Since 2003, the implementation of protection areas has become a primary management tool for biodiversity conservation as it regulates the activities allowed to take place in the GBR. Since then, a minimum of 20 percent of all 70 bioregions has been protected. Despite this amount of management efforts and

the benefits they provided, this ecosystem's health continues to decline. The rate of exchange of larvae, or connectivity, among populations affects the ecosystem's ability to recover after disturbance events. The presence of marine protected areas (MPA) and their ability to provide other reefs with larvae for recovery could play a big role in enhancing the resilience of the whole ecosystem. Our study exploits the numerical hydrodynamic SLIM model (Second-generation Louvain-la-Neuve Ice-Ocean Model) to assess the role of existing MPA's in the resilience they confer to other areas through the transfer of larvae. The simulation of coral and fish larvae dispersion allows us to observe the strength of the connections between reefs and to identify key reefs in the network the GBR forms. Studying the habitat characteristics of such reefs through GIS analysis of environmental data enables us to better understand what makes a reef particularly important. Assessing whether or not the current protected areas contain such reefs and analysing the way reefs in those areas are connected to other reefs help us apprehend the pertinence of the current MPA's. The results of our analysis could be used in order to assess the quality of the current MPA network and to point out its drawbacks, hence enabling the managing sphere to improve it.

SUSTAINABLE MANAGEMENT OF LOVOA TRICHILIOIDES HARMS: PHENOLOGY AND NATURAL REGENERATION IN NATURAL FOREST AND PLANTATION.

Felenou I Tchinnmegni

Higher Institute of Environmental Science

Alain Calice Tsobeng, World Agroforestry Centre ; Eddy Ngonkeu, University of Yaoundé I ; Zacharie Tchoundjeu, World Agroforestry Centre

A study on phenology and natural regeneration of *Lovoa trichilioides* had been conducted in the Kienké-Sud Reserve and Deng-Deng Rserve. Our study was also conducted in the following Forest Management Unit: 10 021 (GVI) and 10 01-2-3-4 (CFC). The specific objectives were firstly to describe the actual state of the forest plantations, secondly to characterise the phenology of *L. trichilioides* and thirdly to evaluate the natural regeneration of this species. Two sets of data were used; Primary and secondary data. The data analysis has led to the following results. The forest plantations were created in the 70s following the regrowth and line planting method. These forest plantations hadn't undergone any silvicultural treatments for at least ten years. Human activities in these forests plantations are noticeable. The flowering occurs between April and May followed by fruit bearing. The maturity of occurs by the end of the year (November to December) followed by seed dissemination. The dimensions of the lives before flowering are approximately the double of the dimension after flowering (9.6 x 4.8 cm against 4.8 x 2.2 cm) The density of seedlings per hectare varies from 12310 to 20461 in forest plantation

according to the stand density. This density varies from 1014 to 47083 seedlings per hectare in natural forest according to the degree of forest perturbation. *L. trichilioides* requires more light to perform its growth and its development; it can't tolerate the competition for light at the early stage. Due to this reason, young trees are very scarce and even absent in forest plantation and natural forest. Its natural regeneration is negligible and even inexistent because only less than 1% of seedlings emerges and become a big tree. *L. trichilioides* is a semigregarious species which dissemination can't exceed a distance of 40 meters from the seed tree.

99-ONE SIZE DOES NOT FIT ALL: CASE STUDIES IN USING VALUES FRAMING FOR CONNECTING FAMILIES TO NATURE

Tara Teel

Colorado State University
Michael MANFREDO, Colorado State University; Brett BRUYERE, Colorado State University; Rebecca THOMAS, Colorado State University

Societal changes occurring as a result of modernization are tied to a decrease in direct day-to-day interaction with nature which in turn has implications for human health and future commitment to natural resource stewardship. While conservation agencies and organizations increasingly embrace the need to address this phenomenon by connecting people with nature through educational initiatives, programs are often focused on traditional constituents and/or those already engaged in nature-based activities. Recent research on human values toward wildlife in the United States provides a framework for thinking about ways to improve these initiatives in the face of changing societal conditions. Findings highlight the need for tailored approaches that readily attend to the diversity of values in contemporary society, advancing the notion that individuals are more inclined to participate in programs consistent with their pre-existing value set. Building from this prior work, the purpose of our study was to develop, implement, and evaluate pilot programs for connecting families to nature that account for the wildlife values of the public in six locations throughout the U.S.: Spearfish, South Dakota; Ka'u, Hawaii; Helena, Montana; Raleigh, North Carolina; New York, New York; and Lincoln, Nebraska. Program development was informed by qualitative (e.g., focus groups) and quantitative (e.g., surveys) research assessments of value orientations toward wildlife and nature, barriers to program participation, and preferences for program formats and content. Lessons learned from this study offer guidance for conservation practitioners wanting to expand the reach and effectiveness of their educational efforts to connect people with the natural environment and garner broad-based support for conservation initiatives in the future.

BUSY OCEAN: DOES ANTHROPOGENIC ACTIVITIES AT SEA AFFECT CETACEAN SPATIAL DISTRIBUTION? A CASE STUDY IN MALTA

Ana Tejedor

Kai Marine Services
Bruno CLARO, Kai Marine Services; Ricardo SAGARMINAGA, Kai Marine Services; Natacha AGUILAR, BIOECOMAC - University of La Laguna; Salvador SÁNCHEZ, BIOECOMAC - University of La Laguna; Lorenzo BRAMANTI, LECOB - Observatoire Océanologique de Banyuls; Sylvia FREY, OceanCare

The information about the spatial interactions between anthropogenic activities and top-predators, such as cetaceans, is fundamental for reducing conflicts between direct users of marine and coastal resources. The mapping of such information is an essential tool that facilitates decision-making for ecosystem-based management. Due to its small scale, the Maltese waters provide a unique opportunity to study this issue at a national level. Data from two research campaigns of LIFE+ Migrate project (2013-2014) was used to perform a geographic descriptive analysis of cetaceans and human activities. The study area was divided into a 10 km resolution grid, and a probability of occurrence was calculated for the presence of cetaceans and each of the selected human activities. Three anthropogenic activities were selected, involving cargo ships, sport motorboats and FADs (Fishing Aggregating Devices). Percent volume contours of 95% and 50% were used to spatially represent the probability density distribution for cetaceans in the area. Results suggested an inverse relationship between abundance of cetaceans and the presence of cargos and sport motorboats. This work presents key data for a successful marine spatial planning in Maltese waters that contribute to cetacean conservation.

INNOVATIVE INSTRUMENTS FOR MANAGING AND CONSERVING URBAN ECOLOGY - SELECT CASE FROM INDIA

Surayya Teki

Adikavi nannaya university

Sustainable urban ecological development warrants Greening cities (surroundings). This drive can be materialized at two levels viz. 1) organizational / institutional level and 2) Individual households. That requires financial outlays. Apart from traditional exchequer budget allocations, innovative financial instruments to raise funds includes levying cess on building plan approval tax by local administrative bodies (municipal corporation and Municipalities), provisioning in Corporate Social Responsibility (CSR) and Individual Social (S. Teki-2011) Responsibility (ISR), Public, Private and People Participation (PPPPs) and soft loans to individual households etc. Urban

agriculture, including growing fruits, vegetables, cereals, pulses, flowers, corn etc., on roof / window tops, on balconies. This would render multi benefits viz. a) supply of fresh and pure food stuffs and flowers, b) financial gains, empirical evidence shows, with about Rs. 12,000 capital expenditure and about Rs. 8000, revenue / maintenance expenditure (per annum) one can get 5 to 6 times returns, c) contributes for sustainable city development and d) managing climate change.

SMART FIRE MONITORING

William Temperley

Joint Research Centre of the European Commission
Ilaria PALUMBO, Joint Research Centre of the European Commission ; Raj AMIN, ZSL ; Steven PEEDELL, Joint Research Centre of the European Commission

Within tropical ecosystems, fire is a widespread natural phenomenon as well as a result of human activities, such as land clearance for agriculture. Poachers notoriously use fire to clear vegetation to control movement of wild animals and increase their visibility. Information on fire occurrence is therefore essential to track and identify human induced threats and pressures and quickly react to them. A standardized law enforcement and ecological monitoring and reporting tool, called SMART, has been developed by a partnership of conservation institutions for strategic management of conservation areas. In this context we are developing a Fire Monitoring plugin for SMART which will provide access to satellite data of fire occurrence. Fire occurrence can be tracked in near-real time using publicly available NASA-FIRMS fire products derived from the MODIS sensor. Although these data are freely available, significant technical barriers prevent their usage where they are needed most, such as in protected areas. Our aim is to ensure conservation practitioners can access this information in the simplest and most timely manner possible. A plugin has been developed which retrieves MODIS fire information and integrates this into the SMART data model, thereby providing query and reporting tools built into SMART direct access to fire occurrence and burned area data. The near real-time nature of the fire information, combined with field derived intelligence provides opportunities for active management. Historical fire information (from 2002 onwards) can also be retrieved, which can be used to define the status of the habitat and identify trends and anomalies. We plan to extend this plugin into an operational product in partnership with managers of protected areas that are significantly affected by fire. Future developments may include using fire data within a threat-alert system in combination with land cover, species and field derived information.

124-THE MITIGATION HIERARCHY, NO NET LOSS AND BIODIVERSITY OFFSETS: WHERE HAVE WE REACHED?

Kerry Ten Kate

Forest Trends

In the past decade, and particularly since 2012, the attention of governments, companies, banks and civil society organisations has focussed on improving the application of the mitigation hierarchy: taking steps to avoid and minimise impacts on biodiversity, to undertake restoration and finally to offset residual impacts with a view to achieving no net loss or a net gain of biodiversity. This paper will take stock of recent development and the challenges that remain in defining best practice, embedding it in government, corporate and financial policy, and building the capacity to ensure it is applied in practice in projects on the ground. It will explore whether there is the political and corporate will to do a good job, the extent to which there is agreement on the standards and methods to apply, whether we are making sufficient progress on the underlying science, and what should be the next steps for the community of conservation biologists and those with whom they work.

TOWARDS A REGIONAL STRATEGY ON INVASIVE PLANTS SPECIES (PROVENCE-ALPES-CÔTE D'AZUR, FRANCE)

Eléonore Terrin

Conservatoire botanique national alpin [INSTITUTE]
Conservatoire botanique national méditerranéen de Porquerolles

Katia DIADEMA, Conservatoire botanique national méditerranéen de Porquerolles ; Noémie FORT, Conservatoire botanique national alpin ; Virgile NOBLE, Conservatoire botanique national méditerranéen de Porquerolles

The french national strategy for biodiversity 2011–2020 identified invasive species as one of the main threats to biodiversity. Thus, one aim is to provide practical measures in order to prevent and to control invasive species. In this context, both environmental and administrative organizations of the Provence-Alpes-Côte d'Azur (PACA) region initiated a regional strategy to associate all stakeholders concerned by invasive species (environnement, agriculture, horticulture, forestry and urban planning professionals sectors). Here we present main steps to elaborate this regional strategy which is planned over two years (2013-2014). Local context, regional issues and stakeholders' expectations will be considered into this regional strategy, with guidelines of the national strategy for biodiversity 2010-2020. Lists of invasive or potentially invasive species in PACA have been elaborated at different scales (administrative and biogeographical scales). Those

lists are intended to be used for the management of natural areas. A regional survey of different professional sector (environment, agriculture, horticulture, forestry) has also been carried out to identify: (i) all stakeholders in the project area, (ii) their perception of invasive species, (iii) their expectations and (iv) the elaboration of a regional assessment of actions concerning invasive species. A Technical Committee composed of professional representatives is set up to give an advisory opinion on methodological and technical guidelines for the project. Three territorial workshops will be held in 2014. Further expectations, local specificities, aims and actions of the strategy, the level of involvement of each stakeholder, opportunities for collaboration and funding possibilities will be listed during these workshops to formulate a regional strategy and an actions plan.

THE GREAT INDIAN CONSERVATION DEBATE: CONTEXTUALIZING POVERTY

Sneha Thapliyal

Indian Institute of Management

It is typically argued that the flows from economically significant ecosystem services of Protected Areas (PAs) are greater than the cost of conservation borne by the population living proximal to these areas. However, there is a significant overlap between global biodiversity hot spots (and hence PAs) and the incidence of poverty. Restricted access to natural resources further compromises livelihood practises and may even lead to poverty traps in a region. Yet, there is a lack of rigorous empirical evidence on the net impact of PAs on the economic well-being within a region. Inference on this causal impact has significant bearings on conservation policies, especially for the developing nations rich in biodiversity but poor in public welfare outcomes. India, with 4% of its geographical area under PA network and over 60% of the rural population directly dependent on forests, exemplifies this conservation debate. Focussing on IUCN type I and II terrestrial PAs in India, the objective of this paper is to assess if PAs exacerbate or alleviate poverty. We compare the performance on poverty outcomes over the last two decades for districts with PAs and their counterfactuals – districts that are nearly identical to the ones with PAs on a host of other attributes but do not have PAs – using the quasi-experimental method of propensity scores matching. We use the quinquennial large-scale nationally representative household-level data on consumption expenditure to estimate poverty for five points in time between 1990 and 2012. For these years, we map the common attributes of districts (covariates) including a host of environmental characteristics assimilated from various national reports and GIS data. Preliminary results indicate that districts with PAs have indeed fared better in poverty reduction. We

posit that this positive effect of conservation is driven largely by tourism-related revenue.

HOW CONNECTED WILL TIGER POPULATIONS BE IN THE FUTURE?

Prachi Thatte

National Center for Biological Sciences

Aditya JOSHI, Wildlife Conservation Trust ; Srinivas

VAIDYANATHAN, Foundation for Ecological Research, Advocacy and Learning ; Uma RAMAKRISHNAN, National Center for Biological Sciences

Harboring more than 60% of the world's wild tigers, India is a stronghold for their conservation. However, tiger habitat in India is getting increasingly fragmented with growing population and anthropogenic development. Tigers are restricted to protected areas and forest fragments embedded in a matrix of multiple landuse types. While conservation efforts focused inside protected areas have led to an increase in tiger numbers over the last few years, the status of tigers outside protected areas is not known. Habitats outside protected areas may act as stepping-stones for maintaining connectivity between protected areas. Recent research suggests that just increasing the number of tigers is inadequate and maintenance of connectivity between populations is critical to sustain genetic variability. We examined connectivity among tiger populations (110 samples, 14 microsatellites) in Central India, one of the six landscape complexes considered important for tiger conservation in India, using scat samples collected from within and outside protected areas. Our results suggest that currently tiger populations have varying levels of connectivity. However, maintaining connectivity in the face of increasing development may be a challenge in the future and presence of tigers outside protected areas may be critical. We carried out simulations to investigate how connectivity may change in the next 100 years under different landscape change and development scenarios with and without the presence of tigers outside protected areas. Preliminary results suggest that connectivity between populations will decrease with high risk of local extinction in some small and/ or isolated populations; this would happen faster in the absence of individuals outside protected areas. Our results can be used to prioritize conservation efforts in sensitive areas and stress the importance of a landscape approach to conservation, shifting the current focus from conservation inside protected areas.

A COLLABORATIVE SCIENCE PLATFORM FOR SEAMLESS LAND USE AND LAND COVER DATA TO INFORM CONSERVATION: THE GLOBAL LAND USE EMERGENT (GLUE) PROJECT

David Theobald

Conservation Science Partners

Dylan HARRISON-ATLAS, *Graduate Degree Program in Ecology, Colorado State University*; Nicole SHAW, *Conservation Science Partners*; Luke ZACHMANN, *Conservation Science Partners*; Brett DICKSON, *Conservation Science Partners*

Central to understanding current patterns of biodiversity, validating models of threats and effects, monitoring habitat change, leveraging past and future data collection efforts, and collaborating across agencies, ownership, and political boundaries is some representation of land use and land cover. We have worked with a variety of conservation partners to construct a platform to collect and share data on detailed land use and land cover, generated through interpretation of high-resolution areal photography. This provides an efficient means to collect data at a fine resolution, for current and historical landscapes, and to leverage expert and local knowledge. We find these “glue” data especially important because they: (a) provide a means to link detailed understanding of land use drivers to the vast collections of remotely-sensed imagery and other landscape data; and (b) connect with interested agencies, groups, and even individuals (citizen science). We will demonstrate how we leverage the Google Earth platform to provide a means to visualize and input data in careful, coordinate, and consistent way. A flexible, comprehensive, multi-scale random-based design provides a probability-based sampling framework necessary for rigorous design-based estimates, while additional opportunistic points are also supported for modeling purposes. We will describe two transboundary examples of the application of GLUE data to generate: (1) US-Mexico land cover and land use dataset for the Madrean archipelago ecoregion; and (2) a flexible, freshwater sampling design for the US and Canada.

SOCIAL-ECOLOGICAL TRAJECTORIES OF PROTECTED AREAS: LESSONS LEARNT FROM THE FRENCH NATURE RESERVES NETWORK

Clara Therville
CNRS

Raphaël MATHEVET, CNRS; Frédéric BIORET, Institut de Géoarchitecture, Université de Bretagne Occidentale

At the global scale, protected areas (PAs) are one of the main tools used for nature conservation. However, the ongoing biodiversity loss and the lack of social acceptance of PAs question their ability to enable long-term biodiversity conservation. As a consequence, since the 1980s, conservation scientists and practitioners have switched from segregative to integrative models of PAs, by opening up their objectives, governance systems and consideration of surrounding landscapes. Within this paradigmatic evolution, PAs are more and more considered as open social-ecological systems (SESs), strongly interconnected with their surrounding landscapes. This evolution is associated with new challenges for

conservationists. How to manage these complex and uncertain SESs? How to characterize and pilot their trajectories to support long-term conservation projects? In the present contribution, we propose a framework for analyzing the trajectories of PAs. As case studies, we focus on French Nature Reserves (NRs), one of the main regulatory tools of the French nature conservation policy. We identify the trajectories of NRs within their social-ecological landscape according to their degree of openness: to the surrounding landscape (spatial), of their management objectives (sectoral), and in their governance systems (institutional). Making use of three related attributes of SESs’ dynamics (resilience, adaptation, transformation), we analyze how NR managers cope with changes in SESs, anticipate their future trajectories and avoid undesirable states. We identify key variables in the implementation of collective action and adaptive management of SESs. We show the values and limits of considering PAs and their surrounding landscapes as a single complex and adaptive SES. By simultaneously integrating their spatial, sectoral and institutional trajectories, our framework is a powerful tool for exploring opportunities and constraints for action and for long-term conservation.

159. TRANSLOCATIONS IN EUROPE, WHAT KIND OF WILDNESS DO WE RESTORE ?

Charles Thévenin

Université de Grenoble

Alexandre ROBERT, Museum National d’Histoire Naturelle; Christian KERBIRIOU, Univ. Pierre et Marie Curie; Sakina HASNAOUI, Univ. Pierre et Marie Curie; François SARRAZIN, Univ. Pierre et Marie Curie

Over the last decades a strong debate about the relevance of population and species-centered approaches versus community, or ecosystem conservation has emerged. In that context translocation programs are often criticized for being costly and strongly biased toward charismatic species. The actual efficiency of these programs is also difficult to analyse due to the heterogeneity of success criteria implemented for each of them. However, the aim of conservation translocations should be to restore the long term viability of populations. Ultimately it should contribute to recover elements of wildness through the restoration of evolutionary trajectories and spontaneous dynamics of genes and phenotypic traits exhibited by the focal species and populations that may contribute to shape community and ecosystem dynamics as well as evolutionary trajectories of resident organisms in the target habitat of translocations. Thus, the choice of the focal species, the efficiency of their translocations, and the ecological and evolutionary consequences of these translocations may depend on these life history and functional traits. In this study we focused on more than 340 animal translocation programs (mostly mammals and birds) that occurred in Europe over the last 150 years. For both groups we compared the taxonomic

distributions of translocated vs non translocated species and the distribution of life history traits and functional traits to identify potential biases among translocated populations. These biases were discussed accounting for the potential link between these traits and the local extinction risks that enhance the potential for reintroduction. All these analyses were placed in the framework of the IUCN regional red list criteria to consider the past and present conservation status of the focal species at various scales as well as the conservation efficiency of the translocations.

TOWARD A BETTER ASSESSMENT OF INVASIVE RODENT IMPACTS ON ISLAND ENDEMIC REPTILES. A PILOT STUDY IN TOWARD A BETTER ASSESSMENT OF INVASIVE RODENT IMPACTS ON ISLAND ENDEMIC REPTILES. A PILOT STUDY IN NEW CALEDONIA

Martin Thibault

Institut Agronomique néo Calédonien (IAC)
Fabrice BRESCIA, Institut Agronomique néo Calédonien (IAC)
; Hervé JOURDAN, Institut Méditerranéen de Biodiversité et d'Écologie marine et continentale (IMBE), UMR UAM - CNRS - IRD - UAPV
; Leo DEBAR, Institut Méditerranéen de Biodiversité et d'Écologie marine et continentale (IMBE), UMR UAM - CNRS - IRD - UAPV

; Eric VIDAL, Institut Méditerranéen de Biodiversité et d'Écologie marine et continentale (IMBE), UMR UAM - CNRS - IRD - UAPV

Among insular vertebrates, reptiles are one of the most threatened taxa which face high pressures from exotic introduced species and human-induced habitat disturbances. However, the magnitude of the impact of invasive species particularly rodents on small reptiles remains poorly investigated, because of the persistent lack of tools to accurately identified reptile chewed fragments in gut content. New Caledonia archipelago (South Pacific) hosts an exceptional terrestrial reptile fauna (105 species, 91.6% endemic) dealing with several invasive species (rodents, cats, ants) and strong human pressures. Our study aimed at evaluating endemic skinks predation by introduced rodents in mining areas. Four rodent trapping sessions were implemented in two mining sites and for two distinct habitats (dense forest and open habitat). 284 rats were trapped from two species: the black rat *Rattus rattus*, and the Pacific rat *R. exulans*. Rodent diet analysis was focused on skink predation by developing a new identification tool based on skink scales morphology. Combined analysis of stomach and caecum contents provided much more information than usual stomach analysis only. Moreover our new identification tool allowed us to determine 91% of preyed skinks at the species level. 15.9% of rat samples

included skink remains for at least 12 different skink species. 5 of them were classified as threatened by IUCN among which the most endangered were *Marmorosphax taom* (CR) and *Kanaky viviparus* (EN). This pilot study provides new insights in the assessment of invasive rodent impacts. It improves our understanding of the respective impacts on native skinks of two sympatric invasive rodent species. We think that generalization of our identification key to other reptile communities and in other habitats, combined with the use of the method we suggest here for specific diet studies will enhance future researches dedicated to the conservation of island endemic reptiles.

73. CONNECTIVITY MEASUREMENT AS A USEFUL TOOL FOR THE SPATIAL MANAGEMENT OF MARINE RESOURCES: THE CASE OF THE GREAT SCALLOP PECTEN MAXIMUS IN THE ENGLISH CHANNEL

Eric Thiebaut

Université Pierre & Marie Curie
Julien OGOR, ENSTA ; *Amandine NICOLLE, ENSTA* ; *Franck DUMAS, IFREMER* ; *Aurélien FOVEAU, Université de Caen Basse-Normandie*

For species with a complex life cycle like the great scallop *Pecten maximus*, which forms the most important fishery in landings in the English Channel, the knowledge of larval dispersal and population connectivity is an essential prerequisite for defining effective strategies of spatial fishery management (e.g. delineation of management units). Faced with the difficulty of quantifying dispersal and connectivity among benthic populations from field observations, a high-resolution Lagrangian biophysical model of scallop dispersal was developed. It included a variable planktonic larval duration related to water temperature and a vertical larval behaviour. Eighteen different scallop beds have been identified from different sources including ICES data and VMS data. For each stock, larval dispersal pathways were calculated for two spawning events per year between 2000 and 2009 to assess the intra- and inter-annual variability of dispersal and connectivity. Results highlight a large variability among stocks in the hydrodynamic processes which govern larval transport (tidal currents vs. wind-induced currents). On the other hand, the larval retention rate and the self-recruitment rates, two metrics commonly reported in studies on local populations' persistence, are highly variable among populations, ranging from about 1 to 35 %; and 5 to 95 % respectively. Although self-recruitment plays a major role for some stocks, the maintenance of other stocks is highly dependent of external larval supply. Using a graph theoretic approach based on the adaptation of community structure algorithms, three major management units which act as metapopulation have been identified: the eastern Channel, the Gulf of Saint-Malo, the SW of England. Complex patterns of exchanges are reported

within each metapopulation with local populations acting as source or sink. The biophysical model can be also a useful tool to determine the efficiency of MPA implementation or juvenile seeding.

PREDICTING GROWTH TRAJECTORIES WITH FUNCTIONAL TRAITS FOR MULTIPLE PLANT SPECIES IN FIRE-PRONE COMMUNITIES.

Freya Thomas

The University of Melbourne

Peter VESK, The University of Melbourne

Data required for optimal fire management of multiple plant species are quantitative information on 'vital rates' and 'life history characteristics', which specifically relate to growth, reproduction and survival. Our research aims to investigate the application of using plant functional traits to generalize patterns of plant growth and reproduction. Including functional traits into models of demographic rates is useful in producing predictions of growth trajectories based on trait information. Data on functional traits can be generalised across species that share similar traits and is easier to gather for many species compared to species-specific demographic data and using hierarchical multi-species models also allows for the growth of unknown or rare species to be estimated. Using height and trait data collected for multiple species along a chronosequence of time-since-fire sites in a region of semi-arid South-Eastern Australia, we built a hierarchical multi-species model of plant growth with parameters that vary by species. Functional traits (wood density, specific leaf area, seed mass and nitrogen content of leaves) are included into this multi-species model as species-specific linear predictors of the model parameters. This approach reveals not just plant growth through time for individual species, but also how functional traits contribute to intraspecific species variation. These results will be discussed in relation to the practical application of generalising growth patterns and designating tolerable fire intervals for multiple plant species.

SOCIAL DIMENSIONS OF CONSERVATION: AN ORGANISATIONAL PERSPECTIVE

Sarah Thomas

Zoological Society of London

I argue in this paper that one of the most important dimensions of biodiversity conservation is the individuals and organisations that undertake this conservation work. There has been a distinct growth of awareness by the conservation community of the importance of the social sciences as a critical component of conservation success. However, this awareness is not necessarily matched by the conservation workforce's knowledge of, attitude towards and efficacy in these social

dimensions of conservation. Many conservationists received their formal training in the natural sciences, yet increasingly find themselves out of their 'disciplinary comfort zones' with the requirement to include social and human elements in their projects and programmes. This paper reports on a study addressing this issue through an organisational perspective, in which the perceptions of the social dimensions of conservation at one UK based NGO were researched. Using a mixed method empirical study, it aimed to uncover sociological themes around the workforce's practices, both within their organisation and on their conservation projects in the field. Secondly, it aimed to gain a sense of how the organisation prioritises, constructs, delivers and evaluates the social elements of their conservation projects. Finally through a co-constructed approach, it aimed to develop an implementation framework for the organisation which included training priorities, strategic direction and operational plans to meet the needs of their growing portfolio of interdisciplinary conservation projects and programmes. The paper presents some of the key findings of this study. These include: 1) Themes around the sociology of conservation practice, 2) The typologies of social and human aspects included in the organisation's conservation projects and 3) The strategic and operational recommendations for change within the organisation as a result of this study.

PRESIDIO OF SAN FRANCISCO CONSERVES AND ENHANCES BIOLOGICAL DIVERSITY OF TERRESTRIAL AND AQUATIC HABITATS THROUGH RESTORATION AND PUBLIC PARTICIPATION

Terri Thomas

Presidio Trust

The Presidio of San Francisco is a 1492 acre national park site on the south side of the Golden Gate Bridge in San Francisco, California. The 13 native plant communities survive on 6 geologic formations and water features include bay, marsh, creeks, ponds and fresh water lake. Recent species inventories identify 17 mammals, 8 reptiles and amphibians, 60 bees, 12 dragonflies and damselflies, 84 spiders, 38 ground beetles and 366 birds inhabit the Presidio. An Army Base for 220 years, its natural resources were built upon, fragmented, and landscaped. Its water features were filled and put in pipes. In the 1990s efforts began to restore endangered and rare species, native plant communities, water features, and enhance native biodiversity. The native plant genetic diversity is preserved through seed collection and native plant propagation on site. A variety of approaches, policies, communication, education and political tools have joined researchers, educators and land manager partnerships to provide San Francisco citizens the opportunity help re-create natural biodiversity. A state-of-the-art database is used to track success of the monitoring results of plants, birds, and

water quality. A discussion of opportunities and constraints of projects and how they were approached; monitoring results and biodiversity impacts; challenges and the learning for adaptive management. Through volunteer involvement, an internship program, and formal and informal education programs, the complexity of ecosystems and the values of individual species and ecological services are passed on in an intimate and personal hands-on approach. Citizen Science, Community Volunteers, and curriculum-based education enables public support that connects local ecosystems to the world. As the Presidio becomes more of a destination for international travel, these systems will be able to interpret the value of restoration to audiences throughout the world.

THE ROLE OF DEPTH IN DIVERSITY INDICES AND MARINE PROTECTED AREA RESILIENCE

Kelly Marie Thomasson
UC, Santa Barbara

Marine Protected Areas (MPAs) function both to protect the species and ecosystems of interest as well as to act as source populations for neighboring environments that face a high rate of exploitation and degradation. Some of these MPAs, caught in the crossfires of conflicting stakeholder opinions, are used in a manner that is suboptimal to the goals of habitat conservation. Many times, MPAs exhibit dangerously high rates of usage when they are established in areas where ecotourism acts a primary revenue source. Despite their potential to be used at a higher rate, Maui MPAs differ greatly in their percent coral cover, their species richness and their Shannon Diversity Indices. These MPA biodiversity indices, relative to those of unprotected sites, change not only as a factor of tourism and recreation, but also based on depth range. Given these factors, conservationists and policy makers are lead to ask: "Does depth play a role in the robustness and the resilience of an MPA differently than it does in a marine area with no protection status?" Using a series of photographic quadrat surveys, an analysis of three biodiversity indices was performed with respect to depth ranges on six protected and unprotected marine regions in Maui country. These quadrats were then quantified for the three biodiversity metrics: percent coral cover, species richness and Shannon Diversity Index. Special consideration was paid to the interaction values resulting from a multivariate analysis of variance (MANOVA) and the significance of depth in each category was analyzed for changes in robustness at two depths in protected and unprotected, biogeographically similar regions. Understanding that MPA design is of paramount importance to that MPA's success, these analyses may help to influence future decisions regarding MPA boundaries and the inclusion of depth meta-habitats.

82-LANDSCAPE PLANNING TO ALLOCATE RESOURCES AMONG FOREST RESTORATION, REHABILITATION AND PROTECTION.

Jim Thomson

Arthur Rylah Institute for Environmental Research

Maintaining and restoring critical ecosystem processes and ensuring the persistence of native biodiversity in human modified landscapes will require a combination of habitat protection, restoration and rehabilitation. But how should limited resources be allocated to these different conservation activities to achieve the best ecological outcomes at regional scales, while minimizing economic and social costs? Here we address the problem of strategic landscape planning in multiple-use mosaic landscapes of the eastern Amazon. We explore trade-offs among protecting relatively undisturbed primary forest, avoiding degradation and restoring degraded primary forest, and rehabilitating forest through passive reforestation and protection of secondary forests. Extensive survey data on bird, invertebrate and tree biodiversity were linked with remote sensing data to model species distributions and biodiversity patterns in a range of land-use types and forest conditions. Validated models were used to map habitat values across two municipalities in the eastern Amazon under current and possible future management scenarios. The resulting maps were used to explore trade-offs among management actions and to identify priority areas for habitat protection, rehabilitation and restoration, using conservation planning software Zonation. These prioritization analyses identified the most cost-effective balance and spatial configuration of forest protection, restoration and rehabilitation, while accounting for connectivity requirements, relative costs, risks of fire and logging, forest code regulations, and uncertainty in species distributions and other inputs. Systemic planning of management options at regional scales can substantially improve expected biodiversity outcomes while minimizing costs and risks, and provide valuable information for regulators, conservation practitioners and landowners in this biologically unique region.

EFFECTS OF SEABIRD ECOSYSTEM ENGINEERING ON INVERTEBRATE FOOD WEB STRUCTURE.

Joshua Thoresen

Auckland University of Technology

David TOWNS, Auckland University of Technology ; Sebastian LEUZINGER, Auckland University of Technology

Seabirds are the archetypal ecosystem engineer, while nesting on islands they transfer nutrients from the sea and disturb the soil through burrowing. However, seabirds are in decline worldwide and so too are the ecosystems they create. Research on these ecosystems is extensive, but little is known about the

effects of seabirds on ecological network dynamics. Eighteen leaf-litter invertebrate ecological networks were constructed across nine seabird and nine non-seabird islands in order to determine how seabirds act to structure these networks. Ten environmental variables associated with seabirds and nine network structural metrics were compared against island type (i.e. seabird vs. non-seabird islands) using Student's t-tests. Principal component analyses, Akaike Information Criterion (AIC) algorithms and linear models were carried out to determine the predominant seabird effect driving the observed changes in network metrics. We found that seabird islands demonstrated significant changes in most environmental variables and all measured network structural metrics, with these islands demonstrating significantly greater network complexity and size. The linear models demonstrated that the predominant driving variables of these changes involved nutrient subsidies and to a lesser extent, habitat area. We concluded that as seabirds return to newly restored (i.e. pest eradicated) islands we can expect the invertebrate ecological networks to become successively larger and more complex over time. This complexity may then serve to increase the efficiency of invertebrate network functionality, the predominant function being nutrient cycling.

SCRATCHING OF SPRUCE BARK ENABLES PEST CONTROL BUT MITIGATES COLLATERAL DAMAGE TO BIODIVERSITY - IMPLICATIONS FOR PROTECTED AREA MANAGEMENT FROM EXPERIMENTAL WINDTHROWS

Simon Thorn

Bavarian Forest National Park

The amount of forest area affected by stand-replacing natural disturbances such as fire, windthrows or bark-beetle outbreaks has increased over recent decades and is expected to increase further. Recently, the past practice of removing the resulting dead or injured trees to restore economical values and to avoid outbreaks of pest species (i.e. post-disturbance or salvage logging) has increasingly become controversial. Hence, protected area managers are increasingly challenged to balance between benign neglect strategies to sustain natural dynamics on the one hand and political constraints to avoid outbreaks of pest species on the other hand; particularly in disturbance-prone conifer dominated forests. To avoid infestations of European spruce bark beetles (*Ips typographus*) but simultaneously retain tree biomass, managers of protected areas debark spruce trees, weakened by natural disturbances. We investigated three different types of mechanical bark treatments (complete debarking, bark scratching and control) applied to 12 small, artificial windthrows in the Bavarian forest National Park. Based on 30,000 individuals of saproxylic beetles

trapped by stem-emergence traps we demonstrate, that a complete debarking of wind-felled trees lead to a significant decrease in species richness of saproxylic beetles. Furthermore debarking caused significant changes in species communities. In contrast, bark scratching did not lead to significant losses of species richness or community changes but reduced the number of *I. typographus* individuals to 10% of the control value. In the light of increasing natural disturbances, we recommend bark scratching as an appropriate tool to prevent pest species outbreaks in wind-felled coniferous forests but likewise retain saproxylic biodiversity.

ERADICATION OF INTRODUCED BROOK TROUT AND RECOVERY OF ALPINE LAKES IN THE GRAN PARADISO NATIONAL PARK (ITALY)

Rocco Tiberti

Alpine Wildlife Research Centre, Gran Paradiso National Park [INSTITUTE] DSTA-Dipartimento di Scienze della Terra e dell'Ambiente, University of Pavia

Bruno BASSANO, Alpine Wildlife Research Centre, Gran Paradiso National Park ; Stefano BRIGHENTI, Alpine Wildlife Research Centre, Gran Paradiso National Park ; Matteo ROLLA, DBB-Dipartimento di Biologia e Biotecnologie, University of Pavia ; Achaz VON HARDENBERG, Alpine Wildlife Research Centre, Gran Paradiso National Park

Alien fish have been introduced into once fishless mountain lakes worldwide, seriously affecting biota. In the Gran Paradiso National Park (GPNP, Western Italian Alps), the impact of introduced brook trouts (*Salvelinus fontinalis*) on biodiversity in high altitude alpine lakes was quantified, and was so strong as to lead the GPNP to undertake an eradication campaign, within the EU financed LIFE+ BIOAQUAE (Biodiversity Improvement of Aquatic Alpine Ecosystems) project. The eradication started in June 2013 in three small lakes (depth range: 3-7.4 m) and one large lake (depth: 22.1 m). Intensive gill netting and electrofishing have been used as non-invasive eradication techniques, without lethal effects for native species, potentially including unique taxa evolved thanks to the island-like nature of alpine lakes (e.g. rare alpine haplotypes of *Daphnia pulex*). The effects of the eradication are being monitored, along with the eradication campaign, comparing the lakes subject of the eradication project with a set of control lakes (both naturally fishless lakes and lakes still containing brook trouts) as a reference to quantify the ecosystem resilience using several indicators (hydrochemistry, water transparency, zooplankton and macroinvertebrate communities, emergent insects, and amphibians populations). At the end of its second season, the eradication action within the LIFE+ BIOAQUAE project was successful in eradicating *S. fontinalis* from two small lakes, the fish population is collapsing in the other two lakes, and there are strong

evidence of ecological resilience, with macroinvertebrates being particularly sensitive to fish removal. To the best of our knowledge, this is the first time that such an eradication programme is successfully implemented in high altitude lakes in the European Alps.

SPRING WETLANDS - THEIR ROLE IN NUTRIENT CYCLING AND MAINTAINING LOCAL BIODIVERSITY

Kamila Tichá

T.G.M. Water Research Institute, p.r.i.

Ondrej Prokop SIMON, T.G.M. Water Research Institute, p.r.i. ;

Lucie PELÁKOVÁ, T.G.M. Water Research Institute, p.r.i.

The beginnings of river systems have often been poorly understood, mapped and researched in many cases, and therefore neglected. Recently, many biologists and conservationists realize their importance and go "to the sources", as shown in the latest studies in different parts of the world. Since 2007, we have examined the headwater area of the river Blanice (CZ, South Bohemia). An extensive survey of macroinvertebrates was carried out, and the ecological status and food preferences of about 80 taxa were determined. Remarkably, in a certain type of springs - spring wetlands - many benthic filter feeders, shredders and detritivores were found in high abundances. How can these feeding guilds subsist in coldwater oligotrophic springs? How come there is plenty of particulate detritus at the very beginning of the river continuum? Subsequently, we examined fine particulate organic matter (FPOM) drained from spring wetlands downstream: the quantity, nutrient content and distinguishable components. The FPOM was relatively rich in nutrients. The C:N and C:P ratios in the local leaf litter deposition were higher than in suspended FPOM, indicating that FPOM is more nutritious for consumers. The results demonstrate that spring wetlands represent a significant source of high-quality detritus not only for feeding its own benthic community, but for downstream ecosystems as well. These "detrital reactors" full of microorganisms, algae, macrophytes and macroinvertebrates receive primary particles and dissolved organic matter, transforming and forwarding them as "tasty" particles to the consumers. Consequently, spring wetlands reduce the eutrophication in primary river networks. Conservation of these relatively small but very important patches in the landscape is essential, mainly in biomes highly modified by human activities.

A BIOCULTURAL APPROACH TO ASSESSING RESILIENCE TO CLIMATE AND ENVIRONMENTAL CHANGE ACROSS RIDGE-TO-REEF LANDSCAPES IN FIJIAN COASTAL COMMUNITIES

Tamara Ticktin

University of Hawaii at Manoa

Rachel DACKS, University of Hawaii at Manoa ; Shimona QUAZI, University of Hawaii at Manoa ; Stacy JUPITER, Wildlife Conservation Society Melanesia program

Understanding how social-ecological systems can be resilient to climate and environmental change poses one of the most pressing challenges today. This is particularly true in the Pacific Islands, which are considered to be especially at risk to the effects of climate change. We used a biocultural approach to assess the main drivers of resilience in Fijian coastal communities across ridge-to-reef systems, encompassing agroforests and coral reefs. We asked: 1) What are the main drivers of resilience and how are these drivers linked across land and sea, and social and ecological realms?; 2) How are these drivers affected by external factors such as markets?; and 3) In what ways can local ecological knowledge (LEK) systems play a role in enhancing resilience? We carried out surveys in 20 coastal communities in five provinces across four Fijian islands. We conducted field surveys of indicators of resilience in 100 agroforests (including tree cover, species, crop and cultivar diversity, spatial heterogeneity, invasive species cover). We documented indicators of ecological resilience (e.g., herbivore biomass, coral to algae ratio) in the reefs adjoining the 20 villages and supported community catch logs in one village per region to document fishing pressures. We also used household and key informant interviews, focus group discussions and participatory mapping exercises to identify indicators of social resilience (including variables that relate to flexibility, capacity to learn, capacity to organize, and material assets) and LEK. We present the results of our analyses with structural equation models, and discuss their implications for both conservation and resilience in Fijian coastal communities.

UNDERSTANDING HOW LAND-USE CHANGE IN THE TRANS-MARA DISTRICT, KENYA IS DRIVING HUMAN-ELEPHANT CONFLICT AND ELEPHANT MOVEMENT.

Lydia Tiller

DICE, University of Kent

Rob SMITH, DICE, University of Kent ; Tatyana HUMLE, DICE, University of Kent ; Noah SITATI, African Wildlife Foundation ; Amin RAJAN, Zoological Society of London

The Trans-Mara District in Narok County neighbours the world famous Masai Mara National Reserve and is an important dispersal area for elephants (*Loxodonta africana*). The two areas are linked by at least 23 natural pathways which enable seasonal migration of elephants. However, unlike the Masai Mara, the Trans-Mara is unprotected and experiencing high levels of habitat transformation because the area has high agricultural potential and a growing human population. This encroachment of agricultural land has destroyed and fragmented elephant habitat and seemingly increased conflict with local farmers, predominantly through crop raiding. To

inform management and mitigation of this conservation problem, this project aims to: (1) quantify land-use and land-cover change within the last 30 years in the Trans-Mara; (2) assess the factors determining elephant movements along key pathways between the Masai Mara and Trans-Mara; (3) determine spatial and seasonal trends of human-elephant conflict in the Trans-Mara, and; (4) use spatial conservation prioritisation methods to identify land-use plans that could allow the long-term persistence of elephants and broader biodiversity in the Trans-Mara. The project will also compare patterns of human-elephant conflict and land-use change with data collected 15 years ago. A variety of methods are being used including land-use change modelling, elephant sign surveys, camera trapping, human-elephant monitoring, systematic conservation planning and remote sensing. This research should inform management and mitigation of human-elephant conflict in the Trans-Mara district.

181. RISK, RESILIENCE, AND PRIORITIZATION: THE EVOLVING ROLE OF CLIMATE CHANGE IN CONSERVATION

Morgan Tingley

University of Connecticut

Conservation strategies have long focused on protecting areas to attenuate risk to species, communities, and ecosystems. While protected status can help species cope with climate change through the dampening of other threats, climate change does not stop at park borders. Thus, climate change requires new strategies, new goals, and a new philosophy toward our conservation priorities. This presentation will open our symposium by focusing on the differences between pre-climate change conservation and the novel challenges and potential solutions currently being posed. In other words, how should climate change affect conservation strategies? The answer to such a question requires examining current conservation strategies as well as what we know about how climate change affects species. Drawing on empirical examples of the complex dynamics governing observed species' range shifts in montane ecosystems, I will examine how well prioritization metrics such as resilience may or may not adequately protect species and ecosystems. Climate change does not alone pose risks to species, however, and conservation actions need to simultaneously balance multiple threats that may have different degrees of certainty, severity, or reversibility. Conservation needs more approaches to tackling these multiple competing threats in ways that provide flexible responses to future outcomes.

SENSITIVITY AND COST-EFFICIENCY OF ENVIRONMENTAL DNA SAMPLING FOR DETECTING AN AQUATIC INVADER (LISSOTRITON V. VULGARIS) IN MELBOURNE, AUSTRALIA

Reid Tingley

The University of Melbourne

Adam SMART, The University of Melbourne ; Andrew WEEKS, The University of Melbourne ; Anthony VAN ROOYEN, Cesar Pty Ltd ; Michael MCCARTHY, The University of Melbourne

Effective management of alien species requires detecting populations in the early stages of invasion. Environmental DNA (eDNA: the genetic material shed from organisms into the environment) can be used to detect aquatic species at low densities, but it remains unclear whether eDNA sampling is more sensitive and cost-efficient than traditional sampling methods. We compared the ability of a traditional survey technique (bottle-trapping) and eDNA sampling to detect a recently established invader, the smooth newt *Lissotriton vulgaris*, at seven field sites in Melbourne, Australia. Over a contiguous four-month period, detection probabilities per-trap ranged from 0.01 to 0.26 among sites where *L. vulgaris* was detected, whereas per-sample eDNA estimates were much higher (0.29 – 1.0). Detection probabilities of both methods varied temporally (across days and months), but temporal variation appeared to be uncorrelated between methods. Only estimates of spatial variation were strongly correlated across the two sampling techniques. Environmental DNA sampling was more cost-efficient than bottle-trapping across a range of survey budgets when optimising survey effort at a single site; however, bottle-trapping was more cost-efficient when we considered a scenario in which extensive primer development and testing costs were necessary. Nevertheless, sampling several sites diluted these initial set-up costs such that eDNA sampling was again more cost-efficient. These results demonstrate that eDNA sampling can be more sensitive and cost-efficient than traditional survey methods.

CANNIBALISM AND REDUCED BODY CONDITION: WHY WOULD CORN CAUSE REPRODUCTIVE FAILURE IN THE COMMON HAMSTER (CRICETUS CRICETUS)?

Mathilde Louise Tissier

Institut Pluridisciplinaire Hubert Curien (IPHC)[INSTITUTE]
Université de Strasbourg

Yves HANDRICH, Institut Pluridisciplinaire Hubert Curien (IPHC) [INSTITUTE] Université de Strasbourg ; Jean-Patrice ROBIN, Institut Pluridisciplinaire Hubert Curien (IPHC)[INSTITUTE] Université de Strasbourg ; Odile PETIT, Institut Pluridisciplinaire Hubert Curien (IPHC)[INSTITUTE] Université de Strasbourg ;

Caroline HABOLD, Institut Pluridisciplinaire Hubert Curien (IPHC)[INSTITUTE]Université de Strasbourg

With agricultural modernization, cropland formerly dominated by mosaics of crops, has been replaced by large plots of cereal monocultures (mostly corn). Besides the widespread effects of corn monoculture on wildlife through increased predation-related mortality rates due to the lack of protective cover in spring, this monoculture also leads to an alarming decrease in food diversity and quality, thus affecting individuals' survival and reproduction. These modifications are involved in the decline of many farmland species such as the Common hamster (*Cricetus cricetus*), an endangered species in almost all European range states, with very severe declines and local extirpations having occurred in some countries. We have previously shown that body mass evolution of wild Common hamsters at emergence from hibernation are negatively related to corn monoculture expansion during the last century. Herein, we experimentally tested in captive individuals the effects of corn consumption on hamsters' reproduction rate in comparison with wheat. We submitted 30 reproductive females to corn- or wheat-based diets, complemented with proteins (earthworms or clover) after mating and until weaning. We show for the first time that a corn-based diet negatively affects hamsters' reproductive success and body condition of pups in a negative manner, reducing by up to 75% the reproductive success of females and by up to 50% pups' body mass at weaning. We discuss about the physiological mechanisms that could be involved. Our future work will aim to understand how this could affect wild individuals by studying the impact of corn and wheat ecosystems on hamsters held in semi-natural conditions.

82-THE IMPLICATIONS OF BIODIVERSITY LOSS FOR ECOSYSTEM FUNCTION AND SERVICES AT THE TROPICAL DEFORESTATION FRONTIER

Joseph Tobias

University of Oxford

Biodiversity often underpins ecosystem function, but the extent to which key processes are impaired by biodiversity loss is difficult to quantify in complex tropical forest systems. Here we estimate the structure of Amazonian frugivorous bird assemblages to examine the impact of anthropogenic land-use change on seed dispersal, a process integral to the maintenance of rainforest tree populations. Focusing on beak size and shape as an index of the fruit size classes consumed by frugivores, we show that the diversity and dispersion of functional traits is much reduced in secondary forest and agricultural land-uses but little changed in primary forests subject to logging and fire. However, we also found evidence that when habitat degradation exceeds 40% the abundance

(population size) of seed dispersers largely collapses in larger beak size classes, and that even 10% degradation can halve the level of dispersal service for trees with larger fruits, including many species of high commercial value. These results indicate that intensification of human land-use leads to a collapse in the seed dispersal service provided by birds, and also suggest that ecosystem function may be radically reduced even when species richness and functional diversity remains high.

THE PERCEIVED COST AND BENEFITS OF THE VIRUNGA-BWINDI MASSIF

Sarah Tolbert

Yale School of Forestry and Environmental Studies

The potential impacts of protected areas (PAs) on local livelihoods are as diverse as the ecosystems they protect. The costs range from the displacement of local communities from their land, to crop raiding by wildlife and restricted access to natural resources. Benefits can include access to employment in the tourism industry, new schools and health centers, and even improved organizational capacity. While the costs and benefits can vary widely, conservation organizations now increasingly take into account the interconnected nature of livelihoods, forests, and biodiversity conservation through integrated conservation and development projects (ICDP). While these programs focus on improving the livelihoods of communities through infrastructure projects, little attention is paid to the local perceptions of the forest ecosystems that the PA aims to protect. To address this need and to help build the understanding of how people living near gorilla protected areas in the Virunga-Bwindi Massif view the forest ecosystem, I examined the perceived costs and benefits of the forest during fieldwork conducted between May-August 2014 in Democratic Republic of the Congo, Rwanda, and Uganda. The results show that the cultural, political, and socioeconomic context greatly influences people's perceptions of the forest. This has an enormous impact on whether forest-related conflicts can be successfully resolved. In the areas in Uganda, for example, where a buffer zone was created to grow tea, people express a greater appreciation for the protected area and are more tolerant to crop raiding by baboons and gorillas. In areas where multiple use strategies are not implemented, however, few people reported any benefit from living next to the PA and expressed more negative attitudes towards conservation. I then conclude by arguing that local perceptions of forest ecosystem must be included in traditional monitoring and evaluation framework, if forest related conflicts are to be resolved.

DETAILED MONITORING OF A SMALL BUT RECOVERING POPULATION REVEALS SUBLETHAL EFFECTS OF DISEASE AND UNEXPECTED INTERACTIONS WITH SUPPLEMENTAL FEEDING

Simon Tollington

Durrell Institute of Conservation and Ecology, University of Kent

Andrew GREENWOOD, International Zoo Veterinary Group/ Wildlife Vets International ; Carl JONES, Durrell Wildlife Conservation Trust ; Paquita HOECK, Institute for Conservation Research, San Diego Zoo Global ; Donal SMITH, Mauritius Wildlife Foundation ; Aurelie CHOWRITMOOTOO, Mauritius Wildlife Foundation ; Heather RICHARDS, Mauritius Wildlife Foundation ; Vikash TATAYAH, Mauritius Wildlife Foundation ; Jim GROOMBRIDGE, Durrell Institute of Conservation and Ecology, University of Kent

Infectious diseases can have substantial impacts on wildlife populations but exploring the sublethal effects of disease outbreaks among natural populations is challenging and requires longitudinal, individual life-history data on patterns of reproductive success and other indicators of fitness. These impacts are sometimes exacerbated in small endangered populations and therefore the success of conservation reintroductions to aid the recovery of such species can be threatened by outbreaks of infectious disease. Intensive management strategies associated with conservation reintroductions can further compound these negative effects in such populations. Mauritius is renowned for successful avian conservation and long-term monitoring programmes which have provided detailed reproductive information on the reintroduced Mauritius parakeet population collected before, during and after a disease outbreak. Deleterious effects of an outbreak of beak and feather disease virus (BFDV) were revealed on hatch success but these effects were remarkably short-lived and disproportionately associated with breeding pairs which took supplemental food. Individual infection status was not predicted by any genetic, environmental or management factors and was not associated with any of our measures of immune function, perhaps suggesting immunological impairment. Experimental immunostimulation did however, provoke a significant immune response. We illustrate the resilience of this bottlenecked and once critically endangered, island-endemic species to an epidemic outbreak of BFDV and highlight the value of systematic monitoring in revealing inconspicuous but nonetheless substantial ecological interactions. Our study demonstrates that the emergence of such an infectious disease in a population ordinarily associated with increased susceptibility, does not necessarily lead to deleterious impacts on population growth and that negative effects on reproductive fitness can be short-lived.

HUMAN DIMENSION OF CONSERVATION PLANNING: THE CASE OF MADAGASCAR

Tendro Tondrasoa

University of Aberdeen

Recommendations from multiple conservation planning efforts have resulted in the current locations of reserves in Madagascar, based exclusively on species habitat and important conservation sites. However, socioeconomic cost of the reserve network has received little to no attention to date. I used a systematic conservation planning framework to identify a cost-effective reserve network for Madagascar. I considered habitat for 327 species of plants and animals and 7 important conservation sites as biodiversity surrogates, and threat and vulnerability of species habitat to alternative land uses as costs to systematic conservation planning. I developed cost-layer maps from current rice field cultivation, fire occurrence data, and deforestation data. I also considered suitable land for rice field cultivation under scenarios of future climate change to assess the likely persistence of the selected reserve network. My results show that at the national level, inclusion of costs in systematic conservation planning did not drastically change the design of the current reserve network. The effect of including costs may be more pronounced at the regional scale. My results were inconclusive with regards to taking into account shifting costs resulting from future climate change. I conclude by giving recommendations regarding new reserve areas regarding the government priority for setting up additional conservation areas.

PARALLELS IN THE OPTIMAL PRESERVATION OF GENETIC AND SPECIES DIVERSITY

David Tonkyn

Clemson University

Managers of threatened captive populations try to select individuals for breeding that jointly have the greatest genetic diversity. At a larger scale, managers of threatened landscapes try to select sites for protection that jointly have the greatest species diversity. I argue that these two problems, of optimal genetic management and optimal reserve design, are nearly identical in form and solution. In both cases, we can specify a clear measure of diversity to maximize, and may have essentially complete information on which to decide, from pedigrees, DNA or GIS mapping. Also in both cases, we generally cannot find the optimal solution because of the astronomical number of choices. This problem is exacerbated by the fact that many threatened individuals (sites) are nearly identical to one another in genes (species), so the choices are both more critical and difficult to make. I discuss the similarities and differences in data, goals and solution methods

to these two classes of problems, and argue that preserving both genetic and species diversity can be treated as optimal relocation problems. There are carriers (animals or regions) that each carry items (genes or species) that are the real concern, and we wish to choose the set of carriers with the best overall set of items. This approach is easily generalized to use all the multivariate data on individuals or sites, incorporate constraints and weights to reflect differences in cost, availability, etc., and allow for single, mixed or multiple objectives, all within a common framework. Therefore, optimization methods developed for one class of problems can sometimes be used for the other. However, there are differences and I conclude with new examples of problems that do not transfer, that exploit the Mendelian inheritance in genetic data, or seek to form spatially compact reserves in landscapes.

BUNDLING AND STACKING IN BIO-SEQUESTRATION SCHEMES: OPPORTUNITIES AND RISKS

Nooshin Torabi

RMIT University

Sarah BEKESSY, RMIT University

Stacking and bundling ecosystem services credits have emerged as mechanisms to promote the conservation of biodiversity in carbon sequestration schemes. Globally, apart from a few certification standards in the voluntary market (e.g. The Climate, Community and Biodiversity Standards), little genuine action has eventuated, but credit sellers and buyers in the markets are continuing to examine the idea of combining these ecosystem services. This research provides timely analysis of the opportunities and barriers of bundling and stacking carbon and biodiversity credits as articulated by policymakers and academics. Corporate social responsibility (CSR) acts as a driving force for businesses to demand co-benefits from carbon plantings; however, uncertainty in the market and policy setting are barriers for both sellers and buyers. Interviewees highlighted substantial benefits of both bundling and stacking, including easing transaction costs for landholders, reduced monitoring costs for regulators and CSR advantages. Nevertheless, there is a risk that stacking can affect the perceived additionality of carbon plantings, which has the potential to erode the integrity of carbon markets. Obstacles to the establishment of stacked/bundled markets include the lack of standards to show that co-benefits are real, dealing with the additionality rule, and designing stacking or bundling scenarios to achieve genuine outcomes for both biodiversity conservation and carbon abatement. Our interviews revealed that bundling biodiversity and carbon credits is the most viable incentivising option. We argue that prerequisites to introducing bundled or stacked carbon credits include prioritising conservation objectives in a landscape scale plan and improvement of carbon modelling techniques to accurately reflect carbon captured by biodiverse carbon plantings.

WILDLIFE IN A HUMAN-DOMINATED WORLD: THE THREAT OF INFRASTRUCTURAL DEVELOPMENT

Aurora Torres

Museo Nacional de Ciencias Naturales - Spanish National Research Council

Jochen A. G. JAEGER, Concordia University; Juan Carlos ALONSO, Museo Nacional de Ciencias Naturales - Spanish National Research Council

Habitat loss and degradation are the primary drivers of the decline and extinction of wildlife populations in terrestrial ecosystems, and roads and human settlements are their main precursors. A decade ago, Kurt Riitters and James D. Wickham (2003) suggested that effects from roads may be the rule rather than the exception in the conterminous US. Since then, knowledge about connectivity metrics, roadless areas, and the effectiveness of defragmentation measures has significantly improved. However, we have missed a critical point that might help respond to the challenges from future developments, including roads: That is, a consistent estimation of the spatial extent of the effects from human structures on wildlife populations. Here, we measure proximity to human structures in Spain, a developed country still harboring a rich vertebrate fauna. We model their overall and habitat-specific areas of influence for birds and mammals, based on taxon-specific functional response curves. The imprint of human structures extends over more than half of all land area for birds (54.2%), whereas for mammals it covers almost all of Spain (97.9%). Moreover, the response curves predict an average decline of about 50% in mammal numbers and 25% in bird numbers across Spain due to the influence of human structures alone, compared to an undisturbed situation, and human influence is still increasing. We conclude that the impact of human structures on wildlife has become massive and that the extinction debt of landscapes may be significant, particularly for wide-ranging mammals. Indeed, we may no longer be able to determine the whole extent of the effects from impervious areas for vulnerable species in most developed countries, as core areas of significant size that could be used as control areas no longer exist.

FROM GENETICS TO CONSERVATION IN LATIN AMERICA AND THE CARIBBEAN: ARE WE REALLY ACHIEVING CONSERVATION GOALS?

Juan Pablo Torres-Florez

Universidade Federal de Sao Carlos

Pedro GALETTI JR., Universidade Federal de Sao Carlos; Warren JOHNSON, Smithsonian Conservation Biology Institute; Mariana NERY, Universidade Estadual de Campinas

The conservation of genetic diversity has long been recognized as an important component of maintaining biodiversity and

is among the goals of efforts to mitigate the current high extinction rate and biodiversity loss. Conservation Genetics has arisen as an important discipline, and rapidly developing molecular methods have facilitated its integration into biological conservation sciences and management practices. Empowered by these technological advances, rapidly decreasing costs, and new analytical tools and databases, the scope and number of projects using molecular genetic approaches is increasing rapidly. However, these advances have not been used very often to specifically address biological conservation policies. Given this common disconnect between theory and conservation practices, we conducted a critical evaluation of the published literature on conservation management in Latin America and the Caribbean to assess how and to what extent genetics and conservation genetics approaches are contributing to biodiversity conservation in this region. We used the Web of Science® to search the title, abstract and keyword fields of all articles published between 1981 and 2013, for either the individual words or complete phrases of “conservation genetics” and “conservation of genetic diversity”. Our search was conducted for each of the Latin America and Caribbean countries. A total of 544 published papers were found among 14 countries. Although the majority of these papers used genetic methods to address at least a broad conservation problem, only a few were really successful at successfully linking their results with specific conservation goals or with relevant conservation policy. We discuss these trends and, provide suggestions of how conservation genetics might have a larger and more successful influence and impact on conservation management practices in developing countries.

EFFECTS OF URBANIZATION ON GROUND-DWELLING ARTHROPODS: A MULTI-TAXA APPROACH

Béla Tóthmérész

University of Debrecen
Szabolcs MIZSER, MTA-DE Biodiversity and Ecosystem Services Research Group, University of Debrecen; Roland HORVÁTH, University of Debrecen; D. Dávid BOGYÓ, Hortobágy National Park Directorate; D. Dávid NAGY, MTA-DE Biodiversity and Ecosystem Services Research Group, University of Debrecen; Leila NAGY, University of Debrecen; Zsuzsa SZABÓ-DEBNÁR, University of Debrecen; Tibor MAGURA, University of Debrecen

The worldwide increase of urbanization is causing significant changes to the environment. Thus, a better understanding of the relationship between urbanization and ecosystem functioning is important for developing strategies to mitigate unwanted environmental impacts. In a multi-taxa research program, effects of urbanization on ground-dwelling arthropods with different mobility, and being at

different trophic level of the food web were studied along a rural-suburban-urban forested gradient in and around a city of Hungary. The following taxa were studied: millipedes (Myriapoda: Diplopoda), spiders (Araneae), isopods (Crustacea: Isopoda), rove beetles (Coleoptera: Staphylinidae) and ground beetles (Coleoptera: Carabidae). Diversity of the five studied arthropod taxa showed diverse trends of changes along the rural-urban gradient. There was no significant difference in the species richness between the rural and urban habitats for the millipedes, isopods and ground beetles. The species richness of rove beetles was significantly higher in the rural habitats compared to the urban ones, supporting the increasing disturbance hypothesis. The species richness of spiders was significantly the highest in the urban habitats. We stress that the change in the number of forest-associated species showed a consistent, robust pattern along the gradient. The number of forest-associated species was significantly higher in the rural habitats than in the urban ones for all studied arthropod groups. Our findings suggest that habitat alteration accompanying with urbanization have detrimental effects on the habitat specialist species. Moreover, our findings suggest that the overall diversity was not the most appropriate indicator of disturbance: species with different habitat affinity should be analyzed separately to get an ecologically relevant picture of the effect of urbanization. This research was supported by the TÁMOP-4.2.2.B-15/1/KONV-2015-0001 project.

THE IMPACT OF NATURE MANAGEMENT ACROSS THE ANNUAL CYCLE IN LONG-DISTANCE MIGRATORY SONGBIRDS

Anders P Tottrup

CMEC, Natural History Museum of Denmark, Uni. of Copenhagen

Mikkel WILLEMOES, CMEC, Natural History Museum of Denmark, Uni. of Copenhagen; Mathilde LERCHE-JORGENSEN, CMEC, Natural History Museum of Denmark, Uni. of Copenhagen; Kasper THORUP, CMEC, Natural History Museum of Denmark, Uni. of Copenhagen

Land-use and climatic changes are threatening wildlife worldwide. For migratory animals depending on several areas often separated by thousands of kilometres to successfully complete their annual cycle these threats are ever more difficult to approach because of lack of data. In cross-continental migratory songbirds, declines have been widely documented. Still, reasons remain poorly understood due to a lack of basic information regarding habitat requirements, spatial-temporal migration patterns and non-breeding ecology. With the aim of assessing direct effects of anthropogenic habitat alterations on migratory birds during breeding and non-breeding seasons, we studied spatial behaviour and habitat suitability across habitat types comparing home-range sizes and conspecific home range overlap using radio

telemetry. Results show surprisingly different non-breeding spatial strategies assessed by comparing home-ranges, territoriality and habitat selection. Combining these results with data on densities and body condition from each site, we show widely varying responses to habitat changes among species. Such information is crucial for predicting consequences of habitat changes on larger scales and population levels.

130 QUANTIFYING THE GLOBAL IMPACT OF DEFORESTATION ON TERRESTRIAL VERTEBRATES

Lukasz Tracewski

RSPB Centre for Conservation Science, Royal Society for the Protection of Birds

Stuart H.m. BUTCHART, BirdLife International ; Moreno DI MARCO, Global Mammal Assessment Program, Department of Biology and Biotechnologies, Sapienza University of Rome ; Gentile Francesco FICETOLA, Laboratoire d'Ecologie Alpine (LECA), Univ. Grenoble-Alpes ; Carlo RONDININI, Global Mammal Assessment Program, Department of Biology and Biotechnologies, Sapienza University of Rome ; Michael DEWITT, Google ; Alison E. BERESFORD, RSPB Centre for Conservation Science, Royal Society for the Protection of Birds ; Graeme M. BUCHANAN, RSPB Centre for Conservation Science, Royal Society for the Protection of Birds

Deforestation is one of the major threats to biodiversity, as loss of forest degrades sites of importance and clears habitat for forest species. Forest loss is not evenly distributed across the planet, and threatens some species more than others. Assessments of species under greatest pressure can inform conservation prioritisation. Until recently, global assessments of forest loss were coarse, which diminished their value for conservation. Here we use the recent 30 m resolution map of forest change between 2000 and 2012, processed through cloud computing, to quantify loss of forest within the ranges of all forest-dependent birds, mammals and amphibians (n=13255 species). We then scaled this rate of habitat loss to three generations or ten years (whichever was longer) for each species, to estimate potential rates of population decline relevant to the IUCN Red List categories and criteria. Subsequently, we quantified the proportion of species in each group that may qualify for uplisting to higher categories of extinction risk than currently applied. Our forest loss calculations were applied consistently across regions and across taxa, including those situations where poor data availability resulted in uncertain assessments in the past. Global maps of forest loss enhance our ability to assess the extinction risk of forest species, uncovering a scenario of increased biodiversity decline.

ASSESSING THREATS AND CONSERVATION ACTIVITIES IN PROTECTED AREAS ACROSS TROPICAL AFRICA

Sandra Tranquilli

University College London

Several protected areas (PAs) have been designed and established in Africa to protect their natural resources. Nevertheless, significant threats from anthropogenic activities persist and conservation efforts in most PAs are still minimal causing decline of wildlife populations. In our study we assessed the impact level of threats to wildlife within 98 PAs and the relationship with conservation activities. We focused on PAs with tropical forest cover from 15 countries across West, East and Central Africa. For each area we assembled information about local threats to wildlife and conservation activities. Our results show that 89% of African tropical PAs are under high pressure from anthropogenic threats, while type and degree varies across the regions. Subsistence and commercial hunting are the most common direct threats to wildlife and mainly prevalent in West and Central Africa. Agriculture and logging represent instead the most common indirect threats, mostly prevalent in West Africa. General linear models were constructed to test the significance of specific conservation activities in relation to the threat impact level. We found that the long-term presence of conservation activities (such as law enforcement, research and tourism) is associated with lower threat impact levels. In general, our results provide important guidelines to policy makers, funding bodies and conservationists. In particular, they highlight deficiencies in the management effectiveness of several PAs occurring in tropical Africa, and conclude that PA management should invest more into conservation activities with long-term duration.

ID #38: USING BEHAVIOURAL ECONOMICS TO ELUCIDATE RESPONSES IN CONSERVATION INTERVENTIONS

Henry Travers

Imperial College London

In this talk, I will present case studies from Cambodia and Uganda to show how methodologies developed within the discipline of behavioural economics are being used to investigate the sensitive subject of wildlife crime and guide the formulation of conservation policies aimed at addressing this important issue. Within conservation, increasing attention is being given to evidence based approaches to improving decision-making and evaluating whether policies have been successful in achieving their stated goals. Yet the success of conservation policies is difficult to define or measure and may

be highly dependent on the local social, political, economic and institutional context. Despite recent advances, assessing the impact of conservation interventions is expensive, difficult to do well and only possible once an intervention has been operational for a sufficient period. This situation can be exacerbated when policies are aimed at tackling illegal wildlife use, a silent crime that is challenging to monitor or investigate directly. As such, even with approaches such as adaptive management, opportunities for improvements, time or goodwill may be lost. Hence, the ability to estimate the effectiveness of policies prior to implementation (either in absolute terms or relative to alternative policy options) offers the potential, if not necessarily to get things right first time, to minimise the risk of unnecessary policy failures and improve the effectiveness of efforts aimed at reducing wildlife crime.

BORN TO BE WILD: HOW TO QUANTIFY THE IMPACT OF AN INVASIVE SPECIES, PROSOPIS JULIFLORA, IN ETHIOPIAN RANGELANDS

Anna Treydte

University of Hohenheim

Emiru BIRHANE, Mekelle University ; Abeje ESHETE, Forestry Research Institute

Invasive alien species are a global phenomenon, often with detrimental effects on native fauna and flora biodiversity. In Ethiopia, rangelands are being invaded by *Prosopis juliflora*, a woody encroacher which drastically reduces forage productivity in already overgrazed areas. Little research has been conducted to quantify the environmental effects of its invasion and management strategies have been rather unsuccessful thus far. Across sites of different *P. juliflora* encroachment categories in the Afar region, Ethiopia, we investigated the prevalent soil physical and chemical properties, soil seed bank, vegetation composition and productivity as well as below- and above-ground Carbon (C) stocks. Plant species richness was reduced while overall plant biomass and above- and belowground C stocks were more than three times higher in highly infested sites compared to sites without *P. juliflora*. Soil moisture, Phosphorus, Nitrogen and C stocks were highest in highly infested sites. The soil seed bank was still intact, including a variety of native plant species, even in soils of highly infested sites. Low recruitment of *P. juliflora* in highly infested sites points towards self-thinning effects while plant population dynamics and remote sensing images show that *P. juliflora* is still spreading rapidly across rangelands. We conclude that soil properties of infested sites are rather beneficial for reclamation and immediate use of the rangeland after removal of this invasive species. Management should focus on preventing *P. juliflora* spread and removal of freshly invaded sites rather than on already highly infested sites; trade-offs between labor costs, forage biomass and potentially beneficial C stocks of the woody vegetation must

be taken into account. After *P. juliflora* removal, immediate use and continuous monitoring and management of the restored sites is necessary to prevent resprouting and further invasion spread.

OPTIMIZING BOREAL FOREST MANAGEMENT TO REDUCE TRADE-OFFS BETWEEN BIODIVERSITY, CARBON STORAGE AND TIMBER

María Triviño

University of Jyväskylä

Tähti POHJANMIES, University of Jyväskylä ; Adriano MAZZIOTTA, University of Jyväskylä ; Eric LE TORTOREC, University of Jyväskylä ; Dmitry PODKOPAEV, University of Jyväskylä ; Artti JUUTINEN, University of Oulu ; Mikko MÖNKKÖNEN, University of Jyväskylä

Human well-being highly depends on ecosystem services and this dependence is expected to increase in the future with increasing population and economic growth. Understanding drivers of ecosystem service supply and biodiversity is important for developing efficient management strategies. Hence, studies that investigate trade-offs between ecosystem services and biodiversity are urgently needed for informing policy-makers. Moreover, in order to ensure the provision of ecosystem services in a landscape, it is important to maintain both ecosystem functions (like carbon storage) and structures (species representation). So far, most studies have focused on trade-offs between two ecosystem services, here we go one step further by analysing three objectives at the same time: (1) revenues from timber harvesting, (2) carbon storage, and (3) sustaining biodiversity. In our study, we apply seven alternative forest management regimes using a forest simulator in a large boreal forest production landscape. First, we estimate the potential of the landscape to provide timber, store carbon and sustain biodiversity (deadwood and species habitat availability) across a 50-year time period. Then, we apply multiobjective optimization to identify conflicts between the three objectives and to find the most preferred trade-offs in forest management regimes with as high timber revenues, carbon sequestration and sustained biodiversity as possible. Our results show that no management regime alone is able to maximize timber, carbon sequestration and biodiversity, and that a combination of different regimes is needed. We conclude that it is possible to achieve win-win situations by applying diversified forest management planning at a landscape-level.

CAN COAL COMBUSTION PRESERVE ENDANGERED BIODIVERSITY OF CONTINENTAL SAND DUNES? ARTHROPODS OF FLY ASH DEPOSITS WITH EVALUATION OF DIFFERENT RESTORATION PRACTICE IN THE CZECH REPUBLIC

Robert Tropek

Institute of Entomology, Biology Centre, Czech Academy of Science[INSTITUTE]Faculty of Science, Charles University
Ilona CERNA, Institute of Entomology, Biology Centre, Czech Academy of Science[INSTITUTE]Faculty of Science, University of South Bohemia ; Oldrich CIZEK, Institute of Entomology, Biology Centre, Czech Academy of Science[INSTITUTE]Faculty of Science, University of South Bohemia ; Jiri HADRAVA, Institute of Entomology, Biology Centre, Czech Academy of Science[INSTITUTE]Faculty of Science, Charles University ; Tomas KADLEC, Faculty of Environmental Sciences, Czech University of Life Sciences ; Petr KOCAREK, Faculty of Science, University of Ostrava ; Igor MALENOVSKY, Faculty of Science, Masaryk University ; Pavel MARHOUL, Beleco NGO ; Pavel PECH, Faculty of Science, University of Hradec Kralove ; Michal PLATEK, Institute of Entomology, Biology Centre, Czech Academy of Science[INSTITUTE]Faculty of Science, University of South Bohemia ; Jiri REHOUNEK, Calla NGO ; Jiri SKUHROVEC, Crop Research Institute ; Jakub STRAKA, Faculty of Science, Charles University ; Pavel SEBEK, Institute of Entomology, Biology Centre, Czech Academy of Science[INSTITUTE]Faculty of Science, University of South Bohemia ; Filip TICHANEK, Faculty of Science, University of South Bohemia

In the continental Europe, drift sand dunes rank highly among the most threatened environments, suffering accelerating losses of associated biodiversity. Despite strong evidence that various vanishing species find refuges at post-industrial barrens, arthropods specialised for the highly specific and extreme conditions of drift sands have not been known to colonise any surrogates. Based on the physical conditions of finely grained fly ash, we hypothesised that they could be colonised by drift sand communities. During our intensive surveys of arthropod communities (mainly wild bees and wasps, various groups of beetles, spiders, hoverflies, leafhoppers, orthopterans, moths, ants and neuropterans) of numerous fly ash deposits throughout the Czech Republic in the recent years, we have revealed that these relatively common landscape structures indeed host arthropod communities of extraordinary conservation value. Altogether we already found about 20 species considered as regionally extinct, several tens of critically endangered species and many other species included to the national and/or European red lists, majority of the most important species are strictly specialized for drift sand dunes. Simultaneously, we focused on effects of different restoration practice on this so far unknown tremendous conservation potential. After revealing technical reclamation (and especially artificial afforestation) as fatal for the majority of the most endangered species, we focused on anti-dust treatments as a potentially effective compromise between protection of human health and biodiversity conservation. In this contribution, the results of our biodiversity surveys as well as the studies of restoration

practise will be reviewed with a suggestion for future research and practical restoration.

PVA: DO POPULATION VIABILITY MEASURES CORRELATE?

Mario Trouillier

Georg-August-University Göttingen - Dept Ecosystem Modelling

Guy PE'ER, Dept Conservation Biology, UFZ ? Helmholtz Centre for Environmental Research ; Katrin MEYER, Georg-August-University Göttingen - Dept Ecosystem Modelling

Population viability analyses are broadly used to support conservation research and applications. Different studies use different viability measures – posing hurdles for comparability and meta-analyses. To enhance the capacity to generalize from PVAs, we compared different viability measures for two simulated species. We used the individual-based, spatially explicit model RangeShifter to simulate fourteen conservation scenarios on four landscape maps. These scenarios were ranked in terms of viability by eight commonly used viability measures (probability of extinction, probability of quasi-extinction, risk of decline, expected population size, expected minimum population size, extrapolated mean time to extinction, intrinsic mean time to extinction, growth rate). We found that the rankings were roughly similar, apart from the population growth rate λ . However, there were no general correlations between viability measure values. One reason for this is that model output data depend on model structure, species parameters and the landscape map. More importantly, each viability measure assesses a different subset of the same dataset. From this, it follows that some viability measures yield complementary information. Following this logic, we reassessed the relationship between extinctions ($N=0$) and other population sizes ($N>0$) to show that persistence should always be reported together with information on the population size distribution. This would enhance our understanding of the skewed distributions of the time to extinction, which is critical from a perspective of the risk affinity defined by decision makers. For future PVAs we recommend a) reporting several viability measures and b) reporting, or depositing, the full model outputs in terms of the population-size distributions over time.

BASAL ANGIOSPERM SPECIES AS LISTENING POSTS FOR CLIMATE CHANGE IN NEW CALEDONIA.

Santiago Trueba

Laboratoire de Botanique et d'Ecologie Végétale Appliquées, UMR AMAP, Institut de Recherche pour le Développement Robin POUTEAU, Laboratoire de Botanique et d'Ecologie Végétale Appliquées, UMR AMAP, Institut de Recherche pour le Développement ; Sylvain DELZON, University of Bordeaux, UMR

BIOGECO; Frederic LENS, *Naturalis Biodiversity Center*; Mark E. OLSON, *Instituto de Biología, Universidad Nacional Autónoma de México*; Taylor S. FEILD, *School of Marine and Tropical Biology, James Cook University*; Sandrine ISNARD, *Laboratoire de Botanique et d'Ecologie Végétale Appliquées, UMR AMAP, Institut de Recherche pour le Développement*

The "basal" angiosperms, encompassing the magnoliids and the ANA grade, are main elements of the New Caledonian forest communities. We show through species distribution models (SDM) for 60 species, that most of the early diverging angiosperms occurs in moist to wet rainforests with annual precipitation ranging from 1,500 to 2,300 mm/year and with moderate diurnal variations in temperature (below 7°C). Geographical shifts in the ranges of rainforest communities are predicted in response to a severe increase of drought according to current global change scenarios. Through measurements of vulnerability to xylem cavitation, a variable reflecting the ability of plants to withstand drought, along with leaf and wood traits such as leaf vein density and wood density, we assess the ecophysiology and drought resistance of 13 representative species. New Caledonian basal angiosperms have a spectrum of xylem cavitation vulnerability (ψ_{50}) of -4.03 to -2.00 MPa with most of species falling in a narrow resistivity range. We show a significant relation of drought resistance values of our studied species with spatial variables such as mean elevation. Additionally, we explore the influence of functional wood and leaf traits on their habitat distribution on the island. We propose monitoring of these species populations, which are restricted to rainforests and could serve as indicators of forest die-back because of their potential sensibility to drought. This study emphasizes the importance of considering together species' ecophysiological traits and habitat preferences in order to understand the response mechanisms of vegetation to climate change. Moreover, we highlight the importance of SDM in the design of biological conservation strategies.

GAMERS LIKE IT GREEN: VIRTUAL BIOPHILIA-LIKE EXPERIENCE IN THE WORLD OF WARCRAFT.

Minh-Xuan Truong

French National Museum of Natural History
Anne Caroline PREVOT, French National Museum of Natural History; *Susan CLAYTON, College of Wooster*

In the modern era of urban human development, the occidental way of life has increased a separation between humans and nature, together with a delegation of our sensory and cognitive abilities to technologies. For example, we delegate our senses of direction to GPS and other GoogleMap, our memory to search engines, and we can't do any calculations without our cell phone anymore! We can also choose virtual social interaction over physical social networking, using chat, video/audio/e-mails, and online video

games. Relationship to Nature is no exception to this and today, technology has begun to change human's long-standing experiences with nature: through videos and documentaries, we travel, discover magnificent windows opened onto wilderness, landscapes, places and species we would not be able to reach and see otherwise. Videogames contribute to this phenomenon. In this study, we focused on how players relate to Nature in the world's number one online role-playing game, the World of Warcraft (WoW, millions of players throughout the world). We proposed an on-line questionnaire to 1200 French-speaking gamers to assess their motivations to play, their relations to nature in the real life and their preferred landscapes in the virtual environment. We combined their answers to ecological descriptions of these virtual tridimensional environments. We showed that players prefer virtual areas displaying an important amount of green vegetation, but that this preference is not related to their nature connection, nor to their motivation to play, which is mostly escaping from their daily life, mostly urban. We discuss these results in terms of virtual biophilia, i.e., an attraction to virtual landscapes that are healthy and full of vegetation landscapes, when it is no longer possible to reach such landscapes in real life.

THE EFFECT OF AMBIENT ENVIRONMENTAL CUES AND INDIVIDUAL STATE ON RESOURCE SELECTION IN AFRICAN ELEPHANTS

Miriam Tsalyuk

University of California Berkeley
Wayne GETZ, University of California Berkeley

Wildlife movement patterns over different landscapes provide valuable information on which resources are important for the species' conservation. However, it is not well understood how the movement response to landscape variables changes over time, over ambient condition, and among individuals within a population. Here we examine how landscape variables, time variation (diurnal, seasonal), ambient environmental conditions (day length, temperature, rainfall), and internal cues (hunger, thirst) interact to determine the directional movement of African elephants (*Loxodonta africana*). We fitted fifteen elephants in Etosha National Park, Namibia, with GPS-GSM collars. We collected detailed landscape variables including vegetation density, cover, productivity, and temporal variability and distances to roads, fences, and water sources. We used Step Selection Function to determine the relative importance of landscape variables. We examined how changes in day length, ambient temperature, and rainfall, affect directional movement on the landscape. We further considered the effect of individuals' internal condition inferred from the time past since the recent drinking/feeding event. We found that elephants in Etosha prefer higher productivity, grass, and shrub biomass, but lower tree cover, and walk closer to water and roads. The importance of surface water, vegetation productivity, and grass

cover decreased as daily precipitation increased but increased with rising temperatures. We also show that environmental context and the inferred internal condition of the animal affect the relative importance of resources that were recently used (water, vegetation biomass and movement rates). Our holistic approach to examining the interaction of both internal and external cues in determining the animal's movement response to surrounding landscape variables sheds light on fine changes in wildlife resources selection over varying spatial and temporal scales.

49 LANDSCAPE CONTEXT DRIVING BIODIVERSITY PATTERNS AND PROCESSES IN FRAGMENTED HABITATS

Teja Tscharntke
Agroecology

49 The theory of island biogeography predicts decreasing species richness with decreasing area and increasing isolation of a habitat (MacArthur & Wilson, 1967), which has been claimed to be one of the few laws in ecology (Lawton, 1999; Holt, 2010). However, there are at least three distinct arguments why fragmentation per se has been often overestimated as a driver of landscape-wide biodiversity losses and why beta diversity has been underestimated as a driver of landscape-wide biodiversity. (1) Mechanisms driving biodiversity patterns in fragmented landscapes include not only the separate effects of habitat loss or fragmentation per se. When a given amount of habitat area is spread out in a landscape (via fragmentation) instead of remaining as a single large patch, beta diversity is increased, which relates to the observation that "single large" support usually less species (also less specialized ones) than "several small" (SLOSS) habitats. (2) Whenever the matrix surrounding habitat fragments is not entirely hostile to species, but rather contains usable resources, island biogeographical and early metapopulation theory have limited applicability. Matrix habitats can be surprisingly rich, even in species normally found in the fragments. (3) Most studies do not effectively discriminate habitat fragmentation from habitat loss (Fahrig 2003), and the few published studies explicitly discriminating these two effects do not support the hypothesis that fragmentation per se (i.e. fragmentation in addition to habitat loss) reduces landscape-wide diversity. Finding sustainable solutions that integrate conservation goals such as promoting landscape-wide biodiversity as well as maintaining viable populations of patch-area-sensitive (e.g. large or vagile) organisms is difficult and underlying conservation priorities need to be more clearly articulated. Tscharntke T et al (2012), *Biological Reviews* 87: 661-685.

141 INTEGRATING BIODIVERSITY IN AGRICULTURE

Teja Tscharntke
Agroecology

141 Under the current scenario of rapid human population increase, achieving efficient and productive agricultural land use while conserving biodiversity is a global challenge. Agriculture practiced under smallholder farmer-dominated landscapes, and not large-scale farming, is currently the backbone of global food security in the developing world. A major argument for wildlife friendly farming and agroecological intensification is that crucial ecosystem services are provided by "planned" and "associated" biodiversity, whereas the land sparing concept implies that biodiversity in agroecosystems is functionally negligible. However, loss of biological control can result in dramatic increases of pest densities, pollinator services affect a third of global human food supply, and inappropriate agricultural management can lead to environmental degradation. Hence, the true value of functional biodiversity on the farm is often inadequately acknowledged or understood, while conventional intensification tends to disrupt beneficial functions of biodiversity. In conclusion, linking agricultural intensification with biodiversity conservation and hunger reduction requires well-informed regional and targeted solutions, something which the land sparing vs sharing debate has failed to achieve so far. Tscharntke T et al. (2012): *Global food security, biodiversity conservation and the future of agricultural intensification. Biological Conservation* 151: 53-59.

PROTECTED AREAS MANAGEMENT AND CONSERVATION UNDER FUTURE CLIMATIC UNCERTAINTY: A CASE STUDY IN CHOBE NATIONAL PARK, BOTSWANA (SUB SAHARAN AFRICA)

Boipelo Tshwene-Mauchaza
University of Oxford

Climate change generates new challenges for biodiversity conservation and management. There are two ways in which climate change affects biodiversity (i) directly via physiological stress and (ii) indirectly via changing relationships among species. However, there is still limited understanding on how change in interspecific relationships as a result of climatic induced shifts will impact future sustainability of species composition and structure. This limitation makes current management and conservation strategies inadequate to ensure species long term persistence and survival within protected areas. This study seeks to provide the first assessment of the scale and type of indirect ecological impact that climate change could have on biodiversity in Chobe National Park (Botswana), by integrating ecological theory with predictive modelling of species. Qualitative information about the types

of ecological changes that might be experienced by species are assessed using literature reviews and expert knowledge. This is augmented with quantitative analysis of the potential impact of climate change on the distribution of habitat types and species, by a novel application of bioclimatic envelope modelling techniques. Species distribution models will be used to model dominant plant species from vegetation assemblages and animal species within the reserve. The model will be applied to a future 2050 and 2090 climate scenario in order to project the distribution of suitable habitat and species under new conditions. The study provides information and insights about future resilience and adaptation, that is, how to make robust protected area policy, management and conservation strategies that are effective in the face of climate change

HEAT STRESS IN AFRICAN PENGUINS IN THE FACE OF CLIMATE CHANGE

Noelle Tubbs

Percy Fitzpatrick Institute, University of Cape Town
Lorien Pichegru, Percy Fitzpatrick Institute, Nelson Mandela Metropolitan University; Peter G Ryan, Percy Fitzpatrick Institute, University of Cape Town; Jonathan A Green, School of Environmental Sciences, University of Liverpool

The African Penguin was classified as 'Endangered' by the IUCN in 2010, due to the loss of 70% of its population in the last decade. Habitat loss from former guano scraping is a major issue as it exacerbates heat stress. Historically, most African Penguins bred in guano burrows that provided a buffered microclimate and shelter from predators. During very high temperatures, adults may leave their nests to cool down in the sea. This is often fatal for broods in surface nests due to predation and exposure. Since climate change increases extreme weather, the situation will only worsen. Previous studies indicate that these effects can be reduced by artificial nests. However, whether they can fully replace natural burrows is still unknown. This study seeks to 1) pinpoint the temperature where heat stress begins, 2) understand behavioural responses to temperature, 3) estimate inter-colony temperature differences, 4) determine how extreme weather affects breeding success and 5) evaluate the effectiveness of artificial nests. Results of a laboratory study showed that penguins' behavioural thermoregulation methods could no longer cope with the rise in ambient temperature once ambient temperatures exceeded 28.5°C (95% CI) – their "heat stress point." This is 2°C lower than expected from studies on other penguin species, suggesting that African Penguins are particularly sensitive to climate change. Field-based studies using operative temperature models show that heat stress may be occurring more often and at lower air temperatures than predicted, from the influences of weather and artificial nest design. Artificial burrows were shown to have extreme temperatures in summer, commonly above African Penguins'

heat stress point. Exposure to sun affected all artificial nest types except natural burrows. The results of this study will help to predict how populations may be affected by climate change, as well as informing management actions to limit impacts.

DYNAMICS IN SPECIES ASSOCIATIONS CHANGE SURROGATE SELECTION FOR MONITORING MANAGEMENT

Ayesha Tulloch

The Australian National University
Iadine CHADES, CSIRO Land and Water; Yann DUJARDIN, CSIRO Land and Water; Martin WESTGATE, The Australian National University; Peter LANE, The Australian National University; David LINDENMAYER, The Australian National University

Changes in threatening processes and environmental conditions make species associations dynamic and difficult to quantify. Limited funding for conservation means that we must select surrogates to represent hard-to-detect species, in spite of uncertainty about species associations. We test how temporal variability in species associations affects decisions about optimal surrogates. We ask if reductions in the temporal representativeness of data (e.g. from reduced-effort monitoring protocols) leads to inadequate surrogates being selected, and explore trade-offs in the benefits and costs of monitoring alternative surrogate sets. We use two case studies of dynamic bird species associations in south-eastern Australia, for finding surrogate species in woodland undergoing restoration, or heathland undergoing combined fire and invasive predator management. We find that reduced temporal representativeness of surrogacy data leads to over-estimation of the true value of the surrogacy decision, and selection of suboptimal surrogates with lower performance. Increasing the monitoring budget to learn about associations marginally increases the relative performance of selected surrogates. In general, fewer data available for selecting surrogates means that more surrogates should be chosen to allow for suboptimal or uninformative surrogates selected due to incomplete knowledge of species associations. Approaches to prioritise surrogate selection are increasing in popularity as the funds for conservation and evaluation fail to meet management budget needs. Our results demonstrate that reductions in data can considerably decrease the efficiency and cost-effectiveness of selected surrogates, but that careful consideration of monitoring protocols tied to hypotheses about how the landscape is likely to change over time can reduce this gap. Surrogate choices that fail to acknowledge dynamics in species associations can lead to changes being missed due to redundant surrogates being chosen.

NON-INVASIVE GENETICS OF THE EURASIAN LYNX OF THE WESTERN CARPATHIANS

Barbora Turbakova

Department of Botany and Zoology, Faculty of Science, Masaryk University [INSTITUTE] Department of Biology and Ecology, Faculty of Science, University of Ostrava
Tomaz SKRBINSEK, Department of Biology, Biotechnical Faculty, University of Ljubljana ; Maja JELENCIC, Department of Biology, Biotechnical Faculty, University of Ljubljana ; Miroslav KUTAL, Friends of the Earth Czech Republic, Olomouc branch [INSTITUTE] Department of Forest Protection and Wildlife Management, Faculty of Forestry and Wood Technology, Mendel University in Brno

The population of the Eurasian lynx (*Lynx lynx*) in the Czech Republic occurs on the edge of the species distribution in the Western Carpathians. The population is threatened by many factors such as habitat fragmentation, migration barriers and poaching. Status of the population in the transboundary area of the Czech and Slovak Republics was investigated on the basis of non-invasive genetic material (scat, hair and urine samples) collected in years 2010–2013 during snow-tracking sessions. Using in total 19 microsatellite loci and the sex specific marker SRY we identified 18 individuals of lynx. Our aim was to describe genetic variability and structure of population, population size using capture-mark-recapture model, effective population size, kinship and spatial distribution. We also compared these results with data from the parallel camera traps survey and snow-tracking. We discuss the key factors important for the lynx conservation in the Central Europe as a basis of a trans-boundary management plan for Eurasian lynx.

SYMPOSIUM 108 REMOTE SENSING FOR CONSERVATION: NETWORKS HOLD THE KEY

Woody Turner

NASA
Allison LEIDNER, NASA

There is a veritable explosion underway of remote sensing platforms and sensors. From satellites, aircraft, and a plethora of in situ devices, remote sensing is providing information about changes in biodiversity at spatial scales from global to microbial. New airborne and satellite remote sensing instruments provide observations of key biological patterns ranging from the biome to the ecosystem to the organism, while also tracking environmental drivers of these patterns (e.g., climate, land use, and sea surface state). At the same time, a revolution in in situ observations (e.g., camera traps, acoustic sensors, small drones, citizen scientists' cell phones, and environmental DNA) is detecting patterns at the ecosystem to organism to genome levels and revealing processes behind some of the larger-scale patterns. Today, a primary challenge

for conservation biology lies in assembling networks to integrate cross-scale observations from multiple sensors on a variety of platforms. Fortunately, computational advances enable processing of ever-larger volumes of information. The reward for developing such interoperable observation networks will be an unprecedented ability to tackle the global problem of biodiversity loss at a global level, as well as regionally and locally.

76-A MULTI-SPECIES COMPARATIVE APPROACH TO ASSESSING DRIVERS OF SUCCESS IN MAMMALIAN CONSERVATION RECOVERY PROGRAMMES

Samuel Turvey

Zoological Society of London
Jennifer CREES, Zoological Society of London ; Richard Young, Durrell Wildlife Conservation Trust ; P.j. STEPHENSON, WWF International

The outcomes of species recovery programmes have been mixed, with high-profile population recoveries contrasting with species-level extinctions. Although each conservation intervention faces its own challenges, it is imperative to assess whether such lessons have wider general applicability. In order to contribute towards evidence-based improvement of future conservation strategies, we conducted a multi-species analysis of 48 mammalian recovery programmes based on peer-reviewed literature and semi-structured interviews with conservation scientists and practitioners. Using both quantitative and qualitative information derived from these data sources, we investigated ecological, management and political factors associated with population recoveries or declines. The importance of identifying and removing threats was emphasised most strongly from our results, indicating unsurprisingly that populations are likely to continue to be negatively impacted if threats are not reduced or removed, and highlighting the importance of management strategies such as robust threat monitoring. Informants also cited poor stakeholder coordination and management as a key weakness in recovery programmes, emphasising the importance of effective leadership and shared goals and management plans. Project outcomes were not influenced by ecological variables, suggesting that recommendations from our results are applicable to other recovery programmes. Despite the fact that the best approach to conserve a particular species will be context-dependent, our results suggest there is value in conducting broader-scale assessments of factors influencing the success of conservation interventions. We encourage further such studies, particularly at more localised scales, and recommend that the conservation community continues to evaluate and learn lessons from past experiences and adapt future strategies accordingly.

EVALUATING CONSERVATION NEEDS IN A WEST AFRICAN BIODIVERSITY HOTSPOT AND AN EBOLA EPICENTRE

Clement G. Tweh

Forestry Development Authority/Wild Chimpanzee Foundation

Menladi M. LORMIE, Forestry Development Authority ; Célestin Y. KOUAKOU, Wild Chimpanzee Foundation ; Annika HILLERS, The Royal Society for the Protection of Birds/Across the River - A transboundary Peace Park for Sierra Leone and Liberia ; Hjalmar S. KÜHL, Max-Planck Institute for Evolutionary Anthropology ; Jessica JUNKER, Max-Planck Institute for Evolutionary Anthropology

Over the past 12 months, Liberia has featured on international news due its prominence in the largest Ebola epidemic in human history. Liberia has yet to receive the same amount of public and media attention with respect to its exceptional biodiversity and natural heritage, and its role as a conservation priority in the region. The country's underrepresented reputation as a biodiversity hotspot and wildlife refuge can partly be explained by its long civil war that thwarted efforts to conduct biological surveys and gather evidence for its biological importance. From 2010-2012, we conducted the first nationwide survey to estimate abundance of chimpanzees (*Pan troglodytes verus*), large mammal diversity and human threats along 320 km of systematically located transect lines. With >7000 chimpanzees living in relatively large and continuous forest habitat, Liberia is home to the second largest and one of the most viable chimpanzee populations in West Africa. Our study also revealed that the majority of populations and some of the most species-diverse mammal communities exist outside protected areas, which cover only 2% of the country. This paucity of conservation protection, combined with proposed plans for large-scale timber and mineral extraction, present a serious threat to this important eco-region. Fortunately, our country-wide baseline dataset has already served as a platform to support government plans to establish a biologically representative network of conservation areas. Together with data on human livelihoods we currently investigate potential links between socio-economic variables and biodiversity, and address the effect of the recent Ebola crisis on natural resource consumption, and the country's economy and society. With this, we aim to inform future conservation strategies that provide human populations with the resources and ecological services they need without jeopardizing the long-term survival of the country's rich natural heritage.

DIFFERENCES IN SITE AND LIFE HISTORY DRIVE DEMOGRAPHIC RESPONSES TO CLIMATIC VARIATION IN SCANDINAVIAN ORCHIDS.

Matthew Tye

Uppsala University

Dag-Inge ØIEN, Norwegian University of Science and Technology ; Asbjorn MOEN, Norwegian University of Science and Technology ; Johan DAHLGREN, University of Southern Denmark ; Nina SLETVOLD, Uppsala University

Climate change has been identified as a threat to species persistence worldwide. However, climatic factors may affect populations in highly different ways. While these differences are apparent at large spatial and taxonomic scales, variation in life history, site factors, and ecological interactions at smaller scales also may influence a population's response to climate change. This study addresses such small scale variation by examining the effects of variation in four climatic variables on eight populations of closely related orchid species (genera *Dactylorhiza* and *Gymnadenia*) at two sites in central Norway. We used over 30 years of demographic and climatic data to construct matrix models parameterized by generalized linear mixed models (GLMMs). We examined the effects of current and previous year precipitation and temperature on standard vital rates (survival, stage transitions, flowering rate and flower production). We also used data on fruit production to estimate the effects of climate on pollination rate. The results show small and highly variable effects of climatic factors both between species as well as different populations of the same species. In addition we found that local climatic factors during the period of fruit production strongly affect the level of fruit production. These results underscore the importance of considering the local site and life history of populations when considering their response to large scale environmental changes such as climate. Understanding this small scale heterogeneity will be key for developing successful conservation and management plans at the population level.

141 LAND-USE INTENSIFICATION AND AGRICULTURAL YIELD - WHO NEEDS BIODIVERSITY?

Jason M. Tylianakis

University of Canterbury

Land-use intensification drives extinctions, which should undermine ecosystem services and, in turn, harm production. Conversely, it has been argued that crop yields generally benefit from increasing intensification (seemingly unaffected by reduced services), and that set-aside conservation areas can mitigate biodiversity loss and allow further intensification of agriculture. However, both sides of these arguments are based several key assumptions, such as: 1) biodiversity consistently promotes ecosystem services in agricultural systems, provided that biodiversity is available in the system; 2) the environmental costs of intensification are limited to the agricultural habitat itself, so intensification does not reduce the value of nearby land spared for conservation; 3) what works

for increasing production now will always work. I will discuss the conditions under which biodiversity is most important for ecosystem services related to agriculture, and how these conditions relate to real-world native vs. production systems. I will also present evidence for offsite impacts of intensification, and discuss how these undermine the effectiveness of land sparing in mosaic landscapes. Finally, I will emphasise that increasing productivity while harming biodiversity may provide production benefits in the short term, but lead to system instability that threatens production in the long term. In essence, conserving biodiversity in production landscapes will be insufficient to maintain ecosystem services, unless we create the specific conditions under which biodiversity most effectively provides ecosystem functions and services in the face of changing environmental conditions.

A NOVEL BUTTERFLY MONITORING SCHEME IN GREECE

Elli Tzirkalli

UNIVERSITY OF PATRAS

EMMANOUEL, AGRICULTURAL UNIVERSITY OF ATHENS ; Nicos GAVALAS, SPEED DEVELOPMENT CONSULTANTS SA ; Christina

KASSARA, NCC NATURE CONSERVATION CONSULTANTS LTD

; Lazaros PAMPERIS, AGRICULTURAL UNIVERSITY OF ATHENS

; Kelly PAPAPAVLOU, AGRICULTURAL UNIVERSITY OF ATHENS

; Olga TZORTZAKAKI, UNIVERSITY OF PATRAS ; Konstantina ZOGRAFOU, UNIVERSITY OF PATRAS ; Vassiliki KATI, UNIVERSITY OF PATRAS

Butterfly Monitoring Schemes (BMS) have been well developed in Europe and are widely recognized as efficient tools guiding conservation evaluation. In spite of its exceptional butterfly diversity, no such scheme has been implemented in Greece so far. In this paper we are presenting the first results of the national monitoring program of Greece that targeted the assessment of the conservation status of ten butterfly species of European conservation concern. We conducted 397 transects of 500 m standard length, located in their majority (80%) within Natura 2000 sites (45) all over the country. Although we visited sites only once, we recorded 138 species (11638 individuals), accounting for 59% of the Greek butterfly inventory. No significant difference between transects located within and outside Natura 2000 was revealed, in terms of their mean species richness and abundance (U test, $W = 10417.5$, $p > 0.05$). Therefore butterfly conservation management should consider the maintenance of adequate butterfly habitats on a broad scale, including areas outside the Natura 2000 network as well. Our preliminary results, combined with atlas data and expert opinions, concluded that only two species merited a favourable conservation status (*Parnassius mnemosyne*,

Zerynthia polyxena), two species had a bad conservation status with declining population trends (*Lycaena dispar*, *Papilio alexanor*), and six species have an inadequate status with declining populations as well (*Apatura metis*, *Euphydryas aurinia*, *Maculinea arion*, *Parnassius apollo*, *Polyommatus eroides*, *Pseudophilotes bavius*). The establishment of a permanent and systematic monitoring scheme is a necessity to increase the reliability of the conservation status assessment of butterflies in Greece, to improve ecological knowledge and to reach well-informed conservation management decisions on national and local scales.

CONSERVATION ECOLOGY OF BUTTERFLIES IN THE MEDITERRANEAN ISLAND OF CYPRUS UNDER THE NATURA 2000 CONTEXT

Elli Tzirkalli

UNIVERSITY OF IOANNINA [INSTITUTE] FREDERICK RESEARCH CENTER

Vassiliki KATI, UNIVERSITY OF PATRAS ; Rob J. WILSON,

UNIVERSITY OF EXETER ; Costas KADIS, FREDERICK RESEARCH

CENTER ; Konstantina ZOGRAFOU, UNIVERSITY OF IOANNINA ;

John M. HALLEY, UNIVERSITY OF IOANNINA

Cyprus has a strong Natura 2000 network with 61 sites (SCIs and SPAs) covering more than 19% of the island. To investigate how well does the current network contribute to the conservation of butterfly species we collected data from 60 sites located inside and outside of the Natura 2000 network, between March-July 2011-2013, using the line transect method (300 m-Pollard walk). A total of 38 species (4708 individuals) were recorded, which represent 72% of the Cyprus butterfly fauna. The Natura 2000 network (34 out of 60 sites) was quite rich in terms of butterfly diversity, hosting 66% of butterfly species in the study area. However, the Natura 2000 network did not maintain significantly more butterfly species, or significantly more butterflies of conservation concern, though it hosted significantly more endemic species (U test, $W = 288$, $p < 0.05$), as compared with the sites outside the network. To test the effects of environmental parameters on the overall species richness of butterflies for all sites, we used Generalized Linear models (GLMs). Our results showed that flowerheads and soil humidity positively influenced butterfly richness. Redundancy analysis also revealed four environmental factors (altitude, flowerheads, herb and rock cover) that clearly affected the butterfly community within the study area. Taken together, the results suggest that the Natura 2000 network in Cyprus contributed significantly to preserve endemic butterfly diversity and that species composition was constrained mainly by gradients of either vegetation or abiotic parameters. These findings have significant conservation implications for the management of Natura 2000 sites but also for areas outside the network that should be taken into account to ensure adequate protection of Cyprus butterflies.

BIRD COMMUNITY COMPOSITION ALONG AN URBANIZATION GRADIENT IN A MEDITERRANEAN CITY

Olga Tzortzakaki

University of Patras

Vassiliki KATI, University of Patras ; Sinos GLOKAS, University of Patras

Urbanization is considered one of the greatest challenges that humanity faces today, since it causes serious environmental degradation including habitat alterations and loss. Recent studies have shown that urbanization alters significantly avian communities. During the last decades, Greek cities have experienced intensive urban web expansion, without adequate spatial planning, producing a particularly restricted web of green patches. Our study examines the effects of urbanization on avian communities for the first time in Greece, taking as a case study the city of Patras. Breeding bird communities were sampled twice during spring time, using the point count method, from 90 randomly selected 500X500m grid cells evenly distributed along an urbanization gradient (urban, suburban, peri-urban zones). A total of 46 species (3306 individuals) were recorded, including 32 breeding species (3233 individuals) that were used for the analyses, of which 8 are of European Conservation Concern. Overall species richness increased from the urban zone (21 species) to the peri-urban one (31 species), though this difference was not significant (Spearman $\rho=0.180$, $p>0.05$). On the contrary, average species abundance exhibited a significantly decreasing pattern ($\rho=-0.316$, $p=0.002$), which was also observed when SPECs were separately considered ($\rho=-0.337$, $p=0.001$). This inverse pattern is attributed to a set of 10 urbanization-enhanced species (3 SPECs), such as sparrows and swallows, which are very abundant in the urban zone. The majority of the species (21) was detected more frequently outside the urban core, but presented generally lower abundances. Our results underline that the peri-urban zone is not as rich as expected, showing a great degree of habitat degradation due to anthropogenic disturbance, as well.

COMMUNITY ENGAGEMENT TO MITIGATE TIGER HUMAN CONFLICT IN BANGLADESH SUNDARBANS

Nasir Uddin

WildTeam

Tiger human conflict (THC) is a common occurring being recorded, every year numbers of human, tiger and livestock has been killed as a consequence of THC. THC is an alarming threat to Bengal tiger conservation in Sundarbans Reserve Forest (SRF). Village Tiger Response Team (VTRT), a voluntary group, was established by WildTeam in 2007 to ensure community engagement in Bengal tiger conservation in

Bangladesh. 350 VTRT members under 49 teams are doing voluntary work in around SRF to mitigate THC. The objectives of this study is to find out the involvement of VTRT and ways how VTRT are helping tiger conservation in SRF. THC management response data were collected from 2011 to 2013 and analyzed to find out VTRT involvement fro THC mitigation in SRF. Study result denotes that VTRTs were participated to mitigate all categories of THC incidents (stray tiger, livestock incidents and human incidents). VTRT responded to 176 cases out of 422 THC incidents. In response to tiger incidents they did 14 crowd conditions to mage stray tiger and did 40 village meeting to aware local people. In last three years. In response of human incident they retrieved 20 human dead bodies from forest, transported 22 injured human in the study period. To make local people aware about tiger attack inside the SRF they conducted 17 village meeting and arranged 11 trainings for villagers by themselves to peripheral villagers of f SRF. In response to livestock incident they collected 50 dead bodies from forest, transported 26 injured livestock to the community, and conducted 29 villages patrolling to mitigate direct THC. And to make people aware about livestock incidents management and to increase their involvement in tiger conservation they conducted 83 village meeting to the community. VTRT the small group of people is acting as inspiration source for local people to save Bengal. So VTRT activities should be promoted by supplying technical skills to ensure future conservation of Bengal tiger.

THE HUMAN AND NATURAL HISTORY OF A BIOLOGICAL INVASION. THE CASE OF GORSE (ULEX EUROPAEUS) ON THE ISLAND OF RÉUNION (INDIAN OCEAN)

Nathalie Udo

CNRS / Université de Rennes 1

Michèle TARAYRE, CNRS / Université de Rennes 1 ; Anne ATLAN, CNRS / Université de Rennes 1

Biodiversity conservation involves the reduction of the threats endangering the survival of species, habitats and landscapes. Among these threats, biological invasions are a major issue. In order to reduce the impact of invasive species, it is necessary to both prevent their introduction and control their expansion. Given that these species often settle in areas where humans play a central role, the integration of the historical dimension and social context could help optimise management measures. This is what we studied in gorse (*Ulex europaeus*), a global invasive species that is strongly linked to human activities. Gorse was used as fodder and for several other agricultural purposes in its region of origin, and it was intentionally introduced from Europe to many colonies during the 19th century. It is now considered as "one of the 100 World's Worst Invasive Alien Species" by the IUCN. The invaded region studied here is the island of Réunion, where the presence

of humans is recent (within the past 350 years), and where archives are available for almost the entire history of human colonisation. By combining ecological methods, documentary research and semi-structured interviews, we were able to accurately retrace the spatiotemporal dynamics of gorse, and to link this with the joint progression of socio-economic and cultural factors. This multidisciplinary analysis helped identify natural and human dispersion factors, which have a very spatial interaction, and suggests that differential management should be considered according to the territories. They also showed how expansion in natural environments could depend on the dynamics of the plant in agricultural areas, and thus the socio-economic factors in the agricultural world. In general, they confirm the importance of a historical approach to understanding the synergistic relationship between socio-economic factors, environmental disturbances and geographic expansion of an alien species.

EFFECTS OF THE CONSERVATION MANAGEMENT ON THE GRASSLAND VEGETATION OF SÁR MOUNTAIN IN HUNGARY

Boglárka Uj

Szent István University

Judit HÁZI, Szent István University ; Gergely PÁPAY, Szent István University ; Dénes SALÁTA, Szent István University ; Károly PENKSZA, Szent István University

We studied the vegetation of grasslands on the Sár Mountain, in Gyöngyös (Hungary). The areas are mowed regularly by the Bükk National Park and mechanical shrub control was done as well. The effects of these habitat management techniques were investigated on grasslands of different degradation levels. Coenological studies were made between May and June in 2013, 2014 with 2x2 m relevés (Braun-Blanquet, 1964). The study areas were characterised according to nature conservation value categories by Simon (1988) and life forms (Raunkiaer 1934, Pignatti 2005) and social behaviour types by Borhidi. Our results showed that the above mentioned management techniques had positive effects on the diversity of grasslands. On the managed grasslands the abundance of woody species decreased, while the abundance of annual and perennial grass species and dicotyledonous herbaceous species increased. The highest species number (58-78) was recorded in the case of control areas. The number of species was high (47-49) in the areas managed by mowing and mechanical shrub control. The lowest species number (43) was recorded in the areas which were not mowed after mechanical shrub control. According to the nature conservation value categories the number of protected species was the highest in the control areas. Our results approved that regular mowing is needed after mechanical shrub control to sustain the diversity of abandoned grasslands in the long run. This project supported by a grant from Switzerland through the Swiss

Contribution: „Sustainable Nature conversation on Hungarian Natura 2000 sites“, and by Research Centre of Excellence – 8526-5/2014/TUDPOL.

AMPHIBIAN DIVERSITY IN AGROFORESTRY SYSTEMS PRACTICED IN NORTHEAST INDIA - A BIODIVERSITY HOTSPOT

Yashmita Ulman

NERIST

Madhu SHARMA, NERIST ; Awadhesh KUMAR, NERIST

The Northeast Indian biodiversity hotspot faces severe threats from conversion of forests into commercial plantations, 'jhum' cultivation, encroachment of forest lands, grazing, habitat destruction, human-wildlife conflict etc. endangering the survival of several taxa. Many of these northeastern states of India have traditional agroforestry systems in practice for their livelihood. The contribution of agroforestry systems in conserving flora and fauna in this part of India is less explored. Present study attempts to compare amphibian species diversity in three different agroforestry systems namely homegardens, tea plantations and agrisilvicultural systems during rainy season in Sonitpur district of Assam. A total of 13 species of amphibians were found belonging to 5 families with the most dominant species being *Duttaphrynus melanostictus* in homegardens (25.45%) and tea plantations (29.71%) and *Euphlyctis cyanophytis* (31.89%) in agrisilvicultural systems. A total of 3005 individuals were recorded. The highest number of individuals, diversity and species richness was found in homegardens ($n=1308$, $H=2.16$, $S=13$), followed by tea plantations ($n=1070$, $H=1.98$, $S=9$). The least number of individuals, diversity and species richness was found in agrisilvicultural systems ($n=627$, $H=1.65$, $S=6$). Homegardens with their multilayered canopy structure similar to forest have better potential to conserve amphibians as compared to that of tea plantations and agrisilvicultural systems. Tea plantations which have shaded trees prove to be a better contender as compared to that of agrisilvicultural systems. The agrisilvicultural systems might not be very suitable habitat as it is moist only during certain months in a year therefore might be showing lowest amphibian diversity. Overall, it may be concluded that in the era of decreasing forest area, agroforestry systems might be an option for conserving species in these biodiversity hotspots.

ESENIAS-TOOLS: REGIONAL INITIATIVE TO CONSERVE BIODIVERSITY

Ahmet Uludag

Duzce university[INSTITUTE]COMU

Teodora TRICHKOVA, IBER-BAS ; Rumen TOMOV, University of Forestry ; Vladimir VLADIMIROV, IBER-BAS ; Milica RAT, University of Novi Sad ; Riccardo SCALERA, IUCN-ISSG

A number of tools and strategies are being developed at either the national, regional and global level to face biological invasions which are among of the main threats to biodiversity alongside climate changes and habitat destruction. Lack of expertise and relevant knowledge are among the key factors affecting a proper response to the problem in some countries and regions. A dedicated network - ESENIAS (East and South European Network for Invasive Alien Species) - was established at the regional level in 2011 to overcome this problem. ESENIAS has been organising yearly workshops aimed at promoting capacity building initiatives and increasing knowledge toward the issue within all countries in the region. A new project has been just launched: "East and South European Network for Invasive Alien Species – a tool to support the management of alien species in Bulgaria (ESENIAS-TOOLS)". This initiative, funded under the Programme BG03 "Biodiversity and Ecosystem Services" within the EEA FM (2009-2014), will result in networking and development of IAS tools within the framework of ESENIAS. The objective is to support the management of alien species in Bulgaria and in the overall region in order to contribute to the conservation of native species and natural ecosystems. These tools will include internet portal, IAS database, early warning tool and common methodologies for collection and analysis of data. One of the aims of the project is to establish connections and collaboration with regional and international groups/ organisations. Eleven institutions from Bulgaria, Croatia, Iceland, Greece, R. Macedonia, Romania, Serbia, and Turkey will take part in the project. We expect the project will provide comprehensive information to improve efficiently the conservation decision making in the ESENIAS region, possibly in view of a dedicated regional strategy. Acknowledgements: The study and participation has been supported by the ESENIAS-TOOLS project.

WHOSE COMMONS, WHEN AND FOR WHAT?

Hita Unnikrishnan

Ashoka Trust for Research in Ecology and the Environment (ATREE)

Harini NAGENDRA, Professor, School of Development, Azim Premji University

Urban expansion is a global phenomenon, and one that occurs by often engulfing and embracing the rural. At this time many common spaces, often with complex histories of governance and stewardships become redefined within the prevailing notions of urbanity. However, such commons often pose challenges that result in conflict with respect to their use, management and ownership. These challenges

are often manifested in the ecosystem services they provide and decisions that revolve around the governance of these resources. In this paper, we use the example of a transformed lake in the South Indian megapolis of Bengaluru to look at different changing notions of urban commons pictured against a backdrop of rapid urbanizations, migrations and landscape change. The period of time we have chosen for this study is from 1885 to the modern day. We look at conflicts at each period of change and argue that many of these have shaped the landscape of today and perhaps may be responsible for current notions of ownership associated with the landscape. We combine landscape level change analysis through geospatial means along with official archival records and oral narratives to weave a story of change and its impacts on urban commons and the ecosystem services derived from them. We then pose that knowledge of historical contexts of ecosystem services, conflict and the mechanisms of conflict resolution around urban commons can help understand the trends in contemporary management of commons and help shape more equitable and ecologically robust policy frameworks with respect to the management of commons.

WILD BEE SPECIES CAN BE ENHANCED BY LEAVING UNCUT REFUGES WITHIN LOWLAND AES GRASSLANDS

Debora Unternährer

University of Bern

Jean-Yves HUMBERT, University of Bern ; Raphaël ARLETTAZ, University of Bern

Pollination services provided by wild bees are nowadays threatened by agriculture intensification. However, positive effects from agri-environment schemes (AES) aimed at protecting farmland biodiversity have only exhibited moderate levels of invertebrate population-level responses. Furthermore, evidence that local populations of invertebrate taxa increase over time are still absent. In Switzerland, a study conducted in 2011 (Buri, Humbert & Arlettaz 2014) has established that wild bees are promoted by spatial-temporal modification of mowing regimes within AES extensively managed meadows. Specifically, it was shown that wild bee abundance and species richness significantly increased in meadows where uncut refuges remained (i.e. at each cut 10-20% of area was left uncut and first cut not before 15 June) in comparison to control meadows without refuges with a first cut not before 15 June. An immediate positive effect of delayed mowing (meadows with first cut not before 15 July) was also observed. In 2014, the same meadows were resampled to see whether the applied alternative mowing regimes had stronger effects on wild pollinators' species richness and abundance after four years (in 2014) in comparison to after one year (in 2011) of implementation. We also expected that by adding a sampling year to the data set, it would allow us to

detect effects that would have otherwise stayed statistically undetected. No stronger effect could be observed in 2014 compared to 2011, i.e. population-level responses, however, our study shows the importance of leaving uncut refuges for wild bee species richness and diversity. Our results enhance the importance of sampling bio-indicator groups over several years before implementing scientifically sound management recommendations.

62. THE ECOLOGICAL BASIS OF SOCIAL VALUES

Ayse Uskul

University of Kent

Conservation professionals would benefit from findings that social-environmental contexts not only shape what individuals think, but how they think. This talk discusses the role of social interdependence shaped by livelihood requirements for a) cognitive tendencies among three livelihood groups (fishermen, herders, farmers) and b) responses to social exclusion experiences among children in two livelihood communities (farmers, herders). We examined how livelihood activity shapes cognitive tendencies by comparing herders, farmers, and fishermen on attention, categorization, and reasoning tasks. Compared to herders, fishermen and farmers focused more on the object in relation to its context, attended more holistically to relationships and similarities among objects, and used rule-based reasoning more than similarity-based reasoning. This suggests that farmers and fishermen who rely heavily on collaboration and emphasize harmonious relationships exhibited greater holistic tendencies than members of herding communities, which emphasize individual decision-making and foster social independence. In line with previous work showing that the strong social bonds associated with interdependence values serves as a protective buffer against the pain of being socially excluded, we also showed that children of interdependent farming communities reported ostracism to be less painful than did children from independent herding communities. Moreover, parents' level of social interdependence predicted their children's responses to the ostracism situation. Finally, we observed that farmers' children punished an individual who ostracized someone else less harshly. This provides evidence that livelihood, shaped by environment, is associated with important differences in human psychology. This could have important implications for conservation professionals interested in introducing collaborative processes for the management of commons resources, particularly in developing countries.

USING BENTHIC MACROINVERTEBRATE COMMUNITIES AS INDICATORS OF SUSTAINABLE RICE CROPPING IN A TROPICAL WETLAND

Erasme Uyizeye

University of Rwanda

Elias BIZURU, University of Rwanda ; Beth KAPLIN, University of Rwanda

Wetlands play an important role in regulation of both the quantity and quality of downstream water resources. However, most Rwandan wetlands are threatened by agriculture, with rice farming being the most dominant crop. An adaptive model was developed for sustainable rice cropping meant to maintain wetland health and ecological function including water filtering and storage. This model consists of alternation of rice parcels with uncultivated parcels left in fallow. The main objective of the study was to evaluate the effectiveness of this innovative new model by assessing the richness of benthic macroinvertebrates as biological indicators. This was coupled with examining physicochemical variables as well as sediment retention, chemical recycling and filtering function capacity. Over a one year period, stratified methods for data collection were used across different treatment types. Soil and water chemical analyses were conducted in the laboratory to test nutrient and heavy metal concentrations in fallow and rice in old and young treatments. Results showed that the new habitats created with the new model of rice cropping contributed significantly to an increase richness of macroinvertebrates at the family level, as well as declines of some heavy metal concentrations. This was an interesting result from an integrated wetland landscape created to provide much more habitat heterogeneity favorable to wetland species. Soil properties and composition displayed high similarities between different treatment types which excludes the role of soil type in variation of benthic biological and physicochemical findings. This innovative rice system management model contributed to the maintenance of healthier ecological function while increasing the long term ecological processes of Ndobogo wetland, hence the sustainability of this wetland agricultural system.

MACROINVERTEBRATE DIVERSITY AND COMMUNITY STRUCTURE IN WOODLAND POOLS AND DITCHES AND THEIR RESPONSE TO ARTIFICIAL DRAINAGE IN ESTONIA

Maarja Vaikre

Tartu University

Liina REMM, Tartu University ; Riinu RANNAP, Tartu University

Since the 20th century freshwater ecosystems have been extensively drained for agricultural and forestry purposes. Despite the magnitude of artificial drainage, its impact on

freshwater biodiversity, especially in small forest waterbodies, is still poorly known. We examined macroinvertebrate species richness and assemblages in forests, comparing (i) temporary waterbodies situated in drained plots, (ii) in natural plots, (iii) ditches, and (iv) wheel rut pools. Our aim was to determine macroinvertebrates characteristic to certain type of waterbodies, the impact of forest drainage on macroinvertebrates and the possible functioning of ditches as an alternative habitat. We surveyed 181 waterbodies within six landscape regions and identified 171 macroinvertebrate taxa. We did not detect any strong uniform forest drainage effect on species richness and assemblages and found only few indicator taxa. The ordering of waterbody types by richness differed between landscape regions. Invertebrate assemblages were relatively similar across waterbody types within landscape regions but differed between regions. Therefore it seems that macroinvertebrates are largely dependent on landscape characteristics and drainage do not reduce species richness at waterbody level. However, taxa accumulation curves pooling all regions indicated, that natural waterbodies situated in drained plots harbour less invertebrate taxa than those in natural plots, ditches and wheel rut pools. Thus drainage may have effect at regional scale. As drainage caused the replacement of natural waterbodies with ditches, it is important to ensure that ditches can provide refuge. Since assemblages and species richness in natural temporary waterbodies and drainage ditches were not significantly different, ditches can be suitable habitat for macroinvertebrates of temporary waterbodies at least in semi-naturally managed forests.

DESERT-ADAPTED SPECIES ARE VULNERABLE TO CLIMATE CHANGE: INSIGHTS FROM THE WARMEST REGION ON EARTH

Cândida G. Vale

CIBIO/InBIO, Centro de Investigação em Biodiversidade e Recursos Genéticos da Universidade do Porto
José Carlos BRITO, CIBIO/InBIO, Centro de Investigação em Biodiversidade e Recursos Genéticos da Universidade do Porto

Climate change is eroding biodiversity and conservation efforts have been focusing on species' potential responses to these changes. Functional traits associated with adaptive and dispersal capacities may contribute in identifying species' vulnerability levels to climate change. Desert-adapted species could be sensitive to climate change as they may live already in their physiological limits, as in the case of the Sahara-Sahel ecoregions. The identification and spatial location of functional groups of Sahara-Sahel endemics and how they might be affected by the predicted magnitude and velocity of climate change are crucial for biodiversity conservation of the region. We collated trait data for all Sahara-Sahel endemics and summarize the functional strategy of each species into functional groups with different adaptations and dispersal

capacities. Future climate scenarios were classified to identify areas where predicted temperature and precipitation approach the physiological limits of each group, i.e. areas where each functional group is potentially more vulnerable to climate change. Seven functional groups with different distribution patterns were identified. Groups were distinctly threatened by specific magnitudes and velocities of temperature and precipitation changes according to their range. Generally, the magnitude and velocity of precipitation changes contributed to more vulnerability in comparison to temperature changes. While some functional groups with high dispersal abilities may colonize distinct areas, other groups with low adaptive and dispersal capacity may be highly vulnerable to climate change. Different traits contributed to the extent to which species are exposed to climate change and apparently the desert-adapted species are the most vulnerable ones. The identification of vulnerable functional groups in the Sahara-Sahel provides indications on vulnerability to climate change in other warm deserts of the world.

210 ARE ROADLESS AREAS IN THE AMAZON OVERESTIMATED?

Mariana Vale

Federal University of Rio de Janeiro
Pierre IBISCH, Eberswalde University for Sustainable Development ; Monika HOFFMANN, Eberswalde University for Sustainable Development ; Simone FREITAS, Universidade Federal do ABC

Hoffmann et al. (this symposium) present a global map of roadless areas, based on the OpenStreetMap dataset, and defining "roadless areas" as terrestrial areas whose boundaries are within at least 1 km to the nearest road. The analysis found considerably large roadless blocks in the tropics, particularly in the Amazon. The Brazilian Institute for Geography and Statistics (IBGE) road data is slightly more complete, showing ca. 157,000 km of roads in the Brazilian Amazon, as opposed to ca. 114,000 km from OpenStreetMap. Using the 1-km buffer and the IBGE dataset, we find that 94% of the Brazilian Amazon is roadless. The 1-km buffer, however, just reflects the direct impacts of roads on ecosystems. In the Amazon, roads especially have an indirect, contagious impact: they trigger uncontrolled colonization, illegal logging and deforestation. Studies show that from 1985 to 2000, there was an average of about 30% forest loss within 0 to 10-km distance from both roads and highways in the Brazilian Amazon. Using the 10-km buffer and the IBGE road dataset, we find that only 62% of the Brazilian Amazon is roadless. Still, > 85% of the area of the region's indigenous reserves and protected areas are roadless. This may be a conservative estimate, because we do not differentiate roads from highways, although from 1985 to 2000 highways' were reported to cause forest loss up to 50-km distance. It is also important to highlight that rivers are a main transportation

way in the Amazon, facilitating manifold types of natural resource use and extraction. They have not been considered in the definition of 'roadless areas' applied here.

THE LANDSCAPE OF ANTHROPOGENIC MORTALITY RISK FOR LIONS: DETERMINANTS, USE, AND CONSEQUENCES FOR LIONS, PARTICULARLY FOR YOUNG INDIVIDUALS.

Marion Valeix

CNRS

Nicholas ELLIOT, University of Oxford ; David MACDONALD, University of Oxford ; Andrew LOVERIDGE, University of Oxford

The expansion of human populations and activities creates new environments that are hostile to many wild species and underlies many declines and extinctions currently occurring worldwide. In this study, we assess the impact of anthropogenic mortality (trophy hunting, conflict, accidental snaring, and vehicle related mortality) on the African lion population of Hwange National Park, Zimbabwe. This ecosystem is one of the ten lion strongholds left in Africa. We used 206 events of lion mortality due to anthropogenic causes recorded between 1999 and 2012 to identify the variables associated with each anthropogenic mortality source. We then used data from 87 GPS-collared lions since 2002 to calculate cause-specific mortality rates for each sex. We combined these results to create a landscape of anthropogenic mortality risk for each sex. Areas of high mortality risk were located at the periphery of protected areas, with areas of very high mortality located in trophy hunting areas for males and areas of high female mortality distributed more widely across land-use types reflecting the importance of differing sources of mortality. However, even lions whose home range barycentre was inside the protected area (up to 20km inside) had sometimes significant portions of their home range in risky areas, illustrating the extent to which 'edge effects' have the potential to impact this lion population. We further revealed that the proportion of risky areas in the home range was higher for young individuals, particularly males, than experienced adults. For young individuals, we also found that all males that dispersed before 31 months died during transience and the dispersal coincided, regardless of age or body condition, with the arrival of unfamiliar adult males; an instability caused by the high mortality of adult males in trophy hunting areas. These results are crucial to fully grasp the impact of edge effects on wild populations living in isolated protected areas.

ECOLOGICAL AND SOCIAL DIMENSIONS OF TREE DIVERSITY CONSERVATION IN COFFEE AGROFORESTRY SYSTEMS

Vivian Valencia

Columbia University

Luis GARCIA-BARRIOS, El Colegio de la Frontera Sur ; Paige WEST, Columbia University ; Eleanor STERLING, Center for Biodiversity and Conservation, American Museum of Natural History ; Shahid NAEEM, Columbia University

Agroforestry is considered a promising alternative to conventional agriculture that can both conserve biodiversity and support local livelihoods. Coffee agroforestry may be particularly important for sustaining trees of conservation concern and late-successional stage, but this possibility remains unclear. Here, we examined whether coffee agroforestry systems can serve as conservation reservoirs of tree species native to nearby forests. We compared tree diversity, composition and structure between coffee agroforests and forests in La Sepultura Biosphere Reserve in Chiapas, Mexico. We found that, although at the landscape level the full set of coffee agroforests appears to conserve comparable tree species richness to nearby native forests, the species composition that is being conserved is different. Coffee agroforests had a lower proportion of trees of conservation concern, a higher proportion of pioneer trees, were dominated by *Inga* spp., harbored lower tree species diversity at the plot level, and were composed of different tree species compared to native forests. We suggest that conservation practitioners and policy makers seeking to promote coffee agroforestry as a conservation strategy should consider how such agroforestry systems differ in species diversity and composition from the native forests of conservation interest. Further, promoting different coffee agroforest management strategies, such as discouraging the replacement of diverse agroforest canopies with *Inga*-dominated canopies, would help improve the conservation value of coffee agroforests through more sustainable practice.

PRESCRIBED FIRE AS AN ALTERNATIVE MEASURE FOR THE CONSERVATION OF GRASSLANDS

Orsolya Valkó

University of Debrecen

Balázs DEÁK, MTA-DE Biodiversity and Ecosystem Services Research Group ; Péter TÖRÖK, University of Debrecen ; Zsolt VÉGVÁRI, Department of Conservation Zoology, University of Debrecen-Hortobágy National Park Directorate ; Béla TÓTHMÉRÉSZ, MTA-DE Biodiversity and Ecosystem Services Research Group

Traditional fire use was an important part of the landscape management for millennia. Nowadays the majority of human-ignited fires are uncontrolled, often having serious negative impacts on human life, property and biodiversity. The impacts of fire on grassland biodiversity are scarcely documented and there are contrasting opinions on the perspectives of prescribed burning management in European grasslands. One hand, prescribed burning can be a cost-effective method

for the management of open landscapes, the reduction of accumulated litter and for decreasing wildfire risk. On the other hand burning can lead to the encroachment of competitor and invasive species and can threaten endangered plant and animal species; thus, inappropriate burning can result in a loss of biodiversity. We reviewed the publications on the application of prescribed burning in European grasslands and also from North-America to identify findings which can be adapted to the European grassland conservation strategy. We found that not only the application of fire management is scarce in Europe but there is also a lack of published studies on this topic. European studies, contrary to the North-American practice, usually used yearly dormant-season burning, and concluded that this burning type solely is not feasible to preserve species-rich grasslands. In North-America, application of burning has a stronger historical, practical and scientific background; it is fine-tuned in terms of timing, frequency and generally combined with other measures, such as grazing, seed sowing or herbicide application. By this complex approach several nature conservation goals can be fulfilled like increasing landscape-scale heterogeneity and invasion control. For establishing fine-tuned prescribed burning management plans for European grasslands the general findings of carefully designed case-studies should be combined with the practical knowledge of conservation managers.

TO DRINK OR NOT TO DRINK? ELEPHANT MOVEMENT STRATEGIES AS SURFACE WATER AVAILABILITY DECLINES IN A SEMI-ARID SAVANNA.

Hugo Valls Fox
C.N.R.S

Hervé FRITZ, C.N.R.S; Michel DE GARINE-WICHATITSKY, CIRAD; Edwin T MAKUWE, Zimbabwe Parks and Wildlife Management Authority; Simon CHAMAILLÉ-JAMMES, C.N.R.S

Water provision for wildlife is a common practice in semi-arid savannas. Sometimes, the viability of populations in protected areas is increased by, or even depends on, this provision. In these cases the distribution in space of perennial water sources is likely crucial, but so far little is known about the water-driven movement strategies of animals: as water sources dwindle and forage depletion occurs, should individuals make long trips far away from water to obtain better foraging prospects or short trips close to water to guarantee drinking opportunities? This affects where animals will impact their environment. We analyzed GPS relocation data of elephant breeding herds during the 2013 dry season in Hwange National Park, Zimbabwe. Elephants prefer drinking at periodic time intervals every 24h, 48h and 72h. The average number of visits to water doubled from June to October due to the addition of short (about 4h) commuting trips between waterholes. As of September, 72h-trips disappeared, however the number of 48h-trips, reaching 5-8 km from water, remained constant. The

number of 24h-trips increased and they were made at higher speed. As a result, during those trips, maximum distance to water increased from 2.5 to 4km, suggesting the avoidance of depleted foraging sites located close to water. Our study confirms that there is a threshold distance beyond which elephants cannot use the landscape during the dry season, but more importantly it reveals that below this distance elephants are able to adjust their use of the environment to foraging constraints.

95 - MITIGATING THE NEGATIVE EFFECTS OF ROADS AND TRAFFIC ON WILDLIFE: HOW EFFECTIVE ARE OUR STRATEGIES?

Edgar Alexander Van Der Grift

Alterra, Wageningen UR

Marcel Pieter HUIJSER, Montana State University, Western Transportation Institute; Carme ROSELL, Minuartia / Universitat de Barcelona

Roads may result in habitat loss, movement barriers and direct mortality. In some cases wildlife population viability may be affected. Several measures are available to help reduce wildlife-vehicle collisions and restore wildlife connectivity across roads: wildlife fences, wildlife crossing structures, and warning signs activated by wildlife detection systems. However, the effectiveness of such measures is not well studied. Although some sort of monitoring is usually carried out, in many cases the methods are not optimal and they may not allow for a proper evaluation of the effectiveness of the measures. Partially based on the SAFEROAD project (www.saferoad-cedr.org), financed by CEDR, we synthesized the effectiveness of mitigation measures through literature review. We selected studies in which the mitigation measures were clearly described and that included quantitative response variables based on study designs that included a before-after comparison and/or a comparison between treatment and control sites. We deduced guidelines for monitoring based on research principles that allow for maximizing inferential strength of study designs. We present the results of our review and formulated guidelines for evaluating the effectiveness of road mitigation measures. Selected key issues in the guidelines will be illustrated through three case studies: (1) roe deer mortality before and after the construction of a wildlife overpass, showing the importance of proper selection of impact and control sites; (2) large mammal mortality at a road section with an animal detection system, showing the effect of length of the mitigated road section and the spatial precision of crash and carcass data; (3) ungulate-vehicle collisions monitoring, showing the importance of establishing proper procedures and indicators for measuring effects of mitigation and managing the conflict.

95 - THE ROAD AHEAD - THE FUTURE OF ROAD ECOLOGY IN A RAPIDLY CHANGING WORLD.

Rodney Van Der Ree

Australian Research Centre for Urban Ecology

There are currently in excess of 64 million km of roads on Earth – enough for 83 round-trips to the moon. Even some of the most important regions for biodiversity have extensive road networks – the Amazon contains ~100,000 km of road. The construction of new roads continues apace, especially in developing countries. China's highway network exceeds that of the USA, but was constructed in less than half the time. The ecological and environmental impacts of roads, railways, utility easements and vehicles and trains are diverse, numerous and mostly deleterious. In this presentation, I attempt to synthesise the presentations within this symposium and provide some directions for the future of road ecology. These directions are derived from this symposium, a recent survey of ~600 practitioners globally, as well as insights gleaned from editing the "Handbook of Road Ecology", to be published in mid 2015 by Wiley publishers. This handbook contains 62 chapters, written by over 100 authors from 25 countries. The recommendations focus on: (i) ensuring the important areas for biodiversity are spared from road construction, including through more strategic landscape-scale planning; (ii) applying offsets only after genuinely attempting to avoid, minimise and mitigate impacts; (iii) achieving greater collaboration among countries, agencies and projects to pool funding and sites for more reliable investigations; (iv) improving the study designs of monitoring programs; (v) adopting a more experimental approach to planning, implementing and evaluating road impacts and mitigation measures; and (vi) ensuring research data is made widely available and conducting meta-analyses of such data. The next few decades will see the construction of 25 million lane-km of road, 90% of which will be in developing countries. The opportunity to build a more-sustainable global road network and implement effective evaluation of mitigation is now.

MODELING DIRECT AND INDIRECT CLIMATE CHANGE IMPACTS ON KEY HABITAT OF GRASSLAND BIRDS: A CASE STUDY ON BREEDING HABITAT OF DUTCH MEADOW BIRDS.

Jerry Van Dijk

Utrecht University

Roland VAN DER VLIET, Utrecht University ; Harm DE JONG, District water control board De Stichtse Rijnlanden ; Maarten ZEYLMANS VAN EMMICHOVEN, Utrecht University ; Henk VAN HARDEVELD, District water control board De Stichtse

Rijnlanden ; Stefan DEKKER, Utrecht University ; Martin WASSEN, Utrecht University

Climate change can directly affect habitat quality, but may also indirectly affect that quality by inducing land use change. Such indirect effects are often ignored in projections of climate change impact on species, but are potentially more detrimental than direct climate effects. The objective of this study was to determine the relative impact of direct and indirect effects of climate change on breeding habitat of four meadow bird species (Black-tailed godwit, Common redshank, Eurasian oystercatcher and Northern lapwing) in the Netherlands. Habitat models were developed that link meadow bird breeding densities to three habitat characteristics that are sensitive to environmental change: landscape openness, land use and groundwater level. These models were used to assess the impact of scenarios of landscape change with and without climate change on meadow bird breeding habitat quality for a case study area in the peat meadow district of the Netherlands. Land use change was modelled in response to changes in groundwater level and soil subsidence. All scenarios led to significantly reduced habitat quality for all species, mainly as a result of conversion of grassland to bioenergy crops, which reduces landscape openness. Direct effects of climate change on habitat quality were largely absent, indicating that human adaptation to climate change rather than direct effects of climate change itself was decisive for the degradation of habitat quality for breeding meadow birds. We therefore conclude that scenario studies exploring impacts of climate change should not only incorporate direct effects of climate change on habitat quality, but also land use change resulting from human responses to climate change to accurately assess the impact of climate change on species.

CONSERVING BUTTERFLIES IN PLANTATION FOREST LANDSCAPES: ROLE OF LOCAL AND LANDSCAPE FACTORS

Inge Van Halder

INRA

Luc BARBARO, INRA ; Hervé JACTEL, INRA

The area of plantation forests is increasing worldwide, but their contribution to biodiversity conservation remains controversial. We present the results of several studies on butterfly diversity in the Landes de Gascogne Forest in southwest France, the largest plantation forest of Europe with almost 1 million hectares of pure maritime pine stands. Within this region we sampled butterflies in different successional stages of pine stands and in two semi-natural habitats, herbaceous firebreaks and deciduous woodlands either present as isolated patches or as riparian forests. Butterflies were simultaneously sampled inside the plots and at their edges. The most important factors determining butterfly community composition were the

composition of understorey vegetation at the local scale and the presence of semi-natural habitats at the landscape scale. Species richness in firebreaks was twice that of other habitat types and both firebreaks and deciduous woodlands had butterfly species not found in pine stands. Riparian forests had a higher forest species richness and hosted more habitat specialists, with higher sensitivity to temperature extremes, than deciduous woodland patches. For deciduous patches forest species richness and community composition did not vary with patch area or isolation; however habitat quality, especially host plant composition, had a significant effect. Edge habitats had a higher species richness and a different community composition than plot interiors, but some species preferred plot interiors. Many species were found in several edge and interior habitat types, including pine stand interiors, and the use of supplementary and complementary resources in different habitats is probably a key process in these dynamic, mosaic landscapes for butterfly conservation.

99-NATURAL NEIGHBOURHOODS FOR CITY CHILDREN

Yolanda Van Heezik

University of Otago

Kate HAND, University of Otago ; Claire FREEMAN, University of Otago ; Aviva STEIN, University of Otago ; Mariano RECIO, University of Otago ; Philip SEDDON, University of Otago

That children need nature for health and well-being is widely accepted, but what type of nature? The assumption that children must interact with wild pristine nature has justified recognition of a "nature deficit disorder" when such contact is lacking. We have evaluated children's reported nature interactions during independent movements, and biodiversity within self-defined neighbourhood nature maps in three cities in New Zealand, to explore nature contact from a child's perspective, in an urban context. In this presentation we address the questions: (1) is biodiversity available and accessible to children living in cities? (2) are children choosing to be in the most bio-diverse areas available to them?; and (3) what social factors support or limit contact with nature? Most children in these cities had access to bio-diverse areas, although availability was limited when independent home range size was small and in higher deprivation areas. When outside the home, children preferred to remain in their own gardens, and often did not use bio-diverse areas available to them. The often restricted independent home ranges emphasizes the importance of gardens as biodiverse areas.

126 HOW ECONOMIC SECTORS CAN CONTRIBUTE TO SUSTAINABLE USE AND CONSERVATION OF BIODIVERSITY

Mark Van Oorschot

PBL Netherlands Environmental Assessment Agency
Marcel KOK, PBL Netherlands Environmental Assessment Agency ; Rob ALKEMADE, PBL Netherlands Environmental Assessment Agency

Addressing the underlying causes of biodiversity loss requires rethinking how food systems operate, how wood and energy are extracted and produced, and how fresh waters and oceans are managed. Land-use is regarded as the main drivers of global terrestrial biodiversity loss. Developments in sectors such as agriculture, forestry, water management and fisheries are responsible for the main drivers of future biodiversity loss. Vice versa, economic sectors depend on biodiversity and ecosystems in various ways to provide them with the resources they need for the world's growing human population. Within sectors a large potential exists of more 'biodiversity-friendly production methods' and 'nature-based solutions'. In agriculture via a combination of agricultural practices to enhance productivity, more sustainable production methods, reducing food losses, and alternative diets. Sustainable forest management should be combined with reduced wood consumption, to ensure that forests are no longer converted. Reducing fishery efforts can halt fish stock depletion, while keeping catches stable. Better land use practices will improve freshwater biodiversity and reduce pollution. Combining such options in scenario analyses shows that it is possible to reduce global terrestrial biodiversity loss and expand protected areas, and at the same time eradicate poverty and hunger, provide access to safe drinking water and modern energy sources, and limiting temperature rise to two degrees. Dependency on natural resources, cost-effectiveness of nature based solutions and also social responsibility are reasons to take up biodiversity in business policies decisions. To speed-up the integration of biodiversity within sector policies effectively, 4 strategies are suggested: (1) integrated water and landscape management (2) promote biodiversity criteria in voluntary market standards; (3) strengthen consumer awareness of biodiversity; and (4) mobilise finance for sectoral solutions.

GENETIC RESCUE OF CRITICALLY ENDANGERED PLANT SPECIES AS A TOOL FOR GRASSLAND RESTORATION

Fabienne Van Rossum

Botanic Garden Meise

Sarah LE PAJOLEC, Botanic Garden Meise ; Olivier RASPÉ, Botanic Garden Meise ; Sandrine GODEFROID, Botanic Garden Meise

Habitat fragmentation and degradation of grassland habitats have been so severe in Western Europe that many of their typical plant species only remain as a few, often small and isolated, populations. These populations are susceptible to genetic, environmental and demographic stochasticity and

are likely to express low reproductive success, reduced gene flow, inbreeding depression, and genetic erosion, threatening their long-term persistence. The usual ecological management practices that aim at restoring habitat quality may not be sufficient for ensuring sustainable population persistence, especially in the absence of a persistent soil seed bank and when they are already too rare for producing enough seeds for conventional hay transfer. Their restoration must therefore go through genetic rescue (e.g. allo- or auto-reinforcements, restoration of connectivity by corridors). In the frame of the EU LIFE project "Herbages" (<http://www.life-herbages.eu>) that aims at improving the conservation status of priority grasslands in Southern Belgium, genetic rescue experiments have been started in autumn 2013 for several grassland species that are critically endangered in Belgium, e.g. *Arnica montana*, *Dianthus deltoides* and *Helichrysum arenarium*. The aim is to increase the effective size of remaining populations (reinforcement) and restore extinct populations (reintroduction) in order to improve connectivity in the landscape. Here we present (i) the experimental design applied, which comprises an estimation of the quality of target and source populations (including genetic diversity and structure), and an assessment of soil seed bank composition of the target sites, and (ii) the first results of the demographic survey (e.g. survival, floral production, reproductive success) aiming at estimating the viability of the transplanted populations, and of the experimental estimation of fitness of the progeny, in order to test for inbreeding or outbreeding depression.

65. WHEN DO OCCUPANCY MODELS PRODUCE RELIABLE INFERENCES FROM OPPORTUNISTIC DATA?

Arco Van Strien

Statistics Netherlands

Chris VAN SWAAY, Dutch Butterfly Conservation ; Tim TERMAAT, Dutch Butterfly Conservation

Opportunistic citizen science data are considered to be a potential valuable source of information on biodiversity. But opportunistic data suffer from all sorts of biases, especially those caused by temporal variation of observation effort and by incomplete reporting of sightings. Occupancy models are able to control for biases encountered with opportunistic data, but it is not always clear whether inferences derived from a particular dataset are indeed reliable. To learn under which conditions we may achieve reliable inferences we examined a number of parameters derived from several opportunistic datasets. We applied occupancy models to estimate trends per region, trends per site, colonisation and extinction, trends in flight period and species richness per site. All results were validated using standardized monitoring data from the same sites. We conclude that validation is important to learn when occupancy models produce reliable inferences.

TOWARDS A GLOBAL BUTTERFLY INDEX

Chris Van Swaay

Dutch Butterfly Conservation

Eugenie REGAN, UNEP-WCMC ; Matthew LING, UNEP-WCMC ; Emilija BOZHINOVSKA, University of Cambridge ; Miguel Alejandro FERNANDEZ, German Centre for Integrative Biodiversity Research (iDiv) ; Onildo João Marini FILHO, Instituto Chico Mendes de Conservação da Biodiversidade - ICMBio ; Blanca HUERTAS, Natural History Museum ; Chooi-Khim PHON, Forest Research Institute Malaysia (FRIM) ; Ádám KÖRÖSI, Eötvös Loránd University ; Jan Cornelis MEERMAN, Biodiversity in Belize ; Guy PE'ER, Helmholtz Centre for Environmental Research - UFZ ; Marcio Uehara PRADO, Deutsche Gesellschaft für Internationale Zusammenarbeit (GIZ) GmbH ; Szabolcs SÁFIÁN, University of West Hungary ; Legi SAM, Griffith University ; John SHUEY, The Nature Conservancy ; Doug TARON, Chicago Academy of Sciences ; Reinier TERBLANCHE, Stellenbosch University ; Les UNDERHILL, University of Cape Town

Insects dominate terrestrial biodiversity in terms of species numbers and biomass and are integral to ecosystem function. Yet there is a dearth of information on their conservation status and trends in populations - in particular at the global scale. We are working towards the production of a Global Butterfly Index as one of the global indicators to monitor biodiversity change. Butterflies, being the most popular group of insects, have proven to be useful indicators in the temperate zone, for example as headline indicator by the European Environment Agency to follow changes in biodiversity over the European Union or as community indicators for climate change. However, developing a global insect indicator has many challenges. For example, the standard butterfly monitoring protocol in temperate regions ('Pollard walks') is not suitable for tropical rainforests. Yet it is essential to monitor population trends in these global hotspots. In this paper we present additional methods such as fruit baiting and time counts that can also be used in citizen science projects to extend butterfly monitoring to these parts of the world. We show how these diverse protocols can be brought together and developed into a single Global Butterfly Index. And we present our next steps towards the development of the first global insect indicator.

HALTING THE LOSS OF EUROPEAN BIODIVERSITY AND ECOSYSTEM SERVICES? QUANTIFYING GAINS, LOSSES AND TRADE-OFFS DUE TO LAND USE CHANGE UNDER A RANGE OF EU POLICY SCENARIOS.

Astrid Van Teeffelen

VU University Amsterdam

Cje SCHULP, VU University Amsterdam ; Ph VERBURG, VU University Amsterdam

In 2010, the European Commission (EC) committed to “Halting the loss of biodiversity and the degradation of ecosystem services in the EU by 2020 (...)”. While the EC has e.g. set a 15% restoration target and studied policy options under a No Net Loss initiative, further action is urgent. To be able to prioritise conservation and restoration actions, it is important to understand past trends of the current state of biodiversity and ecosystem services (ES) and future threats such as land use change and climate change. Until 2020, land use changes are the most direct threat. The understanding of these threats also assists in prioritizing climate change adaptation options. We simulated land use change at 1km resolution up to 2020 for the EU under four policy scenarios that are considered by the EC. The impacts of land use change are next quantified using ten indicators representing biodiversity and a range of ES. Scenarios include: (1) Business as Usual, as a counterfactual scenario; (2) Avoidance; stricter regulations on land conversion and land use intensity; (3) Reduce, as (2) but with additional measures to prevent and compensate impacts; (4) Offset, as (3) but with mandatory requirements to restore habitat to offset unavoidable land take. The results show where in Europe pressures and impacts on land are strongest, and which kind of biodiversity and ES are most at risk. Trends are analysed per landscape type on a range from natural to urban. This allows in-depth inference of land use change impacts and policy effectiveness. We demonstrate what trade-offs exist between alternate land uses and how these may alleviate or worsen as a result of policy interventions. Our results quantitatively indicate that while full implementation of current EU legislation is of prime importance, additional measures in the wider environment, addressing key drivers of land use change, are urgently needed to address widespread losses of biodiversity and ES.

INNOVATIVE MONITORING METHODS IN THE CONTEXT OF ADAPTIVE MANAGEMENT OF HUNTING IN THE AMAZON, COLOMBIA

Managing complex hunting socio-ecological systems within a context of uncertainty requires setting up efficient ways to monitor changes in the system and inform decision making in

an adaptive management process. In such context, building trust through collaboration, institutional development, and social learning enhances efforts to foster ecosystem co-management. This approach draws explicit attention to the learning and collaboration functions necessary to improve our understanding of, and ability to respond to, complex social-ecological systems. Monitoring methods can generate observations over long time periods, incorporate large sample sizes, are relatively inexpensive and invite the participation of harvesters as researchers. We tested a combination of role playing games, traditional knowledge, technological innovations (camera traps and KoBoCollect) to co-develop a monitoring system for wildlife resources and hunting efforts in an indigenous hunting territory in the Amazon Colombia where hunters have organized themselves to develop an adaptive management approach to their hunting activities. The methods involve the active participation of hunters in data collection and an automatic tool for data analysis that allows users to visualize outputs instantaneously (e.g. map of offtakes per species, graph with number of prey per species per month). The information generated is directly usable by hunters for management decisions. We demonstrate the importance of such participatory monitoring models for building institutional trust between stakeholders (indigenous communities, governmental institutions in charge of wildlife management and civil society) as well as provide tools that are directly usable by local decision makers.

ID#7. INFLUENCE OF BELIEFS AND TABOOS ON HUNTING AND WILDMEAT HANDLING PRACTICES IN AN INDIGENOUS RESERVE FROM AMAZONAS, COLOMBIA: IMPLICATIONS ON HUMAN HEALTH AND CONSERVATION

Nathalie Van Vliet

CIFOR

Maria Paula QUICENO MESA, Fundacion SI ; Liliana VANEGAS, Fundacion SI ; German ANDRADE, Instituto Alexander von Humboldt ; Robert NASI, CIFOR

While there is increased knowledge about the links between wildlife consumption and zoonosis in tropical areas, few studies have approached the topic from the perspective of the users, exploring how local knowledge on human health and conservation (often transmitted through beliefs and taboos) influence practices from hunting to the handling of wildmeat and cooking of the meat. Our mixed-method data analysis was set out to explore the beliefs and taboos associated with hunting and wildmeat consumption and the relationship with human health, well-being and conservation in Ticuna indigenous communities from Amazonas, Colombia. This involved qualitative ethnographic data collected at different gender and age groups, on the myths around wildlife taboos

including accounts of symptoms associated with braking taboos, and incentives for abiding by taboos. We then gathered information on how local knowledge on wildlife use influenced practices at all levels from hunting, handling the carcasses, distribution and cooking the meat. We also used quantitative information on wildmeat consumption to understand the linkages between taboos and consumption patterns. We provide evidence that the conservation value of taboos may be limited but that the social value of taboos may be rooted in concerted attempts to preserve a physical, spiritual, moral and cultural integrity. Furthermore, we found that, despite rapid socio cultural transformations, there is a sophisticated traditional ecological and epidemiological knowledge that is likely to protect local people from zoonotic disease and unhealthy diets.

APPLICATION OF A THRESHOLD TO DETERMINE BONTEBOK PURITY: DETRIMENTAL OR BENEFICIAL?

Anri Van Wyk

National Zoological Gardens of South Africa
Desire DALTON, National Zoological Gardens of South Africa ; Antoinette KOTZE, National Zoological Gardens of South Africa ; Paul GROBLER, Genetics Department, University of Free State ; Bettine JANSE VAN VUUREN, Centre for Invasion Biology, Department of Zoology, University of Johannesburg ; Coral BIRSS, CapeNature ; Marli ROELOFSE, National Zoological Gardens of South Africa ; Isa-Rita RUSSO, Cardiff School of Bioscience, Cardiff University ; Michael BRUFORD, Cardiff School of Bioscience, Cardiff University ; Sean HOBAN, National Institute for Mathematical and Biological Synthesis, University of Tennessee

Human-mediated hybridization poses a serious threat to the genetic integrity of threatened interfertile species or sub-species, such as the bontebok (*Damaliscus pygargus pygargus*) and blesbok (*Damaliscus pygargus phillipsi*). The identification of pure parental and admixed populations is mandatory to design sound conservation strategies. Whenever identifications based of morphological traits are difficult, molecular analyses is needed to identify hybrids or introgressed individuals. In this study our objective was to determine an acceptable threshold of bontebok purity that would not result in further loss of genetic diversity. The study was based on 12 microsatellite loci. NEWHYBRID was used to simulate a population with up to four generations of coexistence between bontebok and blesbok, F1 hybrids, F2 hybrids, backcrosses to each parental species and double backcrosses to each parental species. For individual coefficient of membership the Bayesian model-based clustering program STRUCTURE was used. Thresholds of 0.85 to 1.00 were tested to determine where most hybrids would be detected and removed while the least amount of pure animals would be misclassified as hybrids. A threshold of 90%

was identified as being optimal and can successfully identify all pure blesbok, F1 and F2 hybrids as well as backcrosses and double backcrosses to blesbok. Approximately 3% of the backcrosses to bontebok and 40% of the double backcrosses to bontebok would be misclassified as pure bontebok and 1% of pure bontebok would be misclassified as hybrids. Overall a threshold of 90% would identify and remove 94% of hybrid animals successfully while a threshold greater than 95% would remove 8% pure bontebok and 98% hybrids animals. Due to widespread hybridization between bontebok and blesbok conservation plans should be enforced to preserve the integrity of their gene pools and the persistence of pure populations that are genetically unique must remain paramount.

HABITAT FRAGMENTATION AS SURROGATE OF POPULATION CONNECTIVITY: RESULTS FROM AN ISOLATION BY DISTANCE MODEL COUPLED WITH OCEANOGRAPHIC AND GENETIC DATA

Simon Van Wynsberge

University of French Polynesia (UPF) and Institut de Recherche pour le Développement (IRD)
Serge ANDREFOUET, Institut de Recherche pour le Développement (IRD) ; Nabila GAERTNER-MAZOUNI, Université de la Polynésie Française (UPF) ; Cecile FAUVELOT, Institut de Recherche pour le Développement (IRD) ; Josina TIAVOUANE, Institut de Recherche pour le Développement (IRD) ; Daphne GRULOIS, Institut de Recherche pour le Développement (IRD) ; Malin PINSKY, Institute of Marine and Coastal Sciences

Connectivity between populations is the foundation of meta-population dynamic and requires to be accurately characterized for efficient management planning. In the marine realm, seascape genetic attempts to relate patterns of genetic connectivity with environmental forcing, including habitat spatial distribution. This can shed new lights on weak and chaotic genetic patterns. The simplest of this approach related population structure with geographical distance; a model termed as Isolation By Distance (IBD). Beyond geographic distance, it has been shown in the terrestrial literature that habitat patchiness can also strongly impact demographic and genetic connectivity patterns, but similar demonstration is still lacking in the marine realm. In particular for some species with a pelagic life cycle stage, the relationship between habitat patchiness and genetic connectivity is blurred by biological and physical processes influencing the dispersal kernel, such as oceanic currents pathways or pelagic larvae duration (PLD). Here, we first developed a stepping stone gene flow model coupled with biophysical information on larval dispersal to evaluate the extent by which habitat patchiness could explain patterns of measured genetic connectivity between several South West Pacific Islands. The model was applied to the sessile giant clam *Tridacna maxima*, listed on the annexe II of CITES

Washington convention, and remains relevant for any species with similar PLD (≈ 10 days). The model is used to devise the best conservation strategy to maintain the existing giant clam's meta-population.

218 TOWARDS A MULTI-PERSPECTIVE APPROACH IN NATURE POLICY

Henk Van Zeijts

PBL Netherlands Environmental Assessment Agency
Irene BOUWMA, Alterra - Wageningen UR ; Ed DAMMERS, PBL Netherlands Environmental Assessment Agency ; Hans FARJON, PBL Netherlands Environmental Assessment Agency ; Arjen VAN HINSBERG, PBL Netherlands Environmental Assessment Agency ; Anne Gerdien PRINS, PBL Netherlands Environmental Assessment Agency ; Marijke VONK, PBL Netherlands Environmental Assessment Agency ; Jaap WIERTZ, PBL Netherlands Environmental Assessment Agency

In the last decennia, EU policy has matured and has become the bedrock for nature conservation in Europe. The Birds and Habitats Directives are the central pillars of this policy, but have been complemented with other policies, such as promoting green infrastructure and ecosystem services. In implementing this policy and turning it into practice, the challenge is how to 'make people click', how to involve citizens and businesses. The key is to understand their motives to engage with nature and what they perceive as nature. As people have different visions, they will prefer different future states of nature and biodiversity. In the Nature Outlook, PBL Netherlands Environmental Assessment Agency structures the various existing visions of organizations and citizens in the EU into various 'perspectives' to nature. By doing so the study aims to provide inspiration for strategic discussions on EU policy for nature and biodiversity. The objective is twofold. Firstly, the project structures the debate, by presenting the existing visions to nature into a set of perspectives on the state of nature in 2050, roles of actors and possible actions. The perspectives are elaborated in storylines, images, maps and figures. Secondly, a range of policy options with regard to nature and related sectors, will be discussed in the light of the perspectives. Suggestions will be provided for (new) actions and coalitions that could help to integrate biodiversity more in other sectors and to involve civil society. The Nature Outlook uses mixed methods: participatory research with stakeholders, literature analysis of narratives of frames, a survey among citizens about images of nature, and modelling of biodiversity and ecosystem services. At the Natura 2000 symposium in Montpellier, the preliminary results will be presented. Final results will be published in the first half of 2016, during the Dutch presidency of the EU Council.

A FLEXIBLE AND EFFICIENT MODELLING APPROACH TO TARGET ROAD FRAGMENTATION MITIGATION AT THE IMPACT ASSESSMENT PHASE

Hadrien Vanthomme

Smithsonian Institution
Joseph KOLOWSKI, Smithsonian Institution ; Brave NZAMBA, Université des Sciences et Techniques de Masuku ; Alfonso ALONSO, Smithsonian Institution

Environmental impact assessments (EIAs) are mandatory in most countries prior to large infrastructure projects such as roads. Although animal movement and distribution data could guide mitigation of impacts of fragmentation and vehicle collision, the scale of EIAs is often inadequate to collect this information. In our study area in Gabon (Central Africa), we used field data collected over less than 10 weeks to demonstrate a new modelling approach to prioritize mitigation efforts to reduce the effects of fragmentation. We used stratified random transect surveys conducted in two seasons to model the distribution of African forest elephant (*Loxodonta cyclotis*), forest buffalo (*Syncerus caffer nanus*), and sitatunga (*Tragelaphus spekii*) in a mosaic landscape along an unpaved road scheduled for paving. Using a validation dataset of recorded crossing locations, we evaluated the performance in predicting actual road crossings of three types of models of animal movements with explicit species- and season-specific hypotheses. We developed a unique and flexible scoring method for prioritizing 30 m sections of the road for the implementation of fragmentation mitigation measures, allowing managers to adjust thresholds based on budgets and management goals. In addition, the method is flexible enough to incorporate other potential movement models and scoring criteria, allowing for its wider use in other linear infrastructure projects. Incorporating our method in the EIAs of large infrastructure projects could contribute to limit the costs of fragmentation mitigation measures and increase the number of roads with connectivity management plans. We advocate for increased collaboration and partnerships between environmental consultants and road engineers from the private sector and conservation professionals to incorporate fragmentation mitigation measures in road projects, starting at the preconstruction stage, and thus improve operational standards.

IN PURSUIT OF THE COMMON UNDERSTANDING OF FOREST GRAZING: THE CHANGING VIEWS OF HUNGARIAN FORESTERS AND CONSERVATIONISTS

Anna Varga

Centre for Ecological Research, Hungarian Academy of Sciences
Zsófia BENEDEK, Centre for Economic and Regional Studies, Hungarian Academy of Sciences ; Dániel BABAI, Centre for

Ecological Research, Hungarian Academy of Sciences ; László DEMETER, Centre for Ecological Research, Hungarian Academy of Sciences ; György PATAKI, Environmental Social Science Research Group (ESSRG)

Forest grazing is a traditional land use system disappeared in many parts of Europe including Hungary as a result of total ban on livestock grazing in forests in the past decades. However, international experience has recently implied the economic and conservation benefits of such (properly applied) multiple-use systems. Re-introduction requires finding the common ground between stakeholders such as forest managers and conservationists. As the first step in bridging the gap, the views of these groups are revealed. The content of some selected national journals, the key discussion forums of practitioners were analysed with qualitative and quantitative methods. Journal selection was based on the first publication date (to recognise changes in views in the altering legal environment regulating forest grazing). Also, professional quality and general acceptance were regarded, based on ten expert interviews. The Hungarian forester literature has been focusing on forest grazing since the beginning (1862). There was no conclusion about its harms or benefits in the first 100 years: forest grazing was banned in some regions to protect seedlings and soils; but deliberately used to boost forest regeneration in others. As an important source of non-timber forest product income it was subjected to forest management planning until 1961. Since then, views have been mostly negative, with occasional acknowledgements of potential benefits. Until recently, conservationists typically did not focus on forest grazing, or it was regarded only from a landscape history or botanical perspective. Based on field experience, forest grazing has been re-introduced in some protected areas, but there is no sign of it in the national conservation literature. Considering the EU support of agroforestry systems it is crucial to positively influence the views of foresters' (and legislators). To do so, the availability of practical conservation experience as published case studies could be a useful input.

GAP CHARACTERISTICS FROM LIDAR REMOTE SENSING DATA IN AN ALLUVIAL FOREST

Katalin Varga

TU Bergakademie Freiberg Institute of Biosciences
Balázs DEÁK, TU Bergakademie Freiberg Institute of Biosciences ; Cici ALEXANDER, TU Bergakademie Freiberg Institute of Biosciences ; Hermann HEILMEIER, TU Bergakademie Freiberg Institute of Biosciences

Due to severe threatening of biodiversity, the monitoring and reporting on the state of nature has become more and more important in the last decades. Especially the spreading of invasive species requires up-to-date monitoring and reporting for conservation and management efforts. One of the most

endangered ecosystems are alluvial forests, since their high stand dynamics opens many niches for invasive species. However, to monitor natural and close-to-natural stands can be difficult using only field measurements, mainly over extended areas. Especially, canopy gaps are difficult to survey from the ground, but LiDAR data are a powerful tool to acquire synoptic 3D data from the sites. Therefore we used LiDAR data in conjunction with field measurements to analyze the conservation status of an alluvial forest. Two airborne LiDAR datasets were collected during leaf-off (March) and leaf-on (July) condition. The objective of our study is to investigate and quantify the gaps and their characteristics since the spatial properties of gaps have a large influence on the species composition and dynamics of the forest. The investigated alluvial forest associated with the Tisza Lake (Hungary) is endangered by invasive species. The most frequently occurring invasive species are *Acer negundo*, *Fraxinus pennsylvanica* and *Amorpha fruticosa*, which are found in the study area mainly in old and unmanaged gaps. The gaps were formed by management activities and large fallen trees. Gap size, connectivity, shape complexity, vegetation height and vertical structure in the gaps were mapped and analyzed from the LiDAR data. We investigated whether the horizontal and vertical structure complexity of the forest and canopy could indicate the presence of plant invasion in the investigated area. Analysis of canopy gap characteristics allows a more accurate and spatially explicit survey of understory status with respect to establishment of invasive species in order to implement early combatting measures.

HOW GREEN ARE LARGE SCALE WIND FARM DEVELOPMENT PROJECTS? A WIN-WIN SPATIAL PLANNING ALLOWING GREEN INVESTMENTS AND CONSERVING CINEREOUS VULTURES (AEGYPIUS MONACHUS)

Dimitris Vasilakis

University of Patras, Department of Environmental and Natural Resources Management, AGRINIO, GREECE. Hellenic Republic, Decentralized Administration of Macedonia-Thrace, Forestry Service of Soufli
D. Philip WHITFIELD, Natural Research Ltd ; Stefan SCHINDLER, University of Vienna, Department of Conservation Biology, Vegetation & Landscape Ecology ; Kostantinos POIRAZIDIS, Technological Education Institute of Ionian Islands, Department of Ecology and Environment ; Vassiliki KATI, University of Patras, Department of Environmental and Natural Resources Management

Wind industry is among fastest evolving green sectors of renewable energy production, contributing on one hand to gas emission reduction, but negatively affecting on the other hand species that are prone to collision with wind turbine

blades. This paper attempts to resolve the conflict between wind energy investments and conservation. We used telemetry data for an endangered vulture in Thrace NE Greece (19 tagged birds), in order to predict vulture accumulated collision mortality stemming from operating and proposed wind farms, by combining species spatial distribution modelling with a collision risk model. We present a nine-zone species-specific sensitivity map that consists of four zones in the population core area (39% population home range), four zones in the non-core area and a periphery zone, in terms of the population relative spatial use. The annual predicted collision mortality for the thirteen operating wind farms was from 12 to 3 deaths under collisions risk model's avoidance rates from 98% to 99.5%, respectively. In all cases, wind-farm mortality occurred mainly in the population core area and would increase by 11 fold in the future, in case that all current and proposed wind-farms will operate. We proved that the national Strategic Environmental Assessment failed to produce win-win solution for vulture conservation and wind-farm development, as the population is expected to rapidly decline in the future. Our zoning system offered a spatially explicit solution to the problem. We showed that core areas should be excluded from further wind farm development, and any investment should be planned on the basis of the species sensitivity map starting from the periphery towards the non-core areas. The combination of spatial modelling with collision risk models offers a tool for rapid and well-informed conservation decisions when large scale development projects are evaluated on the basis of target species movement ecology.

USE OF SPECIES RICHNESS IN GLOBAL CONSERVATION PLANNING LEADS TO LARGE LOSSES IN SPECIES COVERAGE

Victoria Veach

University of Helsinki

Enrico DI MININ, University of Helsinki ; Federico M. POUZOLS, Rutherford Appleton Laboratory ; Atte MOILANEN, University of Helsinki

In an effort to halt the global decline of biodiversity and expand the current protected area network, interest in identifying global priority areas for conservation action has increased. Several studies suggest identifying conservation priority areas with species richness, particularly richness of small range and/or threatened species. We currently lack evidence detailing the potential loss of species representation if priority areas for conservation are identified using species richness only. Here we compare the average species representation from two spatial conservation prioritization assessments. In the first assessment, priority areas were identified from 12 species richness maps of all and small range amphibians, birds, and mammals and all and small range critically endangered, endangered, and vulnerable species.

In the second assessment, priority areas for conservation were based on the global range maps for 21,671 terrestrial vertebrate species listed by the International Union for the Conservation of Nature (IUCN). Our results show that identifying priority areas for conservation using species richness alone reduces average species representation compared to priority areas identified using species range maps. As methods and software currently exist for processing large numbers of individual species distribution maps in spatial prioritization, the use of species richness appears to be an unnecessary simplification of biodiversity pattern.

ALONG A GRADIENT FROM FOREST TO OIL PALM PLANTATION: INFLUENCE OF HABITAT MODIFICATION ON AFROTROPICAL BIRDS

Elleni Vendras

Georg-August-University Göttingen

Denis KUPSCH, Georg-August-University Göttingen ; Péter BATÁRY, Georg-August-University Göttingen ; Matthias WALTER, Georg-August-University Göttingen

The rising demand for palm oil makes West and Central Africa ever more interesting for oil palm investors, triggering the conversion of rainforests into agro-industrial monocultures. However, studies on the biodiversity and conservation value of such plantations are still very rare. In this study, we examined 6,946 bird encounters from 432 sampling points distributed over 48 one-km² blocks around twelve villages, situated either in Korup National Park, unprotected agroforestry landscape and industrial oil palm plantation, respectively. We applied MARS (multiple additive regression splines) to model species richness of different bird guilds in relation to a disturbance index based on the proportion of natural forest per sample block. In total, we recorded 198 bird species. At the scale of one-km² blocks, overall bird species richness ranged from a minimum of 23 (first-order Jackknife richness estimator: 29.22 ± 1.78 SD) in the oil palm plantation up to 84 (118.67 ± 5.96) in the agroforestry matrix. On average, bird species richness was 3.81% lower in the national park and fell by 34.95% in the oil palm plantation compared to the unprotected agroforestry landscape. Specialized feeders (ant follower/terrestrial insectivores), forest specialists and Guineo-Congolian-forest biome restricted species were negatively affected by the transformation of natural forest, while widespread (sub-Saharan, tropical African) and open-land species increased with disturbance, as shown by MARS. This study documents for the first time in Africa how industrial oil palm plantations impoverish the bird fauna, and highlights the conservation value of forest matrix landscapes created through land use practices by smallholders.

USING PROXIES OF MARINE PROTECTED AREA BOUNDARIES FOR MEASURING CONSERVATION TARGETS IN THE CORAL TRIANGLE

Ruben Venegas Li

University of Queensland

Annick CROS, University of Hawaii ; Alan WHITE, The Nature Conservancy ; Camilo MORA, University of Hawaii

As international collaborative conservation initiatives becomes more common, it is increasingly important to measure their success not only for quantifying how much biodiversity they protect, but also to justify the time and resources invested in them. A common approach to quantify success of marine protected areas (MPAs) is to measure the area of habitat or number of species protected within their borders. This is often achieved using Geographic Information Systems by overlaying the boundaries of the protected area with a map of habitats or species distribution. However, this can be challenging due to missing official MPA boundary layers. A widely used approach to solve this problem is to create a proxy of these boundaries. This is done by creating a circular polygon by buffering a known point inside the MPA, which area matches the official area reported for the respective protected area by a national authority. The Coral Triangle Atlas provides the opportunity to measure the errors from such methods at the Coral Triangle region's scale. We converted 612 existing MPA boundaries into point data at their centroids and created circular polygons of equal areas to the original MPA. This approach allowed us to compare the area of protected coral reef using the buffered proxies and the real boundaries. At both the level of the Coral Triangle region and of individual countries, we found that the buffered proxies resulted in an underestimation of protected reef area. The size of MPAs does not have a significant effect on the error except when the MPAs are larger than 100 km². Therefore, using buffers at a national scale for small MPAs could resolve the problem of missing boundaries and be more cost effective than collecting the real boundaries. However, this is true only if the real size of the MPA is known.

191 HOW EFFECTIVE ARE CONSERVATION INTERVENTIONS AT ACHIEVING BEHAVIOUR CHANGE?

Diogo Verissimo

Georgia State University

Anita WAN, Durrell Institute of Conservation and Ecology, University of Kent

Human behavior is a key driver of all major threats to biodiversity. As such, to conserve biodiversity we must be able to influence human behavior. To this end a number of conservation outreach efforts, including environmental education and social marketing, have been undertaken.

However, these efforts have historically suffered from a lack of evaluation, leading some to question their real impact in terms of mitigating threats to biodiversity. To understand if efforts to influence behaviour are being effective we conducted a systematic review of peer-reviewed and grey literature. We documented what indicators are being used to evaluate behaviour change, what experimental designs are being used to link interventions and conservation outcomes and and if cost-benefit trade-offs were taken into account. Our preliminary results show that conservation interventions that aim to influence behaviour are generally poorly evaluated. Information regarding outputs (eg. number of schools visited or posters printed) is still frequently used as a measure of success and changes in knowledge and attitudes are often used as proxies for behaviour. Furthermore, evaluation does focus on actual behaviour, the experimental designs used largely do not allow for causal links between the conservation effort and the change in behaviour to be determined. Lastly cost-benefits relationships are rarely used to determine what interventions should be carried out. If we are to seriously attempt to influence human behaviour conservationists need to ensure evaluation is included as part of any intervention and not merely seen as an optional add-on. Furthermore, conservation can turn to disciplines such as public health or development which have for decades implemented robust evaluations of their interventions.

DEMONSTRATING COMMITMENT: THE CASE OF WETLAND CONSERVATION IN TAMIL NADU, SOUTH INDIA

Hans Raj Verma

GoTN

The paper discusses the policy and programme interventions for wetland conservation in the south Indian state of Tamil Nadu from the perspective of a stakeholder group that is often side-lined in conservation dialogues viz. the administrators. Tamilnadu has a coastline of 1076 kms and is drained by a number of perennial streams that originate in the Western Ghats. The state's agrarian tradition has a recorded history of over 1000 years. These factors have contributed to the creation of wetland complexes, whose design and function is closely tailored to the local agro-ecological conditions. Some of these complexes have evolved to become heronries, and stand testimony to the symbiotic association with local communities. In view of the rather significant wetland heritage, the state has in recent times dedicated its effort to evolve a consultative mechanism for wetland conservation, which includes the development of strategy and management plans for the fourteen wetland sanctuaries of the state, identification of additional, lesser known wetlands into the ambit of protection and constituting a dedicated authority for

the protection and conservation of marshes in the capital city of Chennai. Simultaneously, the state policy on wetlands is also being evolved that is ingrained on the principle of wise use of wetlands. The paper outlines, on a time line, the processes and outcomes of the state's efforts in conserving wetlands.

LOSS AND CONSERVATION OF PHYLOGENETIC DIVERSITY IN THE MEDITERRANEAN BASIN

Simon Veron

Muséum National d'Histoire Naturelle

Philippe CLERGEAU, Muséum National d'Histoire Naturelle ;

Sandrine PAVOINE, Muséum National d'Histoire Naturelle

Protected areas are mainly designed to maintain species richness and/or rare, vulnerable species. Yet these criteria may not be sufficient to conserve the diverse facets of biodiversity, especially phylogenetic diversity and the functions it provides. Protecting the evolutionary history shared by species has been argued to be highly valuable to conserve biodiversity quality. Phylogenetic diversity has an intrinsic interest as protecting it means protecting the building blocks of the diversity of life. Moreover there is increasing evidence that evolutionary history captures rare features and biodiversity « options values ». However, Earth evolutionary history is poorly protected by conservation actions and protected areas in particular in areas of high species richness. Here we are interested in the conservation of phylogenetic diversity (PD) and evolutionary distinctiveness (ED) in the Mediterranean Basin, the second largest hotspot of Biodiversity. The basin presents high rates of endemism and several branches of the Tree of Life may not be encountered anywhere else. We have evaluated whether the IUCN Red List, the main prioritization tool at the Mediterranean scale, better prioritize amphibians, mammals and reptiles PD and ED than if species were distributed randomly in the List. We showed that basing conservation actions on the IUCN Red List may not protect the Mediterranean evolutionary history. Moreover, for those three groups, we have identified areas where evolutionary history is particularly vulnerable and areas that shelter branches of the Tree of Life that are found nowhere else on Earth. We have highlighted that the protection of those areas is low and that the degree of protection varies between groups. As a result, we support the call of numerous scientists to better consider Earth evolutionary history when designing conservation actions.

133-FINDING COMMON GROUND FOR THE PROTECTION, CONSERVATION AND REVITALISATION OF INDIGENOUS SACRED NATURAL SITES

Bas Verschuuren

Wageningen University, IUCN-CSVPA

Sacred natural sites are hotspots of biocultural diversity and often subject to a diversity of often competing claims. Different meanings and values are attributed to sacred natural sites by different indigenous peoples. We look at these ontological differences between indigenous peoples and contemporary protected area management. We provide an overview of indigenous initiatives that illustrate a call for recognition of self-determination in their efforts to protect sacred natural sites. We then identify opportunities for protected area management, governance, and conservation to include the cultural and spiritual significance of nature in protected areas while focussing on sacred natural sites. We provide examples of the cultural, historic, social, spiritual, and aesthetic significance that natural features and landscapes in protected areas have for people in diverse societies and cultures, both traditional and modern. We identify opportunities for involving mainstream religions and members of the general public in the conservation of sacred natural sites of indigenous peoples.

ALL SNAKES ARE CREATED EQUAL, BUT SOME ARE MORE EQUAL THAN OTHERS: EXAMINING INTER-INDIVIDUAL HETEROGENEITY IN THERMAL PERFORMANCE

Mathew Vickers

CNRS

Aurélie COULON, CESCO, MNHN[INSTITUTE]CEFE ; Fabien AUBRET, CNRS

Dispersal is central to numerous eco-evolutionary processes, including population maintenance, dynamics, and species range expansion. For ectotherms, many dispersal behaviours are thermally dependent via a reaction norm called the thermal performance curve (TPC). Interestingly, not all individuals of a species are equal regarding dispersal. This inter-individual heterogeneity (IIH) in dispersal can be caused by condition (behavioural type, body shape, genetic lineage), or context (density of conspecifics, or quality and distribution of resources) but has been little investigated. We document strong IIH in the TPC for juvenile snakes, *Natrix natrix*, finding that absolute performance is not conserved: simply put, some snakes are born better than others. We also find mixed levels of support for classic hypotheses such as the specialist-generalist trade off. We use our understanding of the TPC to ask whether this heterogeneous landscape inhabited by small terrestrial ectotherms has an equalising effect on absolute performance in terms of dispersal characteristics. We discuss the implications of subsetting a population to generate a species-average TPC, and examine predicted dispersal performance under climate change scenarios. The latent variability in TPC within and between clutches at birth may hold the key to species persistence without invoking further adaptation or acclimation.

MANAGEMENT OF SALTMARSH AT SAINT NIKOLAJ, NORTHERN ADRIATIC, SLOVENIA

Barbara Vidmar

Institute of the Republic of Slovenia for Nature Conservation

Saltmarsh Saint Nikolaj is a small wetland (2ha surface) situated on small patch of unspoiled coastal land between the port of Koper and campsite of Ankaran. It covers 2 ha of surface and is designated as Natura 2000 site (SAC) due to the priority habitat types 1410 Mediterranean salt meadows (*Juncetalia maritimi*) and 1140 Mudflats and sandflats not covered by seawater at low tide. The halophyte plant communities are enriched with two rare plant species thriving only in this place, *Linum marittimum* and *Centaurium spicatum*. The area faces some conservation issues since it was neglected and used as a football place in the past. In that way the land was eroded and many invasive alien species invaded the area. The presentation describes some management approaches to restore and maintain the area. A wooden path above the area was first built in 2006 to prevent the negative impact of walking over the sensitive plant community. In order to eradicate and control the invasive flora several manual and machine interventions have been carried out since then. Some specific methods to increase a number of the two rarest plant species was experimented. The results of the almost ten years of field work in the area supported with monitoring researches should be translated to a management model to be used for small natural sites.

MODELLING BIODIVERSITY SCENARIOS IN MADAGASCAR UNDER BOTH THE EFFECTS OF CLIMATE CHANGE AND ANTHROPOGENIC DEFORESTATION

Ghislain Vieilledent

Cirad

Mario MUNIZ-TAGLIARI, Cirad ; Margaux CHARRA, Cirad ; Clovis GRINAND, ETC Terra ; Tom F. ALLNUTT, Wildlife Conservation Society ; Dimby RAZAFIMPAHANANA, Wildlife Conservation Society ; Miguel PEDRONO, Cirad ; Jean-Roger RAKOTOARIJONA, Office National de l'Environnement

Madagascar is widely known for its exceptional biodiversity which is, for the terrestrial part, mainly concentrated in tropical forests. This biodiversity is severely threatened by both climate change and deforestation. The FRB (Fondation pour la Recherche sur la Biodiversité) project named BioSceneMada (<http://bioscenemada.net>) aims at modelling the biodiversity scenarios in Madagascar under both the effects of climate change and anthropogenic deforestation. In this study we present the first results of the project. We used presence data for more than 5000 species and bioclimatic envelope

models to forecast species distribution under the effects of climate change. Species distribution maps were used to identify potential refugia for biodiversity. Combining these results to the projections of a deforestation model, we also identified the potential biodiversity hotspots under a high risk of deforestation. Project results should help define efficient strategies for conserving Madagascan biodiversity. In particular, we promote the inclusion of top priority areas for biodiversity conservation into the current Madagascar protected areas system.

AREAS OF ENDEMISM ON REGIONAL SCALE REFLECT INFLUENCES OF ADJACENT PHYTOGEOGRAPHIC DOMAINS. A CASE STUDY ON WOODY FLORA OF THE NORTHEASTERN CERRADO OF BRAZIL

Leandro Tavares Azevedo Vieira

Universidade Presbiteriana Mackenzie

Antônio Alberto Farias CASTRO, Federal University of Piauí ; Fernando Roberto MARTINS, University of Campinas

Area of endemism (AOE) is a particular area that contains species restricted to it and it can be hierarchical in organization, thus a large AOE may contain smaller areas of endemism. Brazilian cerrado is the third largest hotspots of the world but with almost none information about specific AOE, although it is well know that northeastern (NE) cerrado has a woody flora different from cerrado core. We searched for local AOE within the NE cerrado, which, in its turn, is a regional AOE of the huge Cerrado. We investigated whether AOE would reflect the influences of adjacent phytogeographic domains. We recorded 6,962 individuals of 936 woody species gathered from 160 surveys and distributed in 48 grid-cells of 1° latitude-longitude. For each grid-cell we compute indices for species richness and endemism which were tested by spatial autocorrelation analysis (SAC). Additionally we performed a parsimony analysis of endemism (PAE) to discover relationships among areas of endemism. Species richness indices were not spatially autocorrelated in contrast to endemism indices. Thus, there are hotspots for endemism but not to richness. The PAE indicated seven AOE. Considering indices of endemism and PAE, we indicated five areas of endemism in the NE cerrado: the coastal cerrados; Araripe plateau; Diamantina plateau; the northern Piauí; and the southwestern NE cerrado. Out of total species, 611 species were restricted to only one AOE whereas 170 species were widespread. Each AOE had different floristic influences from adjacent phytogeographic domains corroborating our hypothesis. The AOE indicated deserve special attention from conservation policies

HABITAT AMOUNT VS. CONFIGURATION: A TEST WITH SMALL MAMMALS OF THE ATLANTIC FOREST OF BRAZIL

Marcus Vieira

Departamento de Ecologia, Instituto de Biologia, Universidade Federal do Rio de Janeiro
Renato CROUZEILLES, Programa de Pós-Graduação em Ecologia, Instituto de Biologia, Universidade Federal do Rio de Janeiro; Maurício ALMEIDA-GOMES, Programa de Pós-Graduação em Ecologia, Instituto de Biologia, Universidade Federal do Rio de Janeiro; Ana DELCIELLOS, Departamento de Ecologia, Instituto de Biologia, Universidade Federal do Rio de Janeiro

Habitat loss and fragmentation are generally associated, as an end result of land use by human activities. Resulting consequences for biodiversity have been studied based on a framework involving patch size and isolation, the configuration of the landscape. However, the amount of habitat remaining may be a simpler and more important proxy of effects on biodiversity, the habitat amount hypothesis. In this study we contrast the two hypotheses, habitat amount vs. configuration, to explain species richness of small mammals in a landscape of the Atlantic Forest of Brazil. Study sites were located in the Macacu river watershed, Rio de Janeiro State. Small mammals were surveyed in 27 sites from 1999 to 2008 using a standard protocol and constant sampling effort. Species richness estimate was the response variable in two sets of general linear models: one with measurements of fragment size and isolation as response variables, and the other with estimates of habitat amount around sampling points of small mammals. These variables were measured within two buffer zones whose width corresponds to mean and maximum estimates of interpatch movements of small mammals. The highest support was for the models with habitat amount at the largest buffer as explanatory variable (Akaike $w = 0.49$) compared to models with fragment isolation metrics ($w = 0.05$), but patch size was important in the best model for habitat amount. Small mammal assemblages seem to respond to habitat amount surrounding the existing populations more than distance between habitat patches. Habitat amount may be more important for biodiversity depending on matrix permeability and movement abilities of the organisms involved. Movements of small mammals in current Atlantic Forest landscapes may be more frequent than previously thought.

163 ADAPTING THE POLICY LANDSCAPE FOR EBA

Raffaele Vignola

CATIE

Tahia DEVISSCHERR, Stockholm Environment Institute- Oxford; Marco OTAROLA, CATIE

Ecosystem-based Adaptation is increasingly recognized as a robust response to the degradation of ecosystem services spurred by the combined pressure of climate change and development paths. While ecosystems are recognized to play an important role many initiatives around the world hardly move from the study and analysis mode to the transformative action in the field. Many site-specific factors can cause limited move from problem-identification to actions. Here, we argue that inter-related process variables and obstacles cross-scale and knowledge systems governance play a key role in moving along the cycle from identification of problems to design implementation, monitoring and adjustment of adequate and efficient EbA responses at the landscape scale. More specifically, moving along this cycle can require the combination of different types of knowledge, the use of flexible and effective communication mechanisms within governance systems and the building of trust among key stakeholders to maintain action-momentum. In this presentation we highlight the results of cross-scale governance analysis, present experiences and provide examples from research in Latin America regarding agricultural governance systems relevant to promote EbA for smallholders in Central America and water adaptation planning in South America. We present the relevance of different types of boundary organizations which can provide the enabling environment for EbA planning and implementation. We show that, depending on the natural resource prioritized, different types of resources from both top-down and bottom-up are needed to ensure long-term commitment/investment required to promote EbA responses.

LINKING THEORY AND PRACTICE: HOW CAN EDGE EFFECTS RESEARCH INFORM CONSERVATION STRATEGIES IN LANDSCAPES UNDER URBAN DEVELOPMENT?

Nelida Villasenor

The Australian National University
Don DRISCOLL, The Australian National University; Philip GIBBONS, The Australian National University; David LINDENMAYER, The Australian National University

With accelerating rates of urbanization worldwide, a better understanding of ecological processes at wildland-urban interfaces is needed to conserve biodiversity. Edge effects theory suggests that the influence of urban boundaries on ecological responses varies with kinds of urban development, but lack of empirical evidence limits conservation strategies. To help guide management and urban planning, we studied mammal responses across 12 urban-forest edges (six high and six low-housing density edges) and six forest controls in southeastern Australia. We first investigated arboreal

marsupials, a forest-dwelling group. We found low-density housing development provided suitable habitat for most arboreal marsupials. In contrast, high-density housing developments had negative effects on species richness and the abundance of most individual species, probably because of low mature-tree cover in these areas. Most arboreal marsupials exhibited no response to the proximity of urban boundaries, but spilled over from forests into urban areas to differing extents. However, urban impacts extended beyond 300 m into adjacent forest for a core-area species (*Petaurus australis*). Our findings suggest (1) mitigate negative impacts of high-density housing developments by providing key habitat structures (trees) and (2) avoid forest core-area loss when planning urban areas. Second, we compared the influence on ground-dwelling mammal occurrence of variables related to urban planning (edge variables: housing density and distance to urban boundary) with those related to local habitat structure. We found edge variables had effects on most species occurrences, but local habitat structure outweighed the impacts of edge effects. Thus, (3) local-scale management of habitat will help mitigate urban impact. Our edge studies suggest residents, managers and land planners can contribute to conserve mammals in Australia and provide insights for biodiversity conservation in an urbanizing world.

RECORDING SMALL, MEDIUM AND LARGE TERRESTRIAL MAMMALS WITH VERTICALLY-ORIENTED CAMERAS TO GUIDE MANAGEMENT STRATEGIES ACROSS URBAN-FOREST EDGES IN AUSTRALIA

Nelida Villasenor

The Australian National University
Don DRISCOLL, The Australian National University ; Philip GIBBONS, The Australian National University ; David LINDENMAYER, The Australian National University

Camera trapping is a non-invasive technique used in ecological research, but its usefulness to record small terrestrial mammals is limited due to a lack of focus and a small proportion of images capturing the full animal profile when cameras aim horizontally. Vertically-oriented cameras (facing to the ground) is a novel technique that can overcome this limitation and record animals of different sizes. For the first time, we used vertically-oriented cameras aimed to a contrasting wooden platform with a measured scale to: (1) aid with species identification and (2) use the results from this technique to guide management strategies for mammals across urban-forest interfaces. We investigated whether edge variables (eg. distance to an urban boundary) or local habitat structure best explained mammal occurrence across forest-urban edges. We deployed cameras at -300, -100, 0 (boundary), 100 and 300m across 12 urban-forest edges, placed three cameras

in six forest interiors (>500m from an urban boundary) and measured habitat structure at each location. We obtained 4,419 images containing animals over 462 camera-trap nights (77 stations x 6 nights). Most images recorded mammals (90% of images). Images had good quality and contrast, allowing us to identify 12 species from 98% of images containing a mammal. Species included a variety of sizes, such as small (*Antechinus stuartii*, *Mus musculus*, *Rattus fuscipes*), medium (*Perameles nasuta*) and large mammals (*Macropus giganteus*). Statistical analyses showed the occurrence of most native and non-native mammals was best predicted by local habitat structure rather than by edge variables, suggesting that local-scale management of habitat (eg. increased understory cover) can help mitigate urban impacts. Our study demonstrates the usefulness of vertically-oriented cameras to record mammals and guide management strategies in Australia, and suggests this technique can be extended to other regions and ecological research.

TRAIT-DEPENDENT RESPONSES OF BUTTERFLIES TO THE CONNECTIVITY OF SEMI-NATURAL ELEMENTS IN AGRICULTURAL LANDSCAPES

Anne Villemey

Irstea
Inge VAN HALDER, INRA ; Annie OUIIN, INRA ; Philip ROCHE, Irstea ; Frédéric ARCHAU, Irstea

In intensively managed agricultural landscapes, remaining semi-natural habitats are fragmented and partly composed of small linear features. A better conservation of farmland biodiversity may be achieved by improving the connectivity of both patchy and linear elements. However, the respective effects of these elements have rarely been tested. Butterflies form a suitable model group for this purpose since they have suffered a major decline over the last decades and are sensitive to landscape connectivity. In 18 landscapes of 5-x-5 km located in 3 contrasted French regions (6 landscapes/region), we sampled 286 transects in patches of grasslands and linear grassy elements along grassland connectivity gradients. We evaluated the response of butterfly diversity to grassland and woody habitat connectivity using a variety of metrics. Connectivity had stronger effects for grassland specialists and species with low dispersal ability. Woody habitat in vicinity to grassland had a positive effect: an increase in cover from 0 to 10% increased butterflies species richness from 4 to 7 and doubled their abundance. Butterflies may indeed benefit from multiple habitat usage through supplementation, complementation or spillover processes. Within grasslands, grassland connectivity had no effect on biodiversity and this may be related to the moderate extent of the gradient within studied landscapes. Butterfly richness and abundance were much lower (-27 and -52%) in linear elements than in grasslands and specialized and sedentary species suffered

most from isolation to grasslands, suggesting a source-sink functioning. Although linear elements may play an important role in butterfly dispersal in agricultural landscapes, they may not be sufficient to preserve specialist and sedentary species. To protect these target species in moderately fragmented contexts, conserving a mosaic of high quality grasslands and woody habitats appears more crucial than enhancing their connectivity.

BEYOND PROTECTED AREAS: CO-BENEFITS OF CARBON STOCKS FOR CLIMATE, GREAT APES AND SYMPATRIC BIODIVERSITY

Ruppert Vimal

Max Planck Institute

Hjalmar KUEHL, Max Planck Institute

Global strategies to mitigate climate change aim at maintaining natural carbon stocks. However, decision makers must simultaneously consider synergies with other environmental issues such as biodiversity conservation and protected areas management. In this study, we evaluate the co-benefits of carbon stocks in tropical Africa and Asia for great apes as the best-known umbrella species for the highly diverse sympatric biodiversity. Thinking beyond the concept of protected areas which provide formal protection for only about 30% of great ape habitat, we show that another 45% of great ape habitat is covered by resource management areas classified as weakly protected or corridors. In such areas, great apes and sympatric biodiversity overlap with enormous natural carbon stocks, but also face varying degrees of human threat. If implemented these climate-biodiversity co-benefit areas would turn the commonly isolated protected areas into a real spatial network allowing continued species dispersal. The spatial congruence of carbon stocks, tropical biodiversity and human impact suggest an exceptional "win win" conservation strategy to reduce biodiversity loss and climate change.

ONLINE CONSERVATION - UPDATED SPATIAL INFORMATION ON THREATENED PLANT SPECIES IN ISRAEL

Gal Vine

Israel Nature and Parks Authority

Merav LEBEL, Israel Nature and Parks Authority ; Margareta WALCZAK, Israel Nature and Parks Authority ; Udi ORON, Israel Nature and Parks Authority ; Or DAVID, Israel Nature and Parks Authority ; Ofer Steinitz, Israel Nature and Parks Authority

Effective biodiversity conservation requires updated knowledge on threatened species. Over 400 types of wild plants are documented in the Red Book of Israeli Plants as being in danger of extinction in Israel. As part of a campaign to minimize extinction danger and to protect threatened species, the Israel Nature and Parks Authority established a

web-based database of threatened plant species. The new website (<http://redlist.parks.org.il>) aims to provide easy access to updated professional knowledge and to increase awareness of the issue among decision makers, conservationists and the general public. The website is developed in the open source Django platform, which allows flexibility and dynamic development. In the current website, each threatened species has its own page with detailed information from the Red Book of Israeli Plants, including a dynamic distribution map and conservation status. The GIS-based observation system provides easy query options for species and sites with graphical and tabular views of plant observations. The system allows users to report from a smartphone or PC on field observations of populations of threatened species including photos. The new records are processed through a validation system supervised by a botanist committee. The new records will be used for updating the distribution maps of plant species and thereby their conservation status. An updated and publically available database for local threatened species is important for improving conservation planning, allocation of conservation efforts and evaluation of management effectiveness over a national level. An important added value of such a database is the involvement of the general public, including naturalists and botany experts, in the identification of knowledge gaps and in ongoing reporting on distribution of species in danger of extinction across the country.

LINKING CONSERVATION KNOWLEDGE AND POLICY - A SPATIALLY INTEGRATED DATA APPLICATION FOR CONSERVATION MANAGEMENT

Gal Vine

Israel Nature and Parks Authority

Ofer STEINITZ, Israel Nature and Parks Authority ; Udi ORON, Israel Nature and Parks Authority

Conservation management involves frequent decision making, supported by various data types, spatial data often as pivot dimension. The Israel Nature and Parks Authority (INPA) protect 400+ nature reserves and national parks and conducts active management of habitats and species, including reintroduction projects, habitat restoration, anti-poaching program and more. Knowledge has been gathered for over 50 years of activity, yet it was not formalized in a database system that allowed online, straightforward access to the information, advanced analysis and simple reporting over the abundance of management actions and biodiversity data of the INPA parks and reserves. The data collection, validation, standardization and GIS work were conducted manually per report and on demand only. A generic web-applications-system was characterized and implemented by the Scientific Division in INPA. The different elements of conservation work were formalized into (a) policy and theoretical knowledge, (b) management action plans and spatial reporting of management, (c) spatial datasets

including biodiversity data. The system is based on a flexible yet robust spatial database that allows keeping complex data in flexible schemas yet analyze and report it in a generic way. The system also connects to CyberTracker software used for observation collection by rangers and ecologists. The system allows definition of complex GIS-driven queries and reports, thus allows live dynamic push of reports to relevant personnel. The system allows online collaboration according to user permissions and workflows defined. The system is based on Django framework extended by other state of the art, open-source technologies, allowing quick and efficient custom made development and adaptation of the system. Having all the data in one online data warehouse with advanced applications over it, allows a better link between decision making, knowledge and data found in the organization, and thus better conservation.

TRYPANOSOMIASIS AND LEISHMANIASIS IN BATS: EVALUATING THE ENVIRONMENTAL DISTURBANCE INFLUENCE IN THE GREATER LACANDONA ECOSYSTEM

Luis Víquez-R

Instituto de Ecología, UNAM

Miriam BERZUNZA, Medicina Experimental, Facultad de Medicina, UNAM ; Ingeborg BECKER, Medicina Experimental, Facultad de Medicina, UNAM ; Rodrigo MEDELLÍN, Instituto de Ecología, UNAM

Habitat loss and forest fragmentation have proven to be two major threats to bats in the tropics, as fragmentation increases, the diversity decreases. The dilution hypothesis states that as the species richness decreases due to habitat loss or disturbance, the incidence of parasites becomes higher. Since bats are known reservoirs of *Trypanosoma* and *Leishmania*, two pervasive zoonotic parasites, the primary objective of our study was to determine the prevalence of *Trypanosoma* sp. and *Leishmania* sp. in bats on conserved and disturbed conditions in the Lacandona forest in southern México. The disturbed area is dotted by human communities extracting forest resources and causing fragmentation and deforestation. Our hypothesis is that in conserved ecosystems bats will have a lower prevalence of the parasites due to the dilution effect. We worked with 2 common tropical rain forest species (*Carollia sowelli* and *Sturnira lilium*). Bats were captured using mist nets in 6 sites (3 under conserved conditions and 3 within the agricultural matrix of the surrounding areas) and tissue samples (heart and spleen) were taken. We obtained the prevalence of both pathogens through direct detection by PCR. We found several positive individuals for both parasites with an overall prevalence of 8.87% for *Leishmania* and 1.60% for *Trypanosoma*. We also found preliminary evidence that *Leishmania* prevalence decreased as the number of bats

species in the site increased. Results of this study are crucial to secure conservation efforts and keep low incidences of pathogens through forest conservation for the benefit of neighboring human communities.

HABITAT MODELLING PREDICTIONS : A TOOL FOR EFFECTIVENESS ASSESSMENT OF MPAS NETWORK

Auriane Virgili

University of La Rochelle

Charlotte LAMBERT, University of La Rochelle ; Emeline PETTEX, University of La Rochelle ; Vincent RIDOUX, University of La Rochelle

According to European Union (EU) Habitats Directive and Birds Directive, EU Member States must extend the Natura 2000 network to marine ecosystems, through the designation of marine protected areas. However, the initial state of cetacean and seabird communities across European waters is often poorly known. It is assumed that a Natura 2000 site is justified where at least 1% of the 'national population' of a species is present during at least part of its biological cycle. The aim of the present work was to provide new information about the distributions of cetaceans and seabirds and evaluate the network of existing Natura 2000 sites and proposed offshore new MPAs. These results would serve as a scientific basis for the negotiation process involved in the designation of these new offshore MPAs. Extensive aerial surveys were conducted during the winter 2011-2012 and the summer 2012 across the Channel, Bay of Biscay and northwest Mediterranean (560,000 km²). Habitat modelling was conducted by using a GAM methodology, with a combination of physiographic and oceanographic variables. For each area, a ratio between species relative abundance predicted within its boundaries and the total relative abundance predicted across the whole French exclusive economic zone was computed and compared to the 1% threshold. This evaluation also included a seasonal component, giving additional information to improve protected areas conservation plans. Our results showed that the existing network was justified for most of coastal seabird species, but a clear lack was identified for offshore seabird species and cetaceans. Moreover, the size of MPA appeared to be a crucial element, with larger MPA having higher responsibilities. Finally, we showed that proposed large offshore MPA would be of great interest, especially for cetaceans, for example less than 1% of fin whales population was included within existing network, while the proposed MPAs would concern 50.5% of the French population.

HOME RANGE AND HABITAT SELECTION OF THE LESSER KESTREL (*FALCO NAUMANNI*) IN THESSALY, GREECE: A FIRST STEP TOWARDS CONCRETE CONSERVATION MEASURES

Konstantinos Vlachopoulos

University of Thessaly

Panagiotis KORDOPATIS, Hellenic Ornithological Society/ Birdlife Greece ; Aggelos EVANGELIDIS, Hellenic Ornithological Society/ Birdlife Greece ; Jakob FRIC, Nature Conservation Consultants ; Stavros POLYMEROS, Hellenic Ornithological Society/ Birdlife Greece ; Thanassis SFOUGARIS, University of Thessaly

The knowledge of the habitat preferences of a bird species is crucial for the implementation of concrete conservation measures. The agricultural landscape of the study area includes different crop types. We studied the habitat selection of the Lesser Kestrel (*Falco naumanni*) using GPS dataloggers attached on ten individuals from five colonies of the Thessaly plain, Central Greece, during the nestling period, from mid May to mid June. In order to assess the habitat selection of the species we used the compositional analysis method. Additionally, we compared the composition of the available habitats within the home range of the species against the preferred ones, based on Aebischer's method. Using GIS software we calculated the Euclidian distance from the nesting sites to the foraging grounds, as well as the home ranges using the minimum convex polygon method. Our results illustrated an obvious preference of Lesser Kestrels mainly towards cereal crops, probably due to their higher prey abundance, and secondary to cotton, a pattern followed by both sexes. The maximum distance from the nests to the foraging patches was 4.1 km in average for the males and 4.03 km for the females, translated to a home range of 13 km² and 14.5 km² respectively. The home range size showed moderate variation between the five studied colonies, attributed to fluctuations of prey abundance of the surrounding areas due to different crop types. Understanding the mechanisms that determine Lesser Kestrels foraging grounds is essential in order to proceed to concrete conservation measures regarding the improvement of their foraging habitat quality through friendly agricultural practices.

FIRST STANDARDIZED LARGE-SCALE GENETIC WILDCAT CENSUS IN GERMANY

Burkhard Vogel

BUND Thuringen

Thomas MÖLICH, BUND Thuringen ; Annika TIESMEYER, Senckenberg Research Institut and Natural History Museum, Conservation Genetics Group ; Katrin STEYER, Senckenberg Research Institut and Natural History Museum, Conservation

Genetics Group ; T. E. REINERS, Senckenberg Research Institut and Natural History Museum, Conservation Genetics Group ; Carsten NOWAK, Senckenberg Research Institut and Natural History Museum, Conservation Genetics Group

European wildcats (*Felis silvestris*) are considered important target and umbrella species for nature-near, rich-structured forests in Germany and other European countries. But wildcat distribution is heavily scattered due to former human persecution and habitat fragmentation in Europe and especially in Germany. Currently, the large-scale conservation project "Safety Net for the European Wildcat" aims at reconnecting isolated wildcat populations and provide migration corridors of 20,000 kilometers length for forest communities. Here we present data from the first large-scale genetic wildcat census, the "Wildkatzensprung", aiming at investigating the connectivity among wildcat populations across Germany. Supported by more than 600 volunteers 800 valerian lure sticks as hair traps are inspected weekly during the mating season over three consecutive years. We present results of the three sampling season 2012 to 2014. Microsatellite analysis of 1670 samples resulted in 1561 wildcat detections representing 519 individual genotypes. The study provides estimates on populations sizes and changes in population composition over the years. Furthermore, an open database with the wildcat DNA samples has been established, to characterize the population structure and migration patterns of individuals throughout Germany.

AN AUSTRALIA-WIDE CONSERVATION GENETIC STUDY OF LITTLE PENGUINS (*EUDYPTULA MINOR*): AUGMENTING POPULATION GENETICS AT NEUTRAL LOCI WITH AN ADAPTIVE IMMUNE GENE, MHC

Sandra Vogel

University of New South Wales

Jennifer SINCLAIR, University of New South Wales ; Gabriel CENTODUCATTE, University of Campinas ; William SHERWIN, University of New South Wales

Genetic diversity of threatened species is frequently quantified using neutral genetic markers, or genes not directly targeted by selection, to provide the basis for management plans. However, patterns of variation and divergence in adaptive traits that are affected by selective processes, such as immune competence, are not always correlated with variation in neutral markers. The validity of approaches relying exclusively on neutral markers for development of conservation strategies is therefore questionable. The present study of conservation genetics and demography in the Little Penguin (*Eudyptula minor*) assesses connectivity among penguin colonies along the southern coast of Australia. A fine-scale analysis of genetic structure was conducted to determine the extent of dispersal between colonies and compare their genetic variability. In

addition to using classical genetic markers (microsatellites and mitochondrial DNA), we present the first study of non-neutral genetic diversity in Little Penguins. Next-generation sequencing of an immune gene of the major histocompatibility complex (MHC) revealed high allelic diversity at the functionally relevant peptide binding groove of an MHC class 2 molecule. Population structuring at the MHC marker is shown to be stronger than structure derived from microsatellites. Correlations with parasite load furthermore indicate that intermediate levels of intra-individual MHC diversity optimise parasite resistance. Together with recent demographic estimates based on methods of minimal invasiveness, genetic data will be used to refine management strategies for E. minor with a particular focus on population viability and resilience to pathogenic threats. This study demonstrates the MHC gene's diversity and suitability to resolve population structure, which make it an ideal marker to use in conservation genetic studies.

DECLINE AND RANGE CHANGE OF ORCHIDS IN WESTERN EUROPE (FRANCE, BELGIUM AND LUXEMBOURG) OVER 20 YEARS

Hélène Vogt Schilb

UMR 5175 CEFE - CNRS[INSTITUTE]Biotope
François MUNOZ, UMR AMAP - Université Montpellier 2 ; Franck RICHARD, UMR 5175 CEFE - Université Montpellier 2 ; Bertrand SCHATZ, UMR 5175 CEFE - CNRS

In recent decades, many studies have documented local declines of orchid species due to environmental changes. However, few data are available about the changes of orchid species distributions at large spatial and temporal scales. We aimed to characterize the recent dynamics of orchid distribution patterns in Western Europe, in regard to (i) land cover changes in the same period and (ii) species' ecology. We analyzed data from a large-scale participatory survey of 134 orchid species recorded over 20 years in France, Belgium and Luxembourg. We designed null models to assess the nature and significance of recorded changes within each administrative unit (i.e. départements, regions and country for France, Belgium and Luxembourg, respectively) and for each orchid species. We found sharp declines of orchids in the northern part of the study area (i.e. northern France, Belgium, Luxembourg), in relation to strong urbanization pressure in those regions, resulting in an overall shift to the Mediterranean area in the south. Western European orchids are thus affected and threatened by both climatic and land cover changes. Moreover, orchid species of wetlands and humid grasslands tended to decline more than species from closed forest and shrubland habitats. From a methodological point of view, we advocate the design of null models to account for spatial heterogeneity in large datasets. This use of null models opens promising perspectives for addressing critical issues on species

ecology and biodiversity conservation at large spatial and temporal scales.

TEMPORAL SHIFTS IN COMMUNITIES OF ORCHIDS IN CORSICA: ROLE OF VEGETATION CHANGES IN A 27-YEAR LONG INTERVAL USING BAYESIAN MULTISPECIES SITE-OCCUPANCY MODEL

Hélène Vogt Schilb

UMR 5175 CEFE - CNRS[INSTITUTE]Biotope
Roger PRADEL, UMR 5175 CEFE - CNRS ; Philippe GENIEZ, UMR 5175 CEFE - EPHE ; Laetitia HUGOT, Conservatoire Botanique National de Corse ; Alain DELAGE, Conservatoire Botanique National de Corse ; Franck RICHARD, UMR 5175 CEFE - Université Montpellier 2 ; Bertrand SCHATZ, UMR 5175 CEFE - CNRS

Shifts in biodiversity distribution patterns are of immediate concern in Mediterranean regions. Long-term diachronic surveys are requested to monitor these temporal dynamics of communities and to address their underlying factors. Here we used this method to specifically investigate the effect of land use changes on the distribution of orchid species in Corsica. Using two field surveys carried out on a 27 year-long interval in the same 45 sites in Corsica, we (i) estimated the detectability, the colonization and the survival probabilities of 37 orchid species, (ii) evaluated the impact of changes in ligneous species cover (LSC) on the dynamics of orchid communities at the local scale and (iii) predicted orchid diversity at the regional scale (i.e. for all sites). Our analysis was performed using a Bayesian multispecies site-occupancy model that took into account imperfect detection of species. Our study showed that detectability markedly differed amongst orchid species ranging from 0.81 to 0.96, and was positively related to population density. Between 1982 and 2011, LSC changed in 82.2% of sites (increase, 75.5%; decrease, 6.7%). Colonization probability of orchids was both significantly lower than survival probability, and negatively related to LSC increase. At regional scale, no significant differences were observed in terms of species richness and composition amongst sites and in regard to LSC increase. Asynchronous vegetation dynamics may drive marked and contrasted changes in orchid communities at the local scale, which in turn makes possible the maintenance of the diversity at larger scale. Practically, site-occupancy models are promising tools to take into account biases due to intrinsic variation in detectability among species in diachronic analyses.

HOW DOES HABITAT CHANGE AT LANDSCAPE SCALE AFFECT FUNCTIONALITY OF SPECIES INTERACTIONS?

Ana-Johanna Voinopol-Sassu

University of Canterbury

Jason M. TYLIANAKIS, *University of Canterbury*[INSTITUTE]
Imperial College London

Biodiversity is necessary to secure most of the ecosystem services needed by humanity, such as global food production. Yet, biodiversity has hardly ever been so threatened as today. In fact, scientists generally agree that a sixth global mass extinction is occurring at the present. Multiple anthropogenic drivers contribute to this biodiversity crisis, but of these, habitat loss and fragmentation are considered to be the most significant. The vulnerability of species to habitat change and fragmentation depends substantially on their traits, which in turn affect how they interact with other species and thus their functional role within interaction networks. Consequently, non-random loss of species and their interactions based on their traits can drive consistent changes in species interaction networks following habitat fragmentation. In addition to species diversity and phylogenetic diversity, also functional diversity may decline. These different components of biodiversity do not necessarily respond equally to environmental change nor do they predict future community composition in the same way. Understanding and maintaining species functional roles within diverse communities is a future objective in both applied nature conservation and conservation science, and this challenge can be addressed using network approach. We formulated a spatially explicit, agent based model to investigate how habitat diversity and different spatial patterning of habitat types in the landscape along a fragmentation gradient affect the persistence of species interaction in meta-networks. Meta-network ecology is based on meta-community and meta-population concepts, where several distinctive networks are connected through interactions or dispersal.

THE DEVIL IS IN THE DETAIL: DISENTANGLING THE MECHANISMS AND DRIVERS OF DECLINE OF THE ALPINE IBEX POPULATION IN THE GRAN PARADISO NATIONAL PARK (ITALY)

Achaz Von Hardenberg

Alpine Wildlife Research Centre, Gran Paradiso National Park Rachel MCCREA, National Centre for Statistical Ecology, School of Mathematics, Actuarial Science and Statistics, University of Kent ; Luigi RANGHETTI, Department of Earth and Environmental Sciences (DSTA), University of Pavia ; Stefano GRIGNOLIO, University of Sassari, Department of Science for Nature and Environmental Resources ; Antonello PROVENZALE, Istituto per le Scienze dell'Atmosfera e del Clima ISAC-CNR ; Bruno BASSANO, Alpine Wildlife Research Centre, Gran Paradiso National Park ; Byron MORGAN, National Centre for

Statistical Ecology, School of Mathematics, Actuarial Science and Statistics, University of Kent

The Alpine ibex population in Gran Paradiso National Park (Northwestern Italian Alps) has suffered a dramatic decline over the last 20 years. Previous models, based on total count data available since 1956, identified density dependence and winter snow cover as the main drivers of the population dynamics until it reached its peak in 1993, but were unable to predict the subsequent decline. The population fall-off is associated with a strong decline in kid survival which passed from an average of 0.58 (rate of kids which reach the yearling stage in 1981-1990) to an average of 0.35 in the last 10 years. Two main hypotheses have been proposed to explain this decline: i) Ageing of the population: in ungulates older females are known to have lower fertility and produce less viable kids; ii) Mismatch between trophic and breeding phenology due to climate change. Here we use an integrated population modelling approach to explore the temporal variability in demographic parameters and modifications in the age structure in this population. We combine a state-space model of total population counts with capture-mark-resight, kid survival, and fecundity data collected over the last 25 years on individually tagged Alpine ibex. Crude protein content in alpine pastures, estimated from NDVI (Normalised Difference Vegetation Index) data, appears to have a positive effect on kid survival improving the fit of the integrated population model and confirming previous suggestions that changes in vegetation due to climate change have driven the decline in kid survival in the last 20 years. Changes in age structure appear instead to affect significantly female productivity. The integrated population modelling approach permitted us to reconstruct age specific survival trajectories for years for which we have only count data available, get more accurate estimates of vital rates and contribute to disentangling the possible causes of the population decline.

CITIZEN SCIENCE PROJECTS IN ENVIRONMENTAL NGOS - BRIDGING THE GAP BETWEEN SCIENTIFIC STANDARDS AND CIVIL ENGAGEMENT

Eick Von Ruschkowski

*Naturschutzbund Deutschland (NABU - Nature and Biodiversity Conversation Union)
Lars LACHMANN, Naturschutzbund Deutschland (NABU - Nature and Biodiversity Conversation Union)*

Citizen science has become a new buzz word in nature and biodiversity conversation projects. In the majority of cases, the debate about "proper" citizen science in Germany is dominated by the scientific community, putting an emphasis on the scientific quality of the data generated from public input. In addition, concern has been voiced out that academic approaches limit public participation to that of cheap

field assistants. NABU, Germany's largest member-based environmental NGO, has been engaged in citizen science projects mostly in the field of ornithology – sometimes for decades before the term even became popular. Aside from the value of the data for monitoring purposes, NABU sees an important benefit from intrinsically motivated, publicly-driven citizen science projects in the empowerment of participation, the creation of environmental awareness and a potential to solve pressing “real-world” matters that are often of lesser priority in academia. As an important success factor, we see the mutual respect for the scientific community and the general public. The presentation will focus on the opportunities and limits of citizen science projects and data, using data from NABU's winter (since 2011) and spring (since 2005) backyard bird counts to illustrate where this data meets scientific criteria of reliability and validity, and can be used to reflect population trends on a broader level. The two campaigns attract between 60 and 90,000 participants each event on an annual basis. The data has been analyzed for statistical significance by e.g. analysis of variance and the results have been compared to other scientific ornithological censuses. In addition, it discusses the implications for the further development of citizen science from an NGO perspective while keeping the balance between scientific matters, civil engagement and volunteerism; and the potential contribution to improve the monitoring of biodiversity objectives.

QUIET AREAS IN EUROPE

Nefta-Elftheria Petros Votsi

Aristotle University

John D. PANTIS, Aristotle University

Global environmental concern is recently focused on biodiversity conservation by the implementation of innovative conceptual multidisciplinary schemes regarding protected areas and their surroundings. Special attention has also been given to Quiet Areas (QAs), recognizing health, biodiversity, economic, aesthetic and educational benefits, thus composing an alternative ecosystem service. In the present study QAs of the European Union (EU) are spatially identified, focusing on country, environmental and altitudinal level. The next step comprises the investigation of the spatial overlap of QAs and Natura 2000 network with view to proposing environmental policy improvements. We adopt a distance-based methodological approach. Human-induced noise sources are detected and buffered until the Quietness threshold, resulting in a map of Noisy Areas. Extracting Noisy Areas from a EU map determines the potential EU's QAs. We then identify QAs which overlap with Natura 2000 sites. Finally, we investigate some abiotic factors of QAs concerning the environmental zones and the relief topology. A particular pattern regarding the Quietness in the EU is revealed. Central Europe demonstrates lower percentages of Quietness while

the “edges” of the EU (Mediterranean and Scandinavian sites) contain higher percentages of Quietness. According to our findings QAs are driven by many different factors and not only, by human activities, emerging the complexity of soundscape composition, even when examined at a coarse scale. European environmental policy demands a mutual framework as far as the designing approaches of each Member State are concerned. QAs could contribute and justify such strategies by integrating other protection networks with the network of Quietness.

MANAGING AGRICULTURAL LANDSCAPES FOR CONSERVATION: WHAT DO MENTAL MODELS OF FARMERS AND SCIENTISTS TEACH US?

Carole Vuillot

CNRS

Raphaël MATHEVET, CNRS

After decades of public policies aimed at intensifying agricultural production in Europe, short-term maximization of yields has led to the simplification of agricultural landscapes and subsequent biodiversity loss. In this context, the interdisciplinary programme “FamLand BiodivERsA ERA-Net” currently studies the links between farmland biodiversity and cropped area heterogeneity at the landscape scale. It aims at providing results to help elaborate new policy that integrates biodiversity conservation in agricultural landscape management. In this programme, to understand the world views of the actors involved, we study individual stakeholders' representations (i.e. mental models, MMs) of the socio-ecological systems and attempt to shed light on the gaps between the MMs of “policy implementers” and “policy thinkers”. Using concept mapping methods we elicited the MMs of the functioning of the agricultural landscape for conservation scientists and farmers working in agricultural landscapes in four different regions of France. These study sites were characterized by different degrees of intensive farming and biodiversity conservation. We compared 140 MMs using qualitative and quantitative analysis based on graph theory indicators. MMs showed that biodiversity components are poorly connected to the farmlands with very few feedbacks. Within a study site, farmers and scientists identified the same components but interactions are different. These results confirmed a sectorial vision of the functioning of the landscape where biodiversity is of marginal significance and the general approach to conservation is one of land sparing. Moreover the lack of consensus on social-ecological interdependencies may contribute to a lack of cooperation and could be the main barrier to the implementation of more efficient integrated policies. We conclude with an invitation to acknowledge the role of scientists as conservation stakeholders and to question our own mental models of farmlands.

ENCROACHMENT OF AN HERBACEOUS LEGUME AFFECTS CARRYING CAPACITY OF ARID GRASSLANDS

Thomas Christian Wagner

Technische Universität München

Christina FISCHER, Technische Universität München

The encroachment called shift of arid grasslands, from grass dominated to shrub dominated communities is associated with serious implications for ecosystem functions and services that often resemble those of plant invasion by non-native species. Especially its mostly negative consequences for forage grasses and pastoral production have been subject to intensive discussion and led to a common negative connotation of this process. However, encroachment is usually solely associated with woody species or shrubs. Within the last decade, a native, annual herbaceous legume, *Crotalaria podocarpa*, has exhibited an extensive spread in arid grasslands in Namibia's great escarpment and apparently repressed the formerly aspect building local grasses in large areas. To quantify the short and long term effects of the proliferation of *C. podocarpa* on the dominant perennial tussock forming forage grass *Stipagrostis ciliata* we studied *Crotalaria* and *Stipagrostis* abundance and biomass production on long-term observation plots since 2009 and investigated possible facilitation of *C. podocarpa* by *S. ciliata*. We found competition with *Crotalaria* to reduce biomass production of *Stipagrostis* individuals by 30% and to weaken the ability of *Stipagrostis* tussocks to recover after drought. *Crotalaria podocarpa* was facilitated by *Stipagrostis* tussocks and caused an ontogenetic shift, resulting in a continuous decrease of grass tussocks in affected areas. Our study demonstrates, that the massive spread of a native annual plant, similar to woody encroachers and invasive species can severely affect arid grassland productivity, reduce its carrying capacity and may also affect biodiversity.

ENHANCED COASTAL FISHERIES IN BANGLADESH (ECOFISH): BIODIVERSITY CONSERVATION AND IMPROVED LIVELIHOODS IN THE PADMA-MEGHNA RIVER ESTUARY

M. A. Wahab

WorldFish Bangladesh

Nathan SAGE, USAID/Bangladesh ; Sarah PARK, WorldFish

Bangladesh comprises hundreds of rivers and tributaries--habitats capable of supporting rich aquatic biodiversity. About 1.3 million fishers rely on these aquatic resources for livelihood and nutritional needs. Overfishing, industrial effluents, and a controversial barrage are associated with decreases in fish catch yields, ultimately threatening these livelihoods. Policy interventions aimed to address these concerns, including the Bangladesh National Report to the Convention on Biological

Diversity and the Hilsa Fisheries Management Action Plan (HFMAP) have had limited impact. The HFMAP (2003) recommends: an 11-day fish trade ban to protect fecund migratory Hilsa; seasonal fish bans in five riverine sanctuaries (each 20-100 km in length) to protect juveniles; fisher ID card registration; fisheries enforcement; and a fishers' compensation scheme for lost earnings during ban periods. Regulations prohibiting the manufacture and use of monofilament fishing nets also support these measures. Improved management of Hilsa shad (*Tenualosa ilisha*) fisheries through these initiatives has the potential to increase the abundance of other, non-target aquatic species. However, limited funds to implement these measures have resulted in few conservation benefits. In order to strengthen Hilsa conservation initiatives, the U.S. Agency for International Development (USAID) developed a partnership with the Department of Fisheries and WorldFish in 2014 to improve the resilience of the Padma-Meghna River estuarine ecosystem and livelihoods that depend upon it. The Enhanced Coastal Fisheries project (ECOFISHBD) has developed a participatory research collaboration to build the capacity of government, non-governmental partners, and fisher communities to strengthen enforcement in sanctuaries; establish fisheries co-management; and support the resilience of women's livelihoods. ECOFISHBD demonstrates collaborative design and adaptive management in a vast, poverty-stricken waterscape.

24 - THE CHALLENGE OF NETWORKED GOVERNANCE FOR LARGE LANDSCAPES AND NATURAL RESOURCE CONSERVATION

Dara Wald

Arizona State University

Erik JOHNSTON, Arizona State University ; Kirsten LEONG, National Park Service ; Laura OGDEN, Dartmouth

Large-scale conservation requires coordinated, networked action that addresses multiple management objectives across interconnected, complex, and dynamic systems. In contrast, traditional resource governance approaches were often designed to address single species or single resource challenges and be managed by an agency unilaterally. In this paper, we argue that with the widespread recognition of the importance of broader participation, network governance represents an increasingly used approach to collaboration and public engagement with its own set of historical, economic, organizational and behavioral barriers. Through the lens of three contemporary, large-scale examples, we illustrate how these specific challenges require a different set of cultural, organizational, strategic and structural capacities to promote norms for legitimate, effective and resilient networks for large landscapes.

TIPPING POINTS IN THE COLLAPSE OF ECOSYSTEM FUNCTION FOLLOWING PRIMARY FOREST DEGRADATION

Anthony Waldron

Oxford University

Toby GARDNER, Stockholm Environment Institute ; Joice FERREIRA, Lancaster University ; Alex LEES, MCTI/Museu Parense Emilio Goeldi ; Jos BARLOW, Lancaster University ; Joseph TOBIAS, Oxford University

Primary tropical forests form a critically important and highly threatened component of terrestrial ecosystems. As public opinion turned against deforestation, exploitation techniques such as selective logging, which appear to leave a largely intact but slightly “degraded” primary forest, have increased rapidly. Degraded forests have nearly the same species richness, carbon stocks and functional diversity as intact forests, and so the four million km² of primary tropical forests affected by degradation (equivalent to about three complete Congo Basin rainforests) currently provoke little concern among conservation or climate change parties. However, to sustain primary forests beyond the current generation of trees, key ecological processes such as seed dispersal and nutrient cycling also need to be maintained, and little is known about how degradation affects these ecosystem functions. Here, we measure changes in inferred seed dispersal down a gradient of forest degradation, across 31 large landscapes (watersheds) in the eastern Amazon forest, by studying changes in abundance for the entire avian frugivore community. In particular, we examine how the impacts of degradation vary across different size classes of disperser beaks, which in turn are associated with the size of fruit dispersed. We show that at ~20% degradation (the average value for the Amazon), the level of seed dispersal service suddenly collapses for all but the smallest beak sizes, even though species richness remains largely unchanged. Small fruits generally produce small trees, and so the clear implication of this seed dispersal collapse is that within a generation, these “primary” forests could be reduced to largely homogeneous assemblages of small tree species, with extensive losses in biodiversity and a substantial release of carbon into the atmosphere. We therefore recommend that firm policy controls on degradation be urgently implemented, pending further research on its functional consequences.

UNDERSTANDING VARIATION AND COSTS OF HUMAN-WILDLIFE CONFLICT AT ECOSYSTEM LEVEL: LESSONS FROM NORTH LUANGWA, ZAMBIA

Andrea P C Wallace

Frankfurt Zoological Society

Rebecca H E SENNETT, Imperial College London ; Nafeesa ESMAIL, Imperial College London ; Maria SAKALA, University of Zambia ; Philip J MUYOMA, University of Zambia

Conflict between subsistence communities and wildlife increasingly undermines conservation efforts. Lethal methods are often used to protect crops or livestock, wildlife may kill or injure humans, food security and livelihoods are compromised, and tolerance of wildlife is reduced. Understanding the patterns and costs of conflict is crucial to developing solutions. Research on human-wildlife conflict has historically focused on community-level interactions without an ecosystem-scale perspective, often masking important variation in experience between connected communities. Similarly, interventions to address conflict typically focus on evident direct costs to humans without accounting for hidden socio-economic impacts. Our study examined human-wildlife conflict in game management areas of the North Luangwa ecosystem, northern Zambia. Data were obtained from observations, semi-structured interviews, focus groups, and key informants. Our results show that patterns and experience of conflict, especially crop and livestock losses, can differ considerably between villages. Results also indicated hidden costs can exceed or exacerbate more-visible direct costs and should not be overlooked or discounted. Although crop loss to wildlife was extensive, crops damaged and main species responsible were site-specific. Elephants followed consistent patterns when targeting crops, whereas livestock losses or injuries to humans by predators were highly variable. Direct costs were mainly loss of food or income, from minor to debilitating. Key indirect or hidden costs were foregone income opportunities, school absenteeism, restricted social movement, and poor health. Farmers guarding crop fields at night had a greater incidence of malaria. We demonstrate that human-wildlife conflict can vary markedly within an ecosystem, which must be understood to address the costs of conflict and promote conservation. Mitigation strategies therefore need to be tailored – one size will not fit all.

INVESTING IN COMMUNITIES: PARTNERSHIPS PROMOTING RESEARCH AND CONSERVATION IN SERENGETI, TANZANIA

Graham E Wallace

Frankfurt Zoological Society

Florentina J KIDEKA, Frankfurt Zoological Society ; Loiruck C NAIMAN, Frankfurt Zoological Society

Tanzania’s Serengeti ecosystem extends from the Loliondo-Ngorongoro Highlands to Lake Victoria, includes iconic Serengeti National Park, and has high biodiversity and conservation value. Human communities adjacent to protected areas are integral to the system; however, rapidly-growing populations are increasing pressure on natural resources at

an alarming rate, threatening system functionality. Focusing on community-conservation partnerships established by Frankfurt Zoological Society, our results confirm it is essential to account for anthropogenic factors and engage communities in order to understand ecosystem processes and develop effective conservation interventions. Importantly, our results go further to demonstrate the value of actively involving local communities in research and supporting them to drive conservation actions. A series of applied research and intervention projects across the ecosystem has facilitated partnerships between communities, local leaders, government agencies, and NGOs, building community-level management capacity while promoting conservation agendas. We show that community conservation microfinance groups have extended livelihood options, improved resilience to socio-economic shocks, and reduced reliance on natural resources for income across many Serengeti villages. Community health workers have disseminated family planning and environmental information to enable sustainable resource-use decisions at household level. Community scouts have been empowered to monitor and protect forest resources while also coaching about sustainable forestry practices. Community research has provided insights about communication flows and optimal methods for distributing conservation messages, and enhanced understanding of contested-resource and land-use issues. Such outcomes highlight large returns from investing in partnerships with communities across key biodiversity landscapes, to better understand conservation issues and address them effectively.

91-USING SCIENTIFIC EVIDENCE IN CONSERVATION MANAGEMENT: WHAT ARE THE BARRIERS AND SOLUTIONS?

Jessica C Walsh

University of Cambridge

Lynn V DICKS, University of Cambridge ; Christopher M RAYMOND, Enviroconnect[INSTITUTE]University of South Australia ; William J SUTHERLAND, University of Cambridge

Evidence-based conservation seeks to improve the effectiveness and transparency of conservation management and policy decisions by integrating systematically collated and appraised scientific research with practical experience and the local context. While reasons for the conservation science-implementation gap are well known, a thorough inventory of these barriers and effective solutions does not exist. We developed a framework to categorise the enablers, barriers and solutions of applying science to practice by reviewing the environmental and medical literature and interviewing 35 conservation practitioners from government and non-government organisations in the United Kingdom and South Africa. The use of scientific evidence is influenced by a complex array of factors, including the nature of the evidence, the

context of the decision, and characteristics of the researchers, practitioners, organisations and the link between research and practice. Most practitioners recognised the need to use scientific evidence to inform their decisions, which was facilitated by generally positive attitudes, collaborations with research institutes and other organisations, having scientists and advisors embedded within the organisation and processes that ensured collective decision making. The main barriers limiting the practitioners' use of scientific evidence were that the research was rarely presented in an accessible format (as they typically have limited access to scientific papers and little time to read them), external research was often not applicable or irrelevant, and the management organisations lacked sufficient funding for science. We collated over 100 possible solutions to overcome the barriers, with many practitioners suggesting the need for better dissemination of tailored research summaries. Future priorities for implementing evidence-based conservation are to evaluate which solutions have the highest potential for improving the uptake of science in practice.

IN SEARCH OF SNAKES: CONSERVATION AND DISTRIBUTIONAL MODELLING OF A DECLINING ISLAND POPULATION OF GRASS SNAKES (NATRIX NATRIX)

Robert Ward

University of Kent

Within Europe a fifth of reptile species are thought to be threatened with extinction, however evidence of snake declines is poor due to several life history traits and limited study. Snakes are linked with their environment at varying spatial scales and typically exhibit negative responses to anthropogenic habitat change, serving as indicators of ecosystem health. The grass snake (*Natrix natrix*) is found across much of Europe. Although relatively common in Britain, they are thought to be undergoing declines in some areas due to a dependence on landscape-level features such as oviposition sites. Within the Channel Islands grass snakes are only found in Jersey where they have declined, with little known about the causes and the population's subsequent distribution and status. Furthermore they are undoubtedly the rarest of the island's four reptile species. Earlier research has found grass snakes to be abundant in the north-west and south-west of Jersey, and historically the species occurred throughout the remainder of the island at a low density. Further declines are likely, and so to assess the population a combination of directed transect walks utilising both visual and refugia survey methods took place in 2014 at 19 sites. An intensive survey effort revealed low detection with the species occurring at 58% of study sites even though suitable habitat was available. A citizen science project encouraging public recording provided

further sightings. The resulting distributional data suggests the population is largely restricted to the west and south-west of the island. A Maxent species distribution model based upon these data highlights a lack of suitable habitat throughout much of the island, with poor connectivity between quality habitat. Furthermore, localities with south-westerly aspects, ponds, scrub and bush, grassland, gardens, coniferous woodland, a close proximity to prey populations, and lower elevations had greater likelihood of species presence.

AN ICONIC ISLAND WITH ICONIC VALUES: CONSERVATION PLANNING FOR K'GARI-FRASER ISLAND THAT INTEGRATES SOCIAL WITH BIOPHYSICAL VALUES.

Angela Wardell-Johnson

University of the Sunshine Coast

Yoko SHIMIZU, University of the Sunshine Coast ; Gabriel

CONROY, University of the Sunshine Coast

K'gari-Fraser Island in SE Queensland is the largest sand island in the world and this significance is recognised internationally through world heritage listing. The unique characteristics that define this island as iconic enable conservation of iconic fauna and natural systems, as well as engagement with nature. The values that define this iconic status and the dynamic ecosystems processes have been impacted both by climate change and changing social values with potentially far-reaching consequences. Values were identified through a range of processes including expert panel consultation eliciting values relating to use, planning, management and research. These values were overlaid within the biophysical context using advanced spatial science techniques. Spatial identification of social values in conjunction with biophysical values was a means of identifying conflicting values with implications for future use and management. This research identified socio-cultural values allocated in iconic national parks through innovative processes of social engagement within a virtual landscape context. The process gave real meaning to engagement with concrete outcomes for conservation.

27 BIODIVERSITY CONSERVATION THREATS IN MEDITERRANEAN-TYPE ECOSYSTEMS OF THE WORLD

Grant Wardell-Johnson

Curtin University

Ben Miller, Botanic Gardens and Parks Authority ; Jasper SLINGSBY, University of Cape Town ; Margarita ARIANOUTSOU, University of Athens ; Peggy FIEDLER, University of California ;

Francisco MOREIRA, Institute of Agronomy, University of Lisbon / InBIO Associate laboratory

Simply by sharing their defining feature of climate, the world's five Mediterranean type ecosystem (MTE) regions share sensitivity to a number of significant threats. These link with other global and local processes to create a palette of biodiversity threats that combine the general and the unique within each region. Jurisdictional differences in policies and responses layer over these to enhance the diversity of issues. While MTEs are recognized as among the world's biomes most threatened by climate change, the complexity of predicted and observed threats are only now beginning to be elucidated and documented. In particular, climate change impacts interact with Mediterranean flavors of processes such as changed fire regimes, urbanization, habitat destruction, overexploitation of resources, invasive species and decreased landscape connectivity with important consequences for biodiversity conservation. Here we synthesize findings on threats to biodiversity across the five MTE regions from the '100 priority questions for biodiversity conservation in Mediterranean-type regions of the world' project. We identify the common features and regional singularities of these threats, prioritize their relative importance, and illustrate with new data on key threats.

INTEGRATING CLIMATE-READY REHABILITATION AND RESTORATION IN OLD STABLE LANDSCAPES FOR A MORE SUSTAINABLE FOREST FUTURE: AN EXAMPLE FROM THE JARRAH FOREST, SOUTH-WESTERN AUSTRALIA

Grant Wardell-Johnson

Curtin University

Michael CALVER, Murdoch University ; Neil BURROWS, Department of Parks and Wildlife ; James CROTON, Water & Environmental Consultants ; Giovanni DI VIRGILIO, Curtin University

Old, stable landscapes (OSLs) are vulnerable to interactions between the consequences of resource exploitation and climate disruption, often leading to transformation of ecosystems. We outline an exemplar to integrate rehabilitation and restoration to enhance the resilience of the northern jarrah *Eucalyptus marginata* Donn ex Sm. forest of Mediterranean-climate, south-western Australia. Hererainfall has declined for over 40 years, with projections for further decline. Since European settlement (1829), this forest has also been structurally transformed by land clearing and resource extraction, including logging and mining. A new hydrological regime foreshadows drying of the regolith, with a disrupted climate leading to fire regimes of higher frequency and greater intensity. Substantive areas of this forest are mined for bauxite, requiring the complete restoration of vegetation post-mining. The forest dilemma intensifies despite state-of-

the-science restoration techniques. However, the integration of restoration following mining with subsidisation of restoration of the surrounds offers a new future for these ecosystems, despite inevitable change. We demonstrate the integration of climate-ready rehabilitation with restoration of the surrounds based on a social mandate for continued high value extractive resource industries of the NJF region. This approach enables retention of important components of the forest structure for a more sustainable future environment for venerable OSLs, and offers hope for rehabilitating, restoring and conserving a semblance of the former forest grandeur.

WHERE ARE THE MAJOR ELEPHANT POACHING HOTSPOTS IN AFRICA AND WHAT SHOULD WE DO ABOUT THEM?

Samuel Wasser

University of Washington

The African elephant is the world's largest terrestrial mammal, a keystone species, and likely to be poached to extinction over most of Africa within the next decade. Targeted law enforcement is the only certain way to urgently stop the killing. However, many factors, including politics, corruption and the sheer size of Africa, make these efforts a formidable task. My laboratory has been genetically assigning geographic origin to large ivory seizures (≥ 0.5 tons) made between 1995-2014 in attempt to identify the number and locations of the major elephant poaching hotspots in Africa. Results show that the major poaching hotspots in Africa are currently concentrated in as few as two areas and that our methods have the required accuracy to locate them. We describe strategies to focus law enforcement on these two hotspots, curtail future elephant losses and disrupt this major transnational organized crime.

A TRAVIS COUNTY ALMANAC: USING NATURE BLOGS TO CONNECT UNDERGRADUATE STUDENTS TO THEIR LOCAL ENVIRONMENT

Michael Wasserman

St. Edward's University

Increased interactions between human populations living in urban areas and local biodiversity inhabiting green space (e.g., city parks, urban nature preserves) provide a number of benefits, including promotion of sustainability and conservation practices among the general public, as well as improved human health. Further, many universities either own or are located near green space that is easily accessible to students. To increase the amount of time undergraduate students from across disciplines spend interacting with their local biodiversity and to improve student understanding of and appreciation for natural ecosystems and how human activity alters ecosystem functioning, I have designed a nature blog

experience inspired by Aldo Leopold's A Sand County Almanac. In this semester-long assignment, students read this classic text, then spend at least one hour each week in a local green space around Austin, Texas, documenting their observations of biodiversity in an informal journal. To enhance their experience, they use smartphones to learn about local species (e.g., Leafsnap, Merlin Bird ID, iNaturalist), record their location, and take photographs or record videos. To examine the effects of this experience on their own health, the students also record perceived stress levels. Using all of this information, at the end of each month, they construct a public blog entry on the A Travis County Almanac website (<https://academic.stedwards.edu/ensp2324/>). Each semester, students produce four to five entries. This website takes a citizen science approach as it continually builds a database of observations and media across space and time. Beginning in September 2013, I have used this assignment in eight classes, involving 159 students sharing a total of 397 posts. Such assignments can be easily incorporated into any environmental science or ecology course, and they have lasting effects on students' concern for biodiversity at local and global levels.

SYMPOSIUM ID_181_MAPPING VULNERABILITY AND CONSERVATION ADAPTATION STRATEGIES UNDER CLIMATE CHANGE ACROSS GLOBAL TERRESTRIAL ECOSYSTEMS

James Watson

Wildlife Conservation Society

The identification of spatial gradients in ecosystem vulnerability to global climate change and local stressors is an important step in the formulation and implementation of appropriate countermeasures. However, there are at least three shortcomings in many current conservation-oriented climate change assessments, regardless of their spatial scale. The first concerns vulnerability assessments, which until recently have been focused solely on the system's 'exposure' to future climate change, without considering that vulnerability to climate change is influenced by the system's sensitivity and adaptive capacity, as well as exposure. The second is that the vast majority of climate change assessments has been conducted on species-specific responses, and therefore been largely unable to inform conservation actions in terms of ecosystem-based adaptation. The third shortcoming is that few species or ecosystem assessments have attempted to identify (and map) the specific adaptation action needed to overcome the threats posed by climate change, especially as related to land use and land use change, the other significant driver of ecosystem change. Here I build on recent work to map ecoregional exposure to future climate, using an envelope-based gauge of future climate stability, and incorporate this with an assessment of each ecoregion's adaptive capacity,

based on the proportion of intact natural vegetation. The relationship between intactness (adaptive capacity) and stability (exposure) varies widely across ecoregions, with some of the most vulnerable, according to this measure, located in southern and south eastern Asia, western and central Europe, eastern south America and southern Australia. To ensure the applicability of these findings to conservation, I provide a matrix that highlights the potential implications of this vulnerability assessment for adaptation planning and offers a spatially-explicit management guide.

91-WHAT RESEARCH DO PRACTITIONERS HAVE ACCESS TO AND HOW CAN ACCESS BE IMPROVED?

James Watson

Wildlife Conservation Society

Richard FULLER, University of Queensland; Jasmine LEE, University of Queensland

Conservation science is a crisis discipline in which the results of scientific enquiry must be made available quickly to those implementing management. We assessed the extent to which scientific research published since the year 2000 in 20 conservation science journals is publicly available. Of the 19,207 papers published, 1,667 (8.68%) are freely downloadable from an official repository. Moreover, only 694 papers (3.61%) meet the standard definition of open access in which material can be freely re-used providing attribution to the authors is given. This compares poorly with a comparable set of 20 evolutionary biology journals, where 31.93% of papers are freely downloadable and 7.49% are open access. Seventeen of the 20 conservation journals offer an open access option, but fewer than 5% of the papers are available through open access. The cost of accessing the full body of conservation science runs into tens of thousands of dollars per year for institutional subscribers, and many conservation practitioners cannot access pay-per-view science through their workplace. However, important initiatives such as Research4Life are making science available to organisations in developing countries. We urge authors of conservation science to pay for open access on a per-article basis or to choose publication in open access journals, taking care to ensure the license allows re-use for any purpose providing attribution is given. Currently, it would cost \$51 million to make all conservation science published since 2000 freely available by paying the open access fees currently levied to authors. Publishers of conservation journals might consider more cost effective models for open access and conservation-oriented organizations running journals could consider a broader range of options for open access to non-members such as sponsorship of open access via membership fees.

130-CHANGES IN THE GLOBAL HUMAN FOOTPRINT WITH POPULATION AND ECONOMIC GROWTH

James Watson

Wildlife Conservation Society

Oscar VENTER, University of Queensland

As the global human population and per-capita consumption increases, humanity's influence on the environment is generally considered to increase apace. With most of Earth's natural systems precariously close to unprecedented change, and world population likely reach 10 – 12 billion this century, there is a need to elucidate the relationship between socio-economic growth and environmental influences. The lack of a comprehensive, temporally consistent and spatially explicit measure of human influence on the environment has limited such analyses. Recent data series enabled us to construct a globally-standardized measure of human influence on the terrestrial environment at 1 km² resolution and compare it with trends in population size, economic growth, and urbanization over the 1993 to 2009 period. We show that by 2009, at least 75% of the planet's surface and 97% of agriculturally suitable areas had been influenced by humans. Over the 1993 to 2009 period, the human footprint grew by around 12%, a rate which was outstripped by human population growth at 23% and economic output at 153%. The highest-income countries and urban centers appear to have experienced some decreases in human footprint, while peri-urban areas across all national income brackets saw the greatest increases. We discover divergent environmental pathways for expanding economies, with countries having decreasing human footprint characterized by high control of corruption and urbanization. Moreover, these countries do not appear to be simply exporting their demands for food and raw material to less developed nations. The human footprint on Earth is changing, but in ways that wealth and governance appear to differentially shape. We should be encouraged and informed by examples of rapid economic growth decoupled from environmental influences.

THE EFFECTS OF SHIFTING TEMPORAL PATTERNS OF LAND-USE CHANGE ON BIODIVERSITY

Simon Joseph Watson

La Trobe University

Human land-uses dominate a large portion of the earth's terrestrial surface area. The negative effects of major land-use transformations (e.g. from 'natural' ecosystems to agricultural land-uses) on biotic communities have been well documented. However, human land-uses are not static or uniform. For example, around the world, crops in agricultural areas regularly change, with consequent (positive and negative) shifts in biodiversity and changes to ecological communities.

Globalised markets and increased mechanisation of human land-uses has resulted in a greater frequency of land-cover change in many human dominated ecosystems. The effect of varying temporal patterns of land-cover change on biotic communities is largely unknown, but it is likely that the patterns will play a key role in processes such as biotic homogenization. Here I use case studies from around the world to present evidence on the effects of different production types on biodiversity, and highlight how the magnitude and temporal patterns of land-cover changes can affect the contemporary biotic community. Variations in the temporal patterns of land-cover change are set to continue in the future and it will be critical to incorporate knowledge of their effects on biota into strategies for conservation of biodiversity.

CLIMATE CHANGE COULD TRUNCATE THE WORLD'S MAJOR MIGRATION FLYWAYS

Hannah Wauchope

University of Queensland

Justine SHAW, Australian Antarctic Division ; Øystein VARPE, University Centre in Svalbard ; Elena LAPPO, Russian Academy of Sciences ; David BOERTMANN, Aarhus University ; Pavel TOMKOVICH, Lomonosov Moscow State University ; Richard Fuller, University of Queensland

Millions of migratory birds breed during the short but highly productive Arctic summer before flying south to overwinter at lower latitudes. The potential impacts of climate change are particularly severe in the Arctic, where the rate of warming is projected to be more than twice the global average. Moreover, shifts in suitable climatic conditions for breeding in migratory species might not be reflected at lower latitudes along other parts of species' flyways, causing migration routes to be disrupted. Here we use ecological niche modelling to estimate the future distribution of climatically suitable breeding habitat for all 24 migratory shorebird species breeding exclusively in the high Arctic. Depending on the climate change scenario used in the models, between 16 and 17 species will lose more than 50% of their current climatically suitable breeding habitat by 2070. Climatically suitable habitat will contract to small refugia on Russian Arctic islands and the Canadian Arctic Archipelago, and flyways not currently connected to these regions, most notably in eastern Asia and Alaska, could experience significant declines. Indeed, the Pacific and East Asian-Australasian flyways are projected to lose up to 38% of their species. Encouragingly, protected area coverage is comparatively good for all species currently, and for 18-20 species in future scenarios, although of course protection from habitat loss is insufficient for species' survival if no climatically suitable breeding habitat remains. Mitigation of climate change seems essential to the conservation of Arctic migratory species and, in the interim, international collaboration to protect climate refugia is urgently needed.

VACCINATION AS A MANAGEMENT STRATEGY FOR CHLAMYDIA IN THE KOALA (PHASCOLARCTOS CINEREUS)

Courtney Waugh

The University of the Sunshine Coast

Adam POLKINGHORNE, The University of the Sunshine Coast ; Kenneth BEAGLEY, Queensland University of Technology ; Jon HANGER, Endeavour Veterinary Ecology ; Jo LOADER, Endeavour Veterinary Ecology ; Peter TIMMS, The University of the Sunshine Coast

The koala (*Phascolarctos cinereus*) is declining across much of its natural range. A myriad of threats are placed on the koala, including motor vehicle accidents, dog attacks, habitat fragmentation and disease. *Chlamydia pecorum* is the most devastating disease in mainland koala populations and accounts for significant morbidity and mortality. Localised population extinctions are predicted to occur within 10 years due to disease in some populations. However, modelling has shown that a five-year vaccination program could halt chlamydial disease related declines, and further modelling has shown that if declines due to disease could be decreased by even 50% then populations would remain stable even with continued anthropomorphic pressures. The development of an anti-chlamydial vaccine is underway with promising results. Here, we present the results from the first and largest field based vaccine study to date. We propose that a vaccination schedule can provide a key tool for management and conservation of this iconic species.

CHLAMYDIA PECORUM IDENTIFIED IN UROGENITAL AND OCULAR REGIONS OF SEXUALLY INACTIVE JUVENILE KOALAS (PHASCOLARCTOS CINEREUS)

Courtney Waugh

The University of the Sunshine Coast

Isabelle RUSSELL, The University of the Sunshine Coast ; Peter TIMMS, The University of the Sunshine Coast ; Amber GILLETT, Australia Zoo Wildlife Hospital

Chlamydia pecorum, a major pathogen of the koala (*Phascolarctos cinereus*), is considered an important factor to the threat of localised extinctions facing koala populations. *Chlamydia pecorum* is primarily considered a sexually transmitted infection, yet recent observations have identified that sexually immature koala joeys are exhibiting clinical symptoms of *C. pecorum*. Urogenital (UGT) and ocular (OC) samples, obtained from mother-joeys pairs and orphaned koala joeys, were analysed for *C. pecorum* DNA using quantitative polymerase chain reaction. This confirmed the presence of *C. pecorum* in koala joey UGT and OC regions suggesting that *C. pecorum* is able to transmit vertically as well as sexually. No correlation could be found between koala mothers exhibiting

C. pecorum infections and joeys exhibiting infections. This suggests that, although vertical transmission may be occurring between mother and joey, it is a less prevalent method of transmission than sexual transmission. Further, the recently developed koala anti-chlamydial vaccination appears to afford some protection to joeys with vaccinated mothers.

A STEP TOWARDS UNDERSTANDING FLUCTUATIONS IN CARRYING CAPACITY FOR AN ENDANGERED FACULTATIVE MIGRANT

Matthew Webb

Australian National University

Aleks TERAUDS, Australian National University ; Dejan STOJANOVIC, Australian National University ; Robert HEINSOHN, Australian National University

Extreme plasticity in movements of nomadic or facultative migrants, usually in response to fluctuating food availability, often results in massive shifts in range size and breeding location. Although supporting data are rare, conservation management for these species needs to extend beyond traditional approaches that consider a species' distribution as static. Using spatially explicit occupancy modelling we describe dramatic spatiotemporal variation in the endangered swift parrot over 6 years. By repeatedly sampling 1000 sites across the entire breeding range we demonstrate highly significant spatial structuring where the population shifts en masse from one location to another to breed. These shifts were driven by the distribution of *Eucalyptus* flowering events, which provide the species primary food source whilst breeding. In the context of massive and continuing habitat loss, our findings are critical to inform conservation because only a fraction of the breeding range is suitable (and occupied) in most years, and that fraction varies dramatically between years. Thus, the spatial configuration of food each year also determines the availability of nesting sites (i.e. cavities in old-growth trees). These keystone features take >150 years to develop and are extremely rare and patchy across most of the landscape. We provide an analytical framework to assess overall fluctuations in (i) area of occupancy and, (ii) the relative availability and spatial configuration of different functional habitats (ie. for foraging and nesting). This allows an assessment of where, and when, spatial or reproductive bottlenecks occur and will better inform the development of spatially explicit conservation strategies that account for plasticity in settlement patterns when breeding. Most importantly, we clearly identify areas of the breeding range that need to be managed in a way that provides enough foraging and nesting habitat for the majority of the population to breed in a given year.

INTEGRATING SOCIAL SCIENCE INTO CONSERVATION SCIENCE: EXAMINING THE LANGUAGE OF 'HUMAN-WILDLIFE CONFLICT'

Amanda Webber

Bristol Zoological Society

Catherine M HILL, Oxford Brookes University ; Alberto ACERBI, University of Bristol ; Daphne KERHOAS, Bristol Zoological Society

The need to integrate social science perspectives into conservation science is now widely acknowledged. This is particularly important for the examination of negative human-wildlife interactions; historically termed 'human-wildlife conflict' (HWC). In these scenarios, wildlife can be injured or killed and the associated economic and social costs mean local people may fail to support or actively resist environmental initiatives. However, the language of HWC implies that animals are conscious protagonists (Peterson et al, 2010) in what is often a social tension between human stakeholders (Dickman, 2010, Redpath et al, 2013). There has recently been a movement to reframe this 'conflict' and find an alternative term (e.g. 'negative interaction', 'human-wildlife coexistence'); however, there is little evidence as yet of a shift away from the 'HWC' label among researchers. We will present the analysis of full texts and metadata made available by major academic publishers which tracks the usage of HWC terms (e.g. 'human-wildlife conflict', 'crop raiding'), the uptake of alternative labels, and the affiliations of authors and of the disciplinary domains of journals. We will discuss how this study (i) is not only important to understand the adoption and diffusion of terminology within the literature but (ii) also provides a useful backdrop for exploring the integration of social science perspectives in the conservation literature.

97. USING CITIZEN-SCIENCE AND CIRCUITScape TO IDENTIFY CORRIDORS AND COLONIZATION SITES IN NEW YORK CITY AND LONG ISLAND, NY

Mark Weckel

American Museum of Natural History

Christopher NAGY, Mianus River Gorge ; Megan HENRIQUEZ, Fordham University ; Rachel ENGSTRAND, American Museum of Natural History ; Jason MUNSHI-SOUTH, Fordham University

Long Island, NY is one of last large land masses in the continental U.S. yet to support a breeding population of northeastern coyotes (*Canis latrans* var.). Predicting likely areas for colonization and potential corridors can help efforts to study the ecological and social impacts of coyotes on Long Island, pre- and post-arrival. To forecast future colonization sites on Long Island, we revisited (and reanalyzed) the results of an earlier citizen science study from nearby Westchester, NY that modeled residential human-coyote interaction (HCI)

as a function of habitat. We argue that the probability of a “backyard” coyote sighting can be a proxy for permeability of the matrix to coyote movement. Therefore, we used HCI predictions to parameterize resistance grids for subsequent Circuitscape analyses. We will present the results of these analyses and also discuss the vital role citizen data can play in tracking the establishment and growth of a Long Island coyote population.

OPERATIONALIZING ADEQUACY IN MARINE PROTECTED AREA NETWORK DESIGN

Rebecca Weeks

ARC Centre of Excellence for Coral Reef Studies

Alison GREEN, The Nature Conservancy ; Eugene JOSEPH, Conservation Society of Pohnpei ; Kevin RHODES, University of Hawaii ; Elizabeth TERK, The Nature Conservancy Micronesia ; Jeremy VANDEWAL, James Cook University

A central tenet of protected-area design is that areas must be adequate to ensure the persistence of focal species. Guidelines recommend that minimum size of protected areas be informed by species’ home ranges, because individuals that move beyond protected area boundaries might be exposed to threats, and thus only partially protected. This is especially important for species that are directly exploited, such as many coral reef-associated fishes. Rules of thumb for marine protected area (MPA) size, informed by species movement or otherwise, are frequently used in post-hoc evaluation of MPA network designs. Post-hoc approaches to considering adequacy are problematic, however, as they often require subjective alterations that reduce the complementarity and efficiency of systematic designs. Post-hoc evaluations also often fail to consider that minimum size recommendations must apply to the habitats that focal species use, rather than the total size of the protected area per se. Using a case study from Pohnpei, Micronesia, we demonstrate a novel approach to MPA network design that explicitly accounts for species’ home range requirements and habitat associations. Using raster habitat maps, MPAs are “seeded” from cells with high suitability scores, calculated as a function of the area of a species’ habitat within the neighbourhood (defined by the species’ home range), and grown until they reach minimum size. We explore the spatial overlap and functional surrogacy of MPA networks designed for different species, and conduct sensitivity analyses to uncertainty in input parameters. Analysis of existing MPAs in Pohnpei demonstrates that almost all are too small to adequately protect key fishery species. Our method complements representation-based approaches to MPA network design, and is likely to appeal to stakeholders motivated more by a desire to effectively manage populations of key fishery species than by biodiversity conservation-oriented objectives.

ANTHROPOGENICALLY ALTERED LANDSCAPES NEGATIVELY AFFECT RESTING SITES BUT CREATE FAVOURABLE FORAGING HABITAT FOR OTTERS IN THE ALPS

Irene Weinberger

University of Zurich

Stefanie MUFF, University of Zurich ; Andreas KRANZ, Alkranz Ingenieurbüro für Wildökologie und Naturschutz ; Lukas KELLER, University of Zurich ; Fabio BONTADINA, SWILD - Urban Ecology & Wildlife Research [INSTITUTE] WSL Swiss Federal Research Institute

Animals have different habitat requirements for behaviours such as foraging or sleeping. Information on specific habitat selection is particularly important for species in anthropogenically altered landscapes. The natural riparian landscape in the Alps has been one of the last pristine refuges of Europe, but is severely reduced by urban sprawl, alteration of river courses and increasing numbers of hydropower plants. The Eurasian otter *Lutra lutra* is a semi-aquatic mammal which has suffered massive declines in Europe in the last century. In recent years, the species is re-expanding its geographic distribution again, also into the Alpine arc, where it had disappeared. The aim of this study was to understand the habitat requirements of the otter in the Alps to facilitate its recovery. We radiotracked nine otters for six to 30 months at night to study foraging habitat selection and during the day to identify dens. Data was analysed using step selection function and logistic regressions. We found that the home ranges were selected along streams wider than 4m, despite these being the most affected by habitat transformations. There, they significantly selected reservoirs with widths up to 12m, but avoided residual waters of this size. However, once the reservoir was broader, selection was reversed. While foraging otters were not affected by the riparian structure, for resting they clearly selected for stretches with natural riparian vegetation and varied the type of the den depending on human disturbance. Our results exemplify a mammal with a flexible selection on foraging habitat, where it tolerates or even benefits from modifications to the rivers, but it appears to be sensitive while resting. We presume that optimal resting sites are the limiting factors for otters in human altered landscapes. These findings are encouraging for a return of the species to the Alps as long as the altered riparian landscape is interspersed with natural stretches at short intervals.

THE LIMITATIONS OF NO-TAKE MARINE RESERVES IN PROTECTING CORAL REEFS FROM REDUCED WATER QUALITY

Amelia Wenger

James Cook University

David WILLIAMSON, James Cook University; Eduardo DA SILVA, James Cook University; Daniela CECCARELLI, James Cook University; Caroline PETUS, James Cook University; Michelle DEVLIN, James Cook University

Near-shore coral reefs have adapted to periodically reduced water quality from terrestrial run-off. Their capacity to cope with and recover from such disturbances is critical for their continued persistence. Globally expanding coastal development, in combination with projected increases in the frequency of extreme weather events under climate change, may lead to the continued degradation of many vulnerable near-shore coral reefs. This paper investigates the spatial and temporal variability of water quality during moderate and major flooding events of the Fitzroy River within the Keppel Bay region of the Great Barrier Reef Marine Park from 2008-2013. We quantified the ecological impacts of the resulting flood plumes on adjacent near-shore reefs using six years of flood plume satellite imagery and long term monitoring data. We then investigated the role of no-take marine reserves (NTR) in reducing reef degradation from flooding and enhancing post-disturbance recovery. Near-shore reefs did not experience any declines in coral cover from moderate flooding in 2008-09, suggesting intrinsic resistance against reduced water quality. However, they had limited ability to cope with more extreme reductions in water quality associated with major flooding in 2010-11. Furthermore, near-shore reefs showed low resistance to subsequent moderate flooding events. The reduction in coral cover strongly correlated with duration of exposure to reduced water quality ($r = -0.89$). Importantly, the NTRs did not influence the response to or post impact recovery from major flooding, suggesting limited ability of NTRs to promote ecosystem recovery following external disturbances. The limitations of NTRs in mitigating the effects of reduced water quality on near-shore coral reefs underscore the importance of integrated management approaches that combine effective land-based management with no-take reserves.

THE USE OF HABITAT ASSOCIATION AS A PROXY FOR SPECIES DISTRIBUTION

Amelia Wenger

James Cook University

Malcolm TURNER, The Great Barrier Reef Marine Park Authority; John OLDS, Queensland Parks and Wildlife; Ian CRAIGIE, James Cook University; Jessica HOPF, James Cook University; Bob PRESSEY, James Cook University

Managers of the Great Barrier Reef's islands face difficult decisions when it comes to prioritising conservation management actions. The islands contain a wide variety of natural and cultural values, which face multiple and dynamic threats, with management constrained financially. In order to improve management decision-making on islands,

a comprehensive dataset on the distribution of priority species across the study region is required. As with most environmental datasets, there are large knowledge gaps where biological surveys have not occurred, thus necessitating alternative ways of acquiring species distribution data. To address these gaps, comprehensive habitat data for the islands, based on satellite and aerial imagery, and in situ surveys, was extracted from a larger database. Then, a series of expert elicitation workshops were conducted to estimate populations of priority species on islands and to determine their habitat associations. Overall, we collected 6,076 records for 40 priority species on 146 islands. These records were comprised of 655 survey, 1341 expert judgement, and 4359 habitat proxy records. Because of the high number of habitat proxy records, we compared the use of habitat presence and absence as proxies for species presence and absence. We found that, when comparing habitat presence to expert judgement on species presence, habitat presence predicted species presence 53% of the time. In contrast, habitat absence correctly predicted species absence 94% of the time. Our results demonstrate that, in the absence of comprehensive biological surveys, habitat absence can reliably predict species absence. Environmental managers can use species absence information to prioritise monitoring programs and to prioritise areas for management actions, while minimizing the risk of overlooking important sites for priority species.

GENETIC LANDSCAPE WITH SHARP ALLELE FREQUENCY SHIFTS IN SWEDISH MOOSE (ALCES ALCES)

Lovisa Wennerström

Stockholm University

Nils RYMAN, Stockholm University; Jean TISON, Swedish Museum of Natural History; Anna HASSLOW, Stockholm University; Love DALÉN, Swedish Museum of Natural History; Linda LAIKRE, Stockholm University

The moose (*Alces alces*) is the most intensely managed game species in Fennoscandia; approximately one third of the population, c. 16,000 animals, is harvested annually through hunting. Despite the species' biological and socio-economic importance there are knowledge gaps with respect to its intraspecific diversity and genetic structure. To delineate the spatial genetic landscape and population history of the Swedish moose we used allozyme variability from over 20,000 georeferenced moose collected all over Sweden in combination with genetic information from 12 microsatellite loci ($n > 1,200$) and mitochondrial DNA sequences. We combined individual-based and traditional statistical approaches with coalescence based simulations. The results indicate a complex history with bottlenecks and recent expansions that is consistent with historical records. The analyses show that Swedish moose are separated into 2

major genetic groups, a northern and a southern one, where the southern group is further divided into three subgroups. The 2 main subpopulations are moderately differentiated and separated by sharp allele frequency shifts occurring over a relatively narrow transition zone in central Sweden that coincides with a similar, previously reported transition zone in Norway. This differentiation is not reflected in mtDNA variation, however, where no significant divergence was observed. This suggests that the 2 major subpopulations in Sweden reflect divergence shaped after the postglacial recolonization of Scandinavia. Spatial autocorrelation assessments indicate that gene flow is relatively restricted in spite of the species potential for long distance migration with an estimated average dispersal distance of only a few km. Present day genetic patterns are most likely affected by both past and present anthropogenic actions. The current management areas largely coincide with genetic clusters, simplifying the integration of genetic information into management.

91-CONSERVATION BIOLOGY - IS THERE EVIDENCE THAT IT IS STILL A DISPLACEMENT BEHAVIOUR FOR ACADEMIA?

Tony Whitten

Fauna & Flora International

In 2001 an editorial in Conservation Biology by myself and two colleagues asserted that conservation biology was indeed a displacement behaviour. Did this discipline actually contribute to conservation outcomes on the ground. The paper caused some negative reaction from some quarters and was dismissed by some. Yet the paper is still used in university courses on conservation. Nearly 15 years on from when the paper was written the basic tenets of the argument are re-examined and the conclusions will be discussed.

CONSERVATION AND BIODIVERSITY VALUE IN REGENERATING TROPICAL FOREST

Andrew Whitworth

University of Glasgow

Roger DOWNIE, University of Glasgow ; Ross MACLEOD, University of Glasgow

Although the value of primary forest for biodiversity conservation is well known, the majority of the world's tropical forests have already had their structure and underlying functions disrupted. The potential biodiversity and conservation value of these regenerating forests remains controversial. We suggest that this is because assessments of regenerating rainforest are often dominated by young regenerating forests, forests with on-going human disturbance (from logging and hunting), few multi-taxonomic studies and a lack of comparisons between disturbance types. We assess the overall biodiversity and conservation value of a regenerating

rainforest in the globally important Manu area of the Peruvian Amazon. Potentially confounding factors were overcome and results were compared to a selection of well-studied primary forest sites and the expected gamma diversity for the region. We show that, for birds, large mammals, amphibians and reptiles, that regenerating forest held 87% (+3.47) of the alpha diversity found in comparable primary forest sites and 83%(+6.66) of primary forest gamma diversity from the region. This is significantly higher than biodiversity values presented by review studies (57%, 59% and 68%), suggesting that confounding effects are causing an underestimation of the potential value of regenerating rainforest for conservation. Further, the regenerating site held 89% (39 out of 44) of the species of high conservation concern predicted for the region, indicating that the high species richness is not simply driven by generalist species of lower conservation value. Species richness of regenerating rainforest after complete clearance was on average 15% (+6.6) lower than historically selectively logged forest. However, species richness of even these historically completely cleared areas was 16% higher than previous suggested average values (60%+-9.58).

SYMPOSIUM #20: CONSERVATION DRONES AND MONITORING OF BIODIVERSITY

Serge Wich

Liverpool John Moores University

Mapping land cover and determining species are two major tasks for conservation workers. Remote sensing technology is increasingly being used to assess changes in land cover. However, conventional satellite- and air-borne sensors can be prohibitively costly and inaccessible for researchers in developing countries. Species abundance is often determined by ground surveys or costly and risky surveys with small manned planes. In addition, ground surveys are often expensive, time consuming, and limited in their spatial coverage. In 2012, Lian Pin Koh and I co-founded the ConservationDrones.org initiative (<http://ConservationDrones.org>) to introduce drone technology to our colleagues in the conservation community for monitoring of land-cover change and species distribution and density. Conservation drones are inexpensive and autonomous unmanned aerial vehicles equipped with cameras to record high quality video and photographic images. Aerial photographs can be stitched together to produce near real-time geo-referenced land use/cover maps of surveyed areas and even 3-dimensional forest models. They can also be used to survey wildlife such as orangutans, chimpanzees, and various other species. I will talk about the various applications of conservation drones for ecological and conservation research.

ASH DIEBACK MAY INFLUENCE BIODIVERSITY OF EPIPHYTIC AND EPIXYLIC CRYPTOGRAMS IN EUROPEAN CLOSE-TO-NATURAL FOREST

Sylwia Wierzcholska

University of Warsaw

Bogdan JAROSZEWICZ, University of Warsaw ; Martin KUKWA, University of Gdansk, Department of Plant Taxonomy and Nature Conservation ; Anna LUBEK, Jan Kochanowski University in Kielce, Institute of Botany

Living and dead European ash trees (*Fraxinus excelsior*) are preferred substrata for cryptogams. The dieback of ash, caused by the fungus *Hymenoscyphus pseudoalbidus*, resulted in a decline in ash abundance in Poland and adjacent countries. In Bialowieza Forest (Poland) ash population was reduced during the last two decades by 2/3 and may put ash dwelling species in jeopardy. Therefore studies on effects of ash dieback on biodiversity became urgent. We have resurveyed 144 ha permanent plot to estimate changes in species abundance, distribution and species composition of plants and lichens. We took the opportunity to study effects of ash decline: changes in the frequency of ash-dependent cryptogam species and their substrate preferences. There were many threatened and red-listed species among cryptogams recorded on ash on the study plot (e.g. *Dicranum viride*) including some lichens recorded exclusively on ash (e.g. *Pertusaria coronata*). Many species survived fading away of their host trees and continued to grow on ash deadwood in the first stages of decomposition, the others were limited to living trees only. Some species (e.g. *Zygodon rupestris*) decreased in comparison to their abundance on the plot 25 years ago. Frequency of others, light demanding cryptogams, increased, probably due to higher light amounts reaching forest floor after canopy decline. Some ash-related cryptogams showed also tendency to increase their abundance on other tree species. The impact of ash dieback on biodiversity of cryptogams in Bialowieza Forest depended on species biology. We did not record any extinctions yet. Moss species in some cases even benefitted from increased amounts of light reaching the forest floor. In the case of lichens recorded only on ash trees, their extinction risk will increase with declining numbers of available host trees. Our results show potential trends in populations of ash associated cryptogams in European countries, where the ash dieback is not so advanced yet.

INTERNATIONAL POLICY AND PRESSURE AROUND CLIMATE-SMART AGRICULTURE

Marit Wilkerson

AAAS S&T Policy Fellowship [INSTITUTE] University of California

Is 'climate-smart agriculture' merely rebranding for good development? What does the label add to the goals of sustainable agriculture? These recurring questions have strong implications for research, policy, and international development. Without a clear understanding of how climate-smart agriculture (CSA) can take shape in the field and what the relatively new label means for policy, researchers and decision-makers cannot coherently promote the practice of CSA. Nor can they adequately identify research gaps for applied conservation and agro-ecological researchers. In this presentation, I will synthesize the global trends in CSA research and policy and detail how emerging the emerging consensus around CSA highlights both critical knowledge gaps and practical development strategies. To underline the importance of CSA to natural resource conservation and food security, I will provide an overview of its origins and detail the level and nature of current agreement around a CSA definition. The particular practices that constitute CSA have been promoted for decades but were never labeled as such until fairly recently. This issue of rebranding highlights the misunderstandings and difficulties behind defining CSA. I will then delve into the state of global climate-smart agriculture policy with particular insights from the U.S. The next necessary step, translating the science and policy of CSA into on-the-ground development projects, remains largely piecemeal and ad hoc. However, certain regions and political bodies are successfully integrating CSA into existing development programs, and the international research and policy community can learn from those successful approaches. I will present the lessons learned from those success stories, distilling them into programmatic best practices. These trends, consensus, and successes point toward the next steps forward for research and policy on integration and implementation of CSA.

210 WE MUST SAVE OUR ROADLESS WILDPLACES - THEY ARE OUR ONLY REMAINING INTACT MANUALS FOR NATURE

David Wilkie

Wildlife Conservation Society

Today 83 percent of the Earth's land surface has been altered by the actions of people. Today commodity producers are already looking for new lands to convert to food, mineral and biofuel production, and pressure to expand such production will only increase in the next decades. But plundering the 17 percent of the planet not yet bent to our will, cannot make up for our failure to sustainably manage the 90 percent of the Earth that we have already altered. Roadless wild places with intact assemblages of native plants and animals, interacting largely outside the influence of humanity, and at densities

where all fulfill their ecological roles are vital. Their complex and redundant nutrient pathways make them both resistant and resilient to environmental shocks, and thus will likely be our best arks for species conservation as the climate changes. Maybe most importantly they are our last manuals for nature. Manuals that thankfully still have all their pages, something that cannot be said for all landscapes and seascapes altered and degraded by human use. These intact, wild places are vital repositories of ecological knowledge without which we will never know how to repair what we damaged or restore what we have destroyed. This presentation will explore the value of and threats to roadless wilderness in the dense forest regions of Central Africa, and propose options for reconciling the tradeoffs between development to raise incomes of some of the poorest people on earth, with the conserve of these dwindlingly few last, intact wildplaces.

EMPLOYING RANK AGGREGATION OF LOCAL EXPERT KNOWLEDGE FOR CONSERVATION PLANNING OF THE CRITICALLY ENDANGERED SAOLA.

Nicholas Wilkinson

University of Cambridge

Nigel LEADER-WILLIAMS, University of Cambridge ; Duc LUONG VAN, Hue University of Sciences

There has been much recent interest in using local knowledge and expert opinion for conservation planning, particularly for hard-to-detect species. Because of the need to compare data collected at simple locations, surveys generally seek to extract quantitative data from informants but this may incur error through cultural misunderstanding or cognitive effects. We present a new approach which couples an intuitive Rapid Rural Appraisal survey technique with rank aggregation algorithms developed for web search by researchers at MicroSoft and Google. We apply this technique to conservation planning for the poorly known saola antelope *Pseudoryx nghetinhensis* across one conservation landscape in Central Vietnam. Using assessments of relative abundance by local people across the knowledge domain of each village, we produce a prioritization map of the area as a whole. Because direct information about the saola is so difficult to obtain, these rank aggregation results are valuable for conservation planning or the targeting of field surveys.

TRADE IN ORCHIDS FOR CHINESE MARKETS

Sophie Williams

Xishuangbanna Tropical Botanic Garden

Jiungyun GAO, Xishuangbanna Tropical Botanic Garden

The use of orchids in China has a long history, dating back to 200BC, with many species highly prized for their medicinal and horticultural value. However, the demand for wild orchids

in China is thought have increased over the last decade and over-exploitation is a now major threat. The diversity of species in trade has not yet been documented. Furthermore, the attributes of orchids desired by consumers, and therefore driving trade, are also unknown. Peoples' preference for certain species tends to lead to systematic harvesting for those species perceived more valuable. We carried out monthly surveys of six regular markets trading orchids in Xishuangbanna Autonomous Prefecture, Yunnan; an area well known for its high orchid diversity. This region borders Myanmar, Laos and Vietnam presenting opportunities for illegal trade into China. We identify over thirty species in trade and show the markets close to the Myanmar border are particularly diverse in orchid species. We are unable to determine the exact source locations of species on sale. However, interviews with collectors suggest movement of orchids across the borders occurs. To assess consumer preferences we interviewed 600 people using a choice based experiment to determine favoured attributes. We show that rarity is a desired characteristic, as are red flowers. There is no difference in preference for species cultivated compared to wild harvested for species in the ornamental trade. This suggests cultivated material could potentially supply the market demand for ornamental orchids. However cultivation as a conservation strategy has little evidence of success and we discuss the challenges of substituting wild by cultivated orchids. We conclude by highlighting which species should be conservation priorities in Xishuangbanna and across China.

WISCONSIN CHAPTER OF SCB: A CASE STUDY IN FOSTERING COLLABORATION IN CONSERVATION

Caitlin Williamson

Natural Resources Foundation of WI

The field of conservation is facing an increasing number of challenges, from growing threats such as climate change, to substantial decreases in conservation funding and support. Wisconsin, USA, in particular has recently faced specific challenges in terms of budget, governance, and legislation that have negatively impacted conservation and natural resources management in the state. In the face of such challenges, it is critical for conservation practitioners and scientists to maintain an outlook of positivity and to focus on strategies that engage the public, find ways to connect research to policy, and promote a collaborative environment where conservationists from different sectors and backgrounds can learn from one another. The newly established Wisconsin Chapter of the Society for Conservation Biology (WSCB) is filling a unique niche in Wisconsin. Its membership consists of students and faculty from universities and colleges, staff from state agencies and non-profits, as well as the private sector. WSCB is finding innovative ways for its members to become meaningfully

involved in conservation research and policy in the state. In this presentation, I detail the steps that the founding WSCB board took to establish an interdisciplinary and engaged chapter, provide examples of the projects and activities that the chapter is involved in and establishing, and identify successes and challenges the chapter faced in starting from scratch. These lessons learned will be useful for other SCB chapters and groups, as well as for other organizations wishing to have an impact on their community and beyond.

BIRDS BE SAFE: CAN A NOVEL CAT COLLAR REDUCE AVIAN MORTALITY BY DOMESTIC CATS (FELIS CATUS)?

Susan Willson

St. Lawrence University

Iyioluwa OKUNLOLA, St. Lawrence University; Jessica NOVAK, St. Lawrence University

The domestic cat (*Felis catus*) has been described as the largest anthropogenic threat to songbird populations in North America. We examined the effectiveness of a novel cat collar in reducing avian and small mammal mortality by cats. A cotton fabric collar cover is worn over a nylon quick-release cat collar, and the bright colors and patterns of the collar cover are hypothesized to warn birds of approaching cats. We conducted two seasonal trials, each lasting twelve weeks, in autumn 2013 and spring 2014. Fifty-four cats participated in the autumn trial, while a subset of 19 cats participated in the spring trial. Cats were randomly assigned to two groups, and collars were removed or put on every two weeks, to control for weather fluctuations and seasonal change. Cats wearing collar covers killed 19 times fewer birds than uncollared cats in the spring trial, and 3.4 times fewer birds in the fall. The collar covers were extremely effective at reducing predation on birds. Small mammal data were less clear, but did decrease predation by half in the fall season. There were no significant effects of location (rural versus village), sex, or age of cats. The brightly colored collar cover we tested is a highly effective device for decreasing bird predation, especially in the spring season when birds may be depredated more easily due to their territorial nature and bright feather colors, as opposed to the autumn season when drab neotropical migrants typically flock together. We suggest that these collar covers be utilized as a conservation tool by domestic cat owners, and that they also be fitted to feral cats living in maintained cat colonies.

NEW FIELD DATA ON THE ENDANGERED L. MITTERMEIERI - NORTHWEST MADAGASCAR

Leslie Wilmet

Liege University - Gembloux Agro-Bio Tec

Roseline C. BEUDELS-JAMAR, Royal Belgium Institute of Natural Sciences, Brussels, Belgium. Rue Vautier, 29. 1000 Bruxelles;

Christoph SCHWITZER, Bristol Zoological Society, c/o Bristol Zoo Gardens, Bristol, UK; Cedric VERMEULEN, Liege University - Gembloux Agro-Bio Tec

Madagascar's extraordinary biological diversity is under increasingly severe threat from anthropogenic degradation of its forest habitats. Genus *Lepilemur* is exemplary of the mammalian fauna of the island. The genus is particularly negatively affected by deforestation and habitat fragmentation, which is reflected by the recent uplisting of many of the 26 *Lepilemur* species into one of the threatened categories of the IUCN Red List. Sportive lemurs have small distribution ranges, and fairly small total populations. Their pattern of distribution appears to have been established through vicariant speciation, probably driven by changes in the configuration of the hydrographic system. Such a pattern suggests a high level of niche conservatism. The main goals of this study is to verify the existence and extent of niche conservatism in three closely related species within genus *Lepilemur*, and to draw conclusions on the applicability of conservation protocols to a broader array of *Lepilemur* species. This study focuses on a poorly-known taxon, *L. mittermeieri*, whose distribution range is located on the Ampasindava peninsula. This species was described in 2007 but since then no investigation has been carried out. We present here our global project as well as the results of a field mission conducted from March to June 2015 in order to specifically 1) investigate habitat use of 8 radio-collared *L. mittermeieri* by the analysis of their home range, feeding ecology and sleeping sites characteristics and 2) to complete forest characterization of the home range of each radio-collared animal. This study is conducted on the Ampasindava peninsula, a priority area for Malagasy conservation.

PROVISIONING ECOSYSTEM SERVICES IN DARJEELING HIMALAYA: FUELWOOD, FORESTS, AND PEOPLE

Alexa R. Wilson

University of Massachusetts Boston

Kamal BAWA, University of Massachusetts Boston

Patterns of energy use at the household level have important implications for many aspects of economic development and landscape sustainability. In mid-montane forest regions of Darjeeling District, Eastern Himalaya, the majority of households rely on fuelwood extracted from natural forests to meet energy needs for cooking, heating, and supporting livelihoods. Fuelwood extraction has been identified as a significant driver of change in forest structure and composition and even deforestation in many developing countries. However, little is known about the impact of fuelwood extraction on forests in this region. To elucidate this impact, we conducted informal household interviews in five buffer

villages of Singalila National Park and three buffer villages in Senchal Wildlife Sanctuary to identify fuelwood extraction sites and to establish permanent monitoring plots. Three fuelwood extraction sites were selected for each village. For each extraction site, we sampled three 10 x 10 m quadrats. The parameters measured included basal area, number of cut stems, species richness, and species abundance. We measured the same parameters in control quadrats with no fuelwood extraction. The GPS coordinates of each quadrat were recorded for future re-sampling. Results indicate differences in species occurrences and differences in understory species abundance and diversity between extraction and control sites. The data generated from this ongoing research will fill the knowledge gap necessary to develop sustainable local and regional forest management strategies and is a critical component in understanding the linkages between rural energy use patterns, people, and the environment.

COMMUNICATING SCIENCE IN ADVOCACY: AN EXERCISE IN SOCIAL AWARENESS

Amber Wilson

Wyoming Outdoor Council

The environmental problems we face are urgent, complex and involve a multitude of stakeholders from many social and economic backgrounds, experiences, and expertise. Solving these problems ultimately requires diverse groups to work together. Successful collaboration requires empathy and commitment to set aside emotion and seek common goals even when they seem unlikely. Controversy surrounds the field of environmental advocacy and those of different or conflicting values and beliefs are often demonized. Environmental advocates may intentionally or unintentionally present an argument that implies poor moral or ethical standing on the part of a person/group rather than acknowledging and crediting the difference in perspectives. When this happens, the opportunity for collaboration is broken. Presentation of scientific findings in a "truth to power" format may come from altruistic intentions, but ultimately it damages the advocate's credibility with those they hope to persuade. The intended audience becomes disinclined to engage in productive collaboration when they have been accused of poor character, while they in truth and self-perception are generally of good intent. The modern environmental advocate must understand the technical science behind issues and communicate the findings in relatable terms, but most critically, they must also practice an empathy, understanding, and patience in their advocacy despite the urgent and often emotionally-charged nature of environmental issues and conflicts. Virtuosity manifests in different forms as people act in ways they believe to be virtuous in their own world-views. Advocates should base their messaging and strategy on the assumption and

acknowledgement that humankind generally strives to be virtuous. I will outline a model for bridging the science/manager/stakeholder gap through an advocacy framework that presents scientific findings on a level playing field. I will discuss examples of the model's successful implementation.

A NEW THREAT TO PENNSYLVANIA'S (USA) MOST DIVERSE STREAM: THE INVASION OF ROUND GOBIES INTO A NEW WATERSHED

Casey Wilson

Allegheny College

Jay STAUFFER, Penn State University

Round gobies, *Neogobius melanostomus*, were discovered in North America's Great Lakes in 1990 and since that time have become among the most abundant benthic fish in all five Great Lakes. In August 2014, round gobies were discovered in French Creek, which is a separate watershed from Lake Erie. This stream holds the greatest species diversity of both fishes and freshwater mussels in the state of Pennsylvania, many of which are listed as threatened or endangered. The purpose of this study was to compare diet overlap between round gobies and darters (Family Percidae). A secondary objective was looking at diet overlap between darter species in the absence of round gobies. Two streams were selected, the first being a tributary to Lake Erie (Elk Creek), where gobies are abundant, and the second in headwaters of the Ohio River drainage, where gobies have recently been discovered (French Creek). Results show that in Elk Creek, round gobies directly compete with native rainbow darters (*Etheostoma caeruleum*) and cause a dietary shift. Current studies in French Creek will continue assessing diet overlap and also habitat partitioning between round gobies and native darters in the specific stretches of French Creek where round gobies have been discovered. Information on the introduction of round gobies to lotic systems with high species richness is lacking, therefore these studies will give better a better understanding of the impacts of gobies in such systems. Nowhere else in the Northeastern United States remains as ecologically intact as French Creek. This stream has been deemed "one of America's last great places" because of its high diversity and relatively unaltered watershed. The implications of this new invasive species on the biological integrity of French Creek is currently unknown, but round gobies in stream systems have been known to dominate resources and severely impact native benthic fish populations.

CENTRAL AMAZON VÁRZEA FLOODPLAIN HYDRODYNAMICS: SEASONAL AND INTERANNUAL HYDROLOGICAL VARIABILITY

Matthew Wilson

University of the West Indies

Maria VEGA, University of the West Indies ; Bruce FORSBERG, Instituto Nacional de Pesquisas da Amazônia

Surface water flow is recognised as the key factor in the establishment and maintenance of wetland ecosystems as it helps to determine the spatial and temporal complexity of wetland habitats. However, the hydrodynamics of seasonally flooded wetlands in the Amazon basin remains poorly quantified through ground observations, satellite observations or modelling. In this research, a detailed hydrodynamic model was developed for ~850 km² of várzea floodplain at the confluence of the Solimões and Purus rivers and used to characterise the seasonal and interannual hydrological variability in the wetland system. The model was constructed using in-situ and satellite data as the main boundary conditions and validated against floodplain flow measurements collected across the area during an intensive fieldwork campaign from mid-rising, through high-water to mid-falling flood conditions. Acoustic Doppler Current Profiler (ADCP) measurements were obtained of flow rates along floodplain channels, runoff from terra firme via measurement of flows out of ria lakes, and main channel discharge. Results indicate that floodplain channels play a fundamental role in floodplain hydrodynamics, carrying the bulk of flood water into the floodplain during rising water. Once main-channel water levels are above-bankfull, overbank flow directly into the floodplain forest becomes significant. Terra firme runoff contributes a relatively small amount of flow. The hydrodynamic model was able to represent well the broad hydrodynamics through the várzea system, particularly along floodplain channels; diffusive overland flow was less well represented due to errors in topographic data caused by floodplain vegetation. The model has allowed a detailed picture of floodplain hydrodynamics to be constructed which will help to improve understanding of the hydrology of wetland ecosystems and its importance for their conservation.

GLACIAL RETREAT AND THE ROLE OF LATE PLEISTOCENE AND EARLY HOLOCENE EVENTS IN THE ORIGIN OF CONSERVATION UNITS: IMPLICATIONS FOR WOODLAND CARIBOU IN CANADA

Paul Wilson

Trent University

Cornelya KLUTSCH, Trent University ; Micheline MANSEAU, Parks Canada

Criteria for establishing Designatable Units (DUs) under the Committee on the Status of Endangered Wildlife in Canada (COSEWIC) require a threshold of "distinct" and "significant". Accurate delineation of conservation units is critical given the assessment criteria for status and the reliance on population sizes and trends defined by where these boundaries are defined. Establishing DUs for caribou in Canada is particularly

challenging given the diversity of morphology, behaviour, and the ecozones in which they inhabit. Significant attention has been given to glacial refugia as reservoirs contributing to the phylogenetic differentiation of conservation units, and evidence of admixture is often interpreted on a contemporary scale for many species, including caribou. We applied microsatellite and mitochondrial DNA markers from 1500 caribou from central Canada where admixture from northern Beringian evolved caribou with caribou lineages derived south of the Pleistocene glacial maxima was evident. Approximate Bayesian Computation (ABC) supports early introgression of Beringian derived DNA into southern evolved lineages consistent with the retreat of glaciers in central Canada, with subsequent evolution of two related contemporary ecotypes from the introgressed lineage: sedentary boreal and migratory tundra caribou. Dates of the divergence of the two ecotypes occurred within the Holocene several thousand years ago at the time of land modifications in the Hudson Bay Lowlands ecosystem. Our findings further show that delineation of current boreal caribou ecotypes is warranted given distinct phylogenetic histories with differential levels of introgressive hybridization. The role of differential lineage admixture in the formation of ecotypes is not limited to central Canada and may have contributed to a higher number of distinct and significant lineages in western and northern Canada that are not currently considered as separate DUs under COSEWIC.

156: CAMERA-TRAPPING VS. IDNA FOR WILDLIFE SURVEYS; COSTS, EFFICIENCY AND RELIABILITY

Andreas Wilting

Leibniz Institute for Zoo and Wildlife Research

Andrew R. TILKER, Leibniz Institute for Zoo and Wildlife

Research ; Azlan MOHAMED, Leibniz Institute for Zoo and

Wildlife Research ; Jürgen NIEDBALLA, Leibniz Institute for

Zoo and Wildlife Research ; Marie-Louise KAMPMANN, Leibniz

Institute for Zoo and Wildlife Research ; Stine RICHTER, Leibniz

Institute for Zoo and Wildlife Research ; Rahel SOLLMANN,

North Carolina State University

Camera-trapping is a very popular method to study wildlife, as camera-traps work independently of the observer, and thus can accumulate survey effort over extended areas and periods of time with comparatively little effort. Camera-traps are further known to record even the most elusive mammals. However, particularly reliable camera-traps are costly, and as camera-traps represent a highly directional and point-based sampling method, even species in the immediate vicinity of the trap will be missed if they do not pass through the camera's sensor field. Recently, a new non-invasive method to study wildlife populations has emerged; the use of invertebrate-derived DNA (iDNA) of vertebrate host species. Invertebrate parasites such as leeches, mosquitos or ticks are generally abundant and easily

collected without costly equipment or extensive training, and joint screening of multiple individuals limits lab costs. Although this method is still largely unexplored, first results indicated that it could become a powerful tool to study a wide range of wildlife species. Here, we present first iDNA sequencing results of terrestrial leeches from the Central Annamites in Vietnam. We analyzed leeches both individually and in pools up to almost thirty individuals, and compare the results in terms of costs, efficacy and reliability to detect target species. Further we compare our molecular data with camera-trap datasets from an adjacent area in Vietnam and we discuss costs, breadth of the target community sampled, and taxonomic resolution of the approaches.

NATURE IN YOUR BACKYARD - CITIZEN SCIENCE IN GARDENS

Silvia Winter

University of Natural Resources and Life Sciences Vienna
Julia KELEMEN-FINAN, Technical office Julia Kelemen-Finan ; Kristina PLENK, University of Natural Resources and Life Sciences Vienna ; Bärbel PACHINGER, University of Natural Resources and Life Sciences Vienna

Gardens and parks represent important refugia in intensive agricultural landscapes for many formerly common species. Citizens can easily observe wildlife in their gardens or backyards in rural and urban areas, while researchers may not get access to these sites. Such wildlife observations could be entered to a single database providing a unique large-scale spatial dataset. Our project "Nature in your backyard – citizen science for schools" joins scientists, NGOs and governmental sections with 16 schools from Lower Austria and Vienna. We aim at linking the presence and relative abundance of hedgehogs, wild bees (in nesting aids), 12 bird and 8 readily identifiable butterfly species to garden structure and management as well as to the surrounding land use. Pupils use online or printed survey forms to gather information on garden size, type, management and structures as well as wildlife observations. Each school will collect data on the chosen species groups in at least 4-5 gardens per school. Identification guides, experimental protocols and hands-on training at the respective garden sites are provided by the scientists and NGOs. In addition, we expanded this science education partnership to a broader citizen science project where we want to involve all gardeners or people attached to gardens to report the presence of hedgehogs in their gardens across Austria. Analogous to the science education partnership, gardeners should report sightings of hedgehogs or footprints by using hedgehog tracking tunnels. Hedgehog citizen scientists will complete an online form on garden management and report presence or absence data of hedgehogs in their gardens in combination with scans or photographs of hedgehog footprints. The wider range and higher number of observations

will lead to better estimations of hedgehog presence in relation to garden structures and management.

163: THE FUTURE OF MARINE ECOSYSTEM SERVICES IN KIMBE BAY, PAPUA NEW GUINEA: IMPLICATIONS FOR LOCALLY MANAGED MARINE AREAS

Russell Wise

CSIRO

James BUTLER, CSIRO ; Tim SKEWES, CSIRO ; Erin BOHENSKY, CSIRO ; Nate PETERSON, The Nature Conservancy

The need to realise the co-benefits of biodiversity conservation, sustainable fisheries, climate adaptation and food security from near-shore marine ecosystems is well-documented. This provides the rationale for the Coral Triangle Initiative and more specifically Locally Managed Marine Areas (LMMAs) in the Indo-Pacific region. LMMAs are delineated near-shore marine areas where rules (e.g. no-take zones and harvest restrictions) are applied with clear ownership and management by local communities, and in many cases have achieved these co-benefits in cost-effective and culturally-sensitive ways. The LMMA network in Kimbe Bay of PNG was informed by principles of successful community-based natural resource management (CBNRM) and is cited as an exemplar of CBNRM and ecosystem-based adaptation. However, during a multi-stakeholder scenario-planning process held in 2013, concerns were raised about the long-term ability of these LMMAs to achieve these co-benefits, given 'business as usual' projections of population growth, economic development and climate change. We sought to assess the effectiveness and sustainability of this LMMA network, given their current characteristics and governance. Two lines of investigation were adopted. First, the social-ecological context of Kimbe Bay was assessed using data from the scenario-planning process and consultations with four communities with established LMMAs. This assessment considered the beneficiaries, the relative contributions to livelihoods, the threats, the trends in condition, the costs of monitoring and enforcement, and the present and future values, of the biodiversity and ecosystem services derived from the LMMAs. Second, the characteristics of the LMMA network were compared with principles for successful CBNRM. These analyses revealed many recommendations for improving the design, governance and management of the LMMAs. These will be presented and discussed.

188-THERMAL BARRIERS TO HABITAT CONNECTIVITY OF JUVENILE STEELHEAD TROUT

Robert Wissmar

School of Aquatic and Fishery Sciences, University of Washington

Ranae HOLLAND, School of Aquatic and Fishery Sciences, University of Washington ; Raymond Timm, Cramer Fish Sciences ; Christopher FRISSELL, University of Montana, Flathead Biological Research Station

Distributions of native salmonid fish in the Pacific Northwest are strongly tied to temperature conditions in their habitats. Conservation concerns arise owing to declining salmonid stocks in conjunction with warming aquatic conditions that can fragment and functionally disconnect cold-water habitats. A significant case in point is the influence of increased summer water temperatures on distributions of juvenile steelhead trout (*Oncorhynchus mykiss irideus*) in the South Umpqua River, Oregon. The Umpqua River is a major steelhead producing ecosystem on the Pacific coast of North America. The Umpqua ecosystem contains tributary streams with different elevation gradients, hydrologic and thermal regimes that provide diverse freshwater rearing habitats for juvenile steelhead and other salmonids. However, variations in summer temperature regimes can present barriers to distributions by life history type. In South Umpqua tributaries, extremes in thermal conditions influence distributions of different steelhead life history stages. A conservation paradigm is explored that uses criteria informed by available knowledge about fish distribution, habitat conditions, biological requirements and annual 7-Day maximum summer temperature regimes. This approach attempts to address direct and indirect effects of temperature, the role of unoccupied habitat and the relevance of scale. Because distributions of life history stages commonly extend beyond the boundaries of their existing or suitable habitat, the conservation paradigm points to natural temperature regimes being preserved whenever possible.

ENGAGING BUSINESS INTO BIODIVERSITY CONSERVATION: THE CASE STUDY OF THE FRENCH SNB VOLUNTARY INSTRUMENT

Anastasia Wolff

AgroParisTech, F-75005

Christian BRODHAG, UMR CNRS 5600 EVS, Ecole des Mines de Saint-Etienne ; Natacha GONDRAN, UMR CNRS 5600 EVS, Ecole des Mines de Saint-Etienne

Although they are subject to multiple environmental regulations, businesses have significant impacts on biodiversity through their operations and products. In response to the call of the Convention on Biological Diversity (CBD) to broaden actors' engagement into biodiversity conservation, notably regarding business, the French government has designed an original instrument that is part of its national biodiversity strategy (Stratégie nationale pour la biodiversité, SNB). This instrument aims at engaging organizations on a voluntary basis in two steps: adherence to SNB principles, concretized afterward by a peer-reviewed commitment plan. We first draw

on the concepts of corporate social responsibility (CSR) to analyze the motivations and effective outcomes for businesses that made SNB-reviewed commitments. Then, an evaluation of the contribution of these commitments to the SNB and CBD objectives is proposed. This case study combines data collected from business commitment plans, administrative documents and in-depth semi-structured interviews with managers in charge of the SNB commitments of their companies. Initial business motivations were mainly contractualist-oriented, eg. improvement of stakeholders' relations and gain of market share. In contrast, the main effective outcomes of this process for businesses are primarily institutionalist: strengthening of the internal consistency of corporate biodiversity plans, gain of internal legitimacy and better regulatory compliance (resulting from voluntary actions). If the marginal impact of this instrument seems undermined by the weak number of present actors and sectors, some commitments tackle issues not covered by regulation. Commitment plans present more procedural than substantive actions and seem to contribute heterogeneously to the SNB and CBD objectives. This is notably related to their relevance for the different business sectors relatively to their maturity, specific impacts and value creation opportunities.

„QUICK & DIRTY“ - A STANDARDIZED PROTOCOL FOR RAPID ASSESSMENT OF BAT ACTIVITY IN AGROFORESTRY SYSTEMS WITH CONSERVATION PURPOSE

Sebastian Wolfrum

Technische Universität München

Anna ZVORYKINA, Technische Universität München ; Hannah GÖBEL, Technische Universität München ; Lucie CHMELÍKOVÁ, Technische Universität München ; Julia HUBER, Technische Universität München ; Harald SCHMID, Technische Universität München ; Kurt-Jürgen HÜLSBERGEN, Technische Universität München

Increasing land use competition is a great challenge. Agroforestry (AF) is said to benefit many species and thus could satisfy both agricultural and conservation demands. Nevertheless bats, which are highly relevant as bioindicators and for conservation, are rarely assessed. This may be due their nocturnal activity and the large effort and knowledge required. Therefore, a method for rapid assessment of bat activity was developed to evaluate whether and how bats use agroforestry systems e.g. for commuting or foraging. Bat activity was analyzed at Scheyern research station located in the Bavarian tertiary hills in southern Germany. Agroforestry systems were established in 2009 on two organically managed fields with seven crops in rotation and two integrated managed fields with four crops in rotation. Each short-rotation coppice system comprises of three 8.25 m wide tree strips, where each

strip consists of three double rows of different trees. The first harvest was in February 2013. We used simple heterodyne detectors and a standardized protocol to record bat activity on presence/absence basis within 15 second intervals for a total of 20 minutes per plot. On 10 dates during summer 2013 and 16 dates during 2014 activity was recorded after sunset in eight randomly ordered plots. Four habitat types (AF-organic, AF-integrated, grass strip and hedgerow) were sampled with two plots each. To validate the simplified method bat calls were also recorded and analyzed in more detail using an automatic bat detector system. The simple method is much faster and cheaper than the advanced technique. However, results are similar and can thus be used for a rapid and cost efficient assessment and monitoring of bat activity. Furthermore, results suggest that agroforestry can be recommended as conservation measure to improve arable habitats for bats.

THE IMPLICATIONS OF CONSERVATION POLICIES ON MAMMAL DIVERSITY AND MOVEMENT WITHIN A COSTA RICAN BIOLOGICAL CORRIDOR

Margot Wood

Texas A&M university

Current government payments for ecosystem service (PES) policies, in place in Costa Rica since 1997, strive to protect water, biodiversity, scenic beauty and carbon. PES landholder participants that live in the SINAC (Sistema Nacional de Areas de Conservacion) designated biological corridors are given funding priority because their lands are considered essential for connecting segregated wildlife populations held within the National Parks. Eligible PES land uses include agroforestry, regeneration through tree plantation and primary forest protection. The corridor network intends to aid in conservation and ecological functioning of the existing protected areas. The purpose of the study is to assess the ecological function of the Paso de Las Nubes biological corridor. We use populations of medium and large mammals as study organisms and indicators of ecological health and movement capability. Our research objectives are to determine if (a) spatial conservation targeting increases vegetation in the Paso de las Nubes Biological Corridor and (b) if this targeting creates or maintains mammalian dispersal corridors between the two neighboring protected regions. Lastly, how (c) alterations to the PES funding, land targeting and biological corridor policies impact ecological dispersal processes. We collected species presence and absence data throughout the biological corridor using camera traps and hair traps. We collated that data with interview data to gain species lists for each PES property. We also collected vegetation data throughout the biological corridor. We will detail the diversity held in corridor and buffer regions of the parks. We will also describe the land use changes within the biological corridor occurring since the creation of

the policy, and how these changes vary from areas outside of the official conservation corridor.

21 EVALUATING THE IMPACTS OF CONSERVATION ON HUMAN WELLBEING: A CASE STUDY ON THE NORTHERN TANZANIA RANGELANDS

Emily Woodhouse

Wildlife Conservation Society / University College London
Katherine HOMEWOOD, University College London ; J. Terrence MCCABE, University of Colorado ; E.j. MILNER-GULLAND, Imperial College London ; David WILKIE, Wildlife Conservation Society

The research demonstrates the application of a human wellbeing framework in understanding multi-dimensional impacts of conservation interventions on local people, and more broadly in considering aspects of justice. The Simanjiro plains, east of Tarangire National Park, are a key dispersal area for large mammals, and are of vital importance to Maasai livelihoods. Pastoralist livelihoods are, however, rapidly diversifying, resulting in changing needs and priorities. The recent history of the region is characterised by conservation conflict, and state control over land and wildlife revenues continues to be strengthened despite rhetoric about community-based conservation. In the broader context of these policy and landscape changes, we evaluated the impact of a payment for ecosystem services (PES) intervention which aims to prevent agriculture on the plains. A locally driven conceptualisation of wellbeing, grounded in qualitative discussions, gave priority to local knowledge and socio-cultural values. Rather than analysing average impacts, we disaggregated data by gender, age and village to understand differences in needs and aspirations, and the distribution of impacts across groups. Improving security was an overarching priority, shaping ideas and experiences of wellbeing, and was grounded in a history of land alienation, uncertainty, and a lack of control over decision-making. This suggests that interventions focused on providing land security at a community level, and attentive to procedure and trust-building will be vital in sustainable ecosystem management and human development efforts. Finally, we reflect on the justice implications of the research, both locally and globally, in terms of the resolution of trade-offs in dimensions of wellbeing between interest groups.

118 APPLYING A LOCALLY DRIVEN, 3D CONCEPT OF HUMAN WELLBEING IN CONSERVATION

Emily Woodhouse

Wildlife Conservation Society / University College London
Katherine M HOMEWOOD, University College London ; Emilie BEAUCHAMP, Imperial College London ; Tom CLEMENTS, Wildlife Conservation Society ; J. Terrence MCCABE, University

of Colorado ; David WILKIE, Wildlife Conservation Society ; E.j MILNER-GULLAND, Imperial College London

Understanding the social impacts of conservation interventions is vitally important to ensure conservation is at the very least not harming people, and instead aiming to support human development. These impacts are commonly measured through externally defined asset and monetary based poverty measures. We highlight how the concept of human wellbeing stands apart from standard poverty and welfare indicators to take into account the multiple dimensions of people's lives that they have reason to value. The strength of the wellbeing concept lies in its breadth, but this has also tended to result in vague conceptualisations, and superficial engagement. We present a universal framework for wellbeing, which can be adapted to locally meaningful formulations, allowing local voices to be heard and putting at the centre those people most affected by policy and environmental change. This conceptualisation combines three dimensions – objective, subjective and relational – with the thematic categories of material assets, health, social relations, security and autonomy. Drawing upon case studies in Tanzania and Cambodia, we discuss how the concept can be applied to impact evaluations on the ground, and how conservationists can navigate trade-offs between quantitative and qualitative approaches to support causal and explanatory analysis. In considering the implications of a wellbeing approach for conservation policy, the research elucidates how the use of mainstream economic measures can distort decision-making in ways that constrains sustainable development outcomes.

ENVIRONMENTAL AND SPATIAL VARIABLES INFLUENCING THE CATCH OF SMOOTH HAMMERHEAD SHARKS (SPHYRNA ZYGAENA) WITHIN THE SHARK MESHING PROGRAM OFF THE COAST OF NEW SOUTH WALES, AUSTRALIA.

Alexander Wray-Barnes

University of Newcastle
David POWTER, University of Newcastle ; Natalie MOLTSCHANIWSKYJ, University of Newcastle ; Victor PEDDEMORS, New South Wales Department of Primary Industries

Understanding the factors influencing the distribution of a vulnerable species is critical for adaptive management. This is especially necessary for data deficient species which experience potential human induced population pressures such as harvest and climate change. This study assesses the role of environmental conditions on distribution and catch of the vulnerable smooth hammerhead shark (*Sphyrna zygaena*). A long-term catch dataset from the Shark Meshing Program in New South Wales beaches, Australia, was overlaid with SST, rainfall (sea surface salinity proxy) and Chlorophyll data

obtained from satellite data extracted for net positions. A total of 1,423 *S. zygaena* were caught over the 24 year study period. Sharks ranged in size from 30-400 cm total length (TL); though 96.4% were immature (< 210 cm TL). Almost 50% of the catch of *S. zygaena* were from eight nets close to estuary mouths, indicating possible nurseries. Generalised Linear Modelling of catch occurrence against environmental parameters show catch greatest during periods of low rainfall, from nets above sandy substrates, and the period before, during and after new moon. Models suggest that increase in SST may explain the temporal decrease in catch, however, population declines may also play a role. Preliminary results indicate that Chlorophyll a may increase catch occurrence. This research highlights the importance of specific estuaries as nurseries and thus identifying possible locations for protected areas. This also highlights that remotely sensed information alongside long-term catch data can be used to further understand the distribution and environmental preferences of data deficient marine species.

118-THE EQUITY LANDSCAPE

Becky Wright

University of California Santa Barbara
Benjamin HALPERN, Imperial College London, Silwood Park Campus [INSTITUTE] National Center for Ecological Analysis and Synthesis [INSTITUTE] University of California Santa Barbara ; Matthew BURGESS, University of California Santa Barbara ; Carissa KLEIN, University of Queensland ; Steve GAINES, University of California Santa Barbara

Resource management typically requires limits on human use of natural resources to protect biodiversity and the services on which people rely. These actions often lead to differences in who pays the costs and who reaps the benefits, as well as tradeoffs among social, economic and ecological management objectives. Understanding the mechanisms and consequences of these equity concerns remains a core question for the design and evaluation of conservation actions. Here we present a new framework for how to think about equity through the lens of getting things done. First we identify different types of equity as being inputs, such as who gets to participate in management decisions, and/or as outputs, such as who gets the benefits of the conservation intervention. We define "the equity landscape" as how a given community the distribution of resources, costs, and benefits. The equity landscape then determines the equity inputs and outputs of a conservation intervention. There are hypothetical scenarios where the equity landscape favors a moderate, low or high degree of equity. Similarly, management may place a moderate, low or high value on equity objectives. This framework allows us to compare and discuss the tradeoffs of where management sets target equity values, and how different contexts might determine equity's role in conservation success. We survey the

literature and apply this framework to different conservation outcomes. In some scenarios, fitting a conservation intervention equity inputs and outputs to the existing equity landscape will lead to the highest probability of success, whereas other scenarios might require deviating from the equity landscape and changing the equity inputs and outputs.

UNDERSTANDING THE MOTIVATIONS AND SATISFACTIONS OF VOLUNTEERS TO IMPROVE THE EFFECTIVENESS OF CITIZEN SCIENCE PROGRAMS.

Dale Wright

BirdLife South Africa

Les UNDERHILL, University of Cape Town ; Matt KEENE, Environmental Protection Agency ; Andrew KNIGHT, Imperial College London

Citizen science is increasingly recognised as a useful approach for conducting scientific research and public outreach, producing multiple benefits for nature conservation and the volunteers involved. Understanding the motivations, satisfactions and other aspects of volunteers' psychology is essential for conservation scientists wishing to mobilize this resource. By employing programme evaluation in combination with psychometric assessment one can begin to understand the complex relations which exist between citizen science programmes and their volunteers. Such empirical evaluations help promote evidence-based conservation practices. We tested a psychometric instrument for assessing the motivations, satisfactions, and advocacy role of volunteers with the Second Southern African Bird Atlas Project (SABAP2), including a logic model that articulated the theory of operation of SABAP2 with regard to its volunteers. Data were collected through stakeholder and volunteer surveys, and focus groups with the programme's management. Qualitative and quantitative data analysis included content analysis, statistical tests of internal consistency and factor analysis. An inventory, the Environmental Volunteer Functions Inventory (EVFI), was tested for assessing volunteer motivations in this and other volunteer-based research programmes. Robust scales were also developed for assessing volunteer satisfaction and level of ambassadorship. These scales revealed that volunteers in SABAP2 are satisfied with the program and exhibit behaviours suggesting they act as advocates for the program. A platform for adaptive management of the SABAP2 program and further evaluations of this, and similar programs, represents a major outcome of this research. The components of an effective citizen science programme are also described.

THE IMPORTANT BIRD AND BIODIVERSITY AREAS PROGRAM IN THE WESTERN CAPE PROVINCE, SOUTH AFRICA: TRANSLATING KNOWLEDGE INTO ACTION ACROSS THE REGIONAL NETWORK.

Dale Wright

BirdLife South Africa

As the country partner to BirdLife International, BirdLife South Africa is tasked with managing South Africa's Important Bird and Biodiversity Areas (IBAs). The regional IBA work in the Western Cape Province was initiated in January 2012, with the objective to assess, monitor and conserve this network of twenty-four IBAs in the Western Cape. The initial step in this process has been to conduct comprehensive IBA Assessments for all sites, describing the status of threats, species and habitat, and conservation action at each IBA. Upon completion of the assessments these data are analysed through a rigorous prioritization exercise in order to rank IBAs for conservation intervention. The prioritization sums the threat score obtained from assessments, with an IBA species score based on the number and conservation status of the IBA trigger bird species present at the site, to determine the priority ranking of each IBA. A decision tree analysis is applied to the combined score to determine the most appropriate course of action and guide implementation at each site and across the entire network. The decision tree examines factors such as the current protection status, protected area expansion priorities, existing conservation action and opportunities for intervention. It is essential that such prioritizations are applied in conservation in order to direct limited resources to the most critical sites. The regional programme is applying a multi-faceted, evidence-based approach to conserving the network of IBAs. Tools being employed include private landowner-driven biodiversity stewardship at key sites; habitat rehabilitation at farms across the landscape; fundraising for socio-economic development projects; initiating academic research projects targeting knowledge gaps; developing Local Conservation Groups for IBA monitoring and grass roots implementation; conducting outreach and raising awareness through various platforms.

REFRAMING THE CONCEPT OF 'ALTERNATIVE LIVELIHOODS'

Juliet Helen Wright

Imperial College London[INSTITUTE]ZSL Institute of Zoology
Nicholas A. O. HILL, Zoological Society of London[INSTITUTE] University of Cambridge ; J. Marcus ROWCLIFFE, ZSL Institute of Zoology ; Noëlle F. KÜMPEL, Zoological Society of London ; Dilys ROE, International Institute for Environment and Development ; Francesca BOOKER, International Institute for Environment and Development[INSTITUTE]Center for International Forestry Research ; Mike DAY, International Institute for Environment

and Development[INSTITUTE]Center for International Forestry Research ; E. J. MILNER-GULLAND, Imperial College London

In developing countries, conservation programmes that aim to reduce local exploitation of natural resources frequently include livelihood-focused interventions. "Alternative livelihood projects" are one such intervention, aiming to reduce the prevalence of activities deemed to be environmentally damaging by substituting these activities with another activity which provides at least equivalent benefits. Alternative livelihood projects are very widely implemented, but the inherent assumptions fail to recognise the complexities of poor rural people's livelihood strategies. In response to a 2012 IUCN resolution calling for a critical review of alternative livelihood projects, we here consider what is meant by the term 'alternative livelihoods' and examine the associated assumptions. We present a typology of three broad categories of intervention - alternatives, compensation and incentives - and take a sustainable livelihoods perspective to conceptualise how alternative livelihood projects fit alongside other livelihood-focused interventions. Sustainable livelihoods approaches have been used in development to consider the multiple factors that influence people's livelihoods, and highlight the range of activities a household engages in as part of a dynamic livelihood strategy aimed at achieving both tangible and intangible goals. Given the diversified nature of livelihood strategies, it cannot be assumed that the benefits from an alternative will substitute, rather than supplement, the benefits that can be gained from exploiting natural resources. Interventions based on flawed or simplistic assumptions about people's needs, aspirations and the factors that influence livelihood choices are unlikely to achieve conservation objectives. It may be more appropriate to target interventions at those most vulnerable to resource access restrictions and to enhance or diversify their livelihood strategies making them more resilient to change.

218 STATE OF THE EU CONSERVATION DIRECTIVES, SUCCESSES AND FAILURES - A PERSPECTIVE FROM EUROPE'S ENVIRONMENTAL NGOS

Friedrich Wulf

Friends of the Earth Europe

The Birds and Habitats directives (BHD) are the cornerstones of the EU's efforts to conserve its biodiversity. With over 27.000 sites covering 18.36% of the EU's land area and more than 250.000 km² at sea, the Natura 2000 network installed under the directives is one of the world's largest, most sophisticated and commended protected area networks. In its article 6, the Habitats directive contains a strong tool to defend the areas against impacts that might adversely affect their integrity. The network's sites have been selected to protect certain

habitat types and species which are either threatened or for which Europe has a global responsibility. Progress towards reaching a favorable conservation of these species and habitats is reported every six years and published in the state of Nature report. The results of the most recent report, which will be published this April, and the evidence gathered during the so-called "Fitness check" of the Nature directives the EU is undertaking this year, prove that the system works in principle, that it is beneficial for both society and economy, and that there is no alternative to these directives in order to preserve the EU's biodiversity and achieve its own 2020 Biodiversity targets. Failures and lags in progress are due to wrong policy decisions in other sectors – notably the recent CAP reform, but also in land use and energy policies – and a lack of implementation, and not due to wrong legislation. There is a clear need for a better understanding of biodiversity's importance, its benefits for people and the economy, for better policy decisions in other sectors, and better implementation of the directives, including through supplying the necessary funding.

INTER-GOVERNMENTAL, MULTI-DONOR, AND ACADEMIC COORDINATION TO IMPLEMENT A TRANSPARENT NATIONAL FOREST MONITORING SYSTEM IN BANGLADESH

Karl Wurster

US Agency for International Development

Mike ROBSON, Food and Agricultural Organization (FAO) ; Md. Yunus ALI, Bangladesh Forest Department ; Sasha GOTTLIEB, US Forest Service ; Matieu HENRY, Food and Agricultural Organization (FAO) ; Imran AHMED, Bangladesh Forest Department

Planning and implementation of sustainable forestry projects requires coordination between national and international actors to maximize the effectiveness of national and local actions and ensure their sustainability. In Bangladesh, the focus on short-term projects funded by donors and development organizations frequently limits long-term planning and commitment of government budgets. In early 2014, USAID, FAO, and the Bangladesh Forest Department (BFD) began co-designing two USAID-funded projects to develop and implement a sustainable national forest inventory and monitoring system as part of the Bangladesh REDD+ MRV. These complementary projects implemented by FAO and the US SilvaCarbon program integrate recent scientific advances, new technologies, the national context, different inter-governmental, multi-donor, and academic visions, and decades of experiences in monitoring forests worldwide to build national capacity and maximize the sustainability of the Bangladesh national forest monitoring system. Additionally, the BFD is setting up new technical units within the government

to which trained officers will be posted to use a combination of remote sensing and ground-based forest inventory for monitoring the status forest and ensure long-term financial support. By training Bangladeshi counterparts on the most relevant, cost-effective, and accurate methods for forest monitoring the BFD will be able to conduct future inventories independently. The complementary four-year projects were initiated in July 2014 with a three-day multi-stakeholder planning workshop attended by over 50 Bangladeshi stakeholders from the government, environmental NGOs, and academic institutions and facilitated by FAO, USAID, and SilvaCarbon experts. Since January 2015 over 100 Bangladeshi partners have been trained, the forest inventory methods have been developed and the first national forest cover map was created. The national forest inventory will be completed in early 2018.

CAMPAIGNING FOR BIODIVERSITY CONSERVATION IN BANGLADESH

Karl Wurster

United States for International Development
Sumaiya FIROZE, United States for International Development ; Wasif HASAN, United States for International Development ; Colin HOLMES, United States for International Development ; Troy BECKMAN, United States for International Development

For over two decades USAID has worked in Bangladesh to promote biodiversity conservation and sustainable economic development. Projects have made huge strides in developing and implementing community-government protected area management and has created alternative livelihoods for poor, resource dependent people. Unfortunately, many of these conservation successes are not known or understood by the general public, particularly the youth in Bangladesh. In order to tell the story of how USAID projects are balancing biodiversity, conservation, and climate change goals with sustainable economic development, a series of communication tools are being used. Starting in 2014, USAID/Bangladesh developed a communications and outreach campaign that is focused on biodiversity. The campaign created local, national, and globally reaching outreach materials and products to communicate the importance of conserving biodiversity. USAID activities include policy dialogues on biodiversity conservation with the host government officials; involving journalists in investigative biodiversity reporting; engaging youth to increase their understanding and participation in conservation; developed outreach materials about the importance of Bangladesh's fragile ecosystems, and the importance of protecting and conserving natural environments. This presentation highlights lessons learned from this campaign and is focused on successes, challenges, and mistakes; particularly when engaging young and old journalists during trainings, and students for a film competition.

73 - SEASCAPE GENETICS FOR THE DESIGN OF A MARINE RESERVE NETWORK FOR A LONG-DURATION PELAGIC LARVA

Amanda Xuereb

University of Toronto

Janelle CURTIS, Department of Fisheries and Oceans ; Isabelle CÔTÉ, Simon Fraser University ; Frédéric GUICHARD, McGill University ; Louis BERNATCHEZ, Université Laval ; Marie-Josée FORTIN, University of Toronto

Ocean circulation plays an important role in shaping patterns of spatial genetic structure in marine organisms, particularly those with a passively dispersing larval stage. We integrate biophysical oceanographic models and genomic data to investigate the influence of ocean currents on larval dispersal and gene flow in the giant California sea cucumber (*Parastichopus californicus*) in the north-eastern Pacific Ocean. Using a biophysical model of ocean circulation developed for the Pacific coast of Canada, we simulate larval dispersal trajectories using a Lagrangian particle-tracking model and use these trajectories to generate a connectivity matrix among 18 sampled sites, spanning the west coast of Canada. We then simulate changes in allele frequencies as a function of larval dispersal probabilities from each location based on the connectivity matrix. We compare our simulation of gene flow to an empirical genomic dataset of ~4,000 variable single nucleotide polymorphism (SNP) markers from 432 sampled sea cucumbers. Furthermore, we identify potential loci under selection to examine spatial patterns of adaptive variation. Our work shows the importance of using of ocean circulation models to explain patterns of neutral and adaptive genetic structure in marine systems characterized by a long-lived dispersive stage with a high potential for gene flow.

EFFECTS AND MECHANISMS OF PROTECTED AREAS ON NATURAL CAPITAL AND HUMAN WELL-BEING IN CAMBODIA

Wu Yang

Conservation International

Madeleine BOTTRILL, Conservation International ; Will TURNER, Conservation International ; Carlos CANO, Conservation International ; Max WRIGHT, Conservation International ; Marc STEININGER, Conservation International ; Annette OLSSON, Conservation International ; Tracy FARRELL, Conservation International

Despite extensive conservation efforts and policy interventions, over the past decades the Earth's natural capital has been experiencing unprecedented degradation and decline from local to regional and global scales, posing great threats to the sustainable provision of ecosystem services for human well-being. Recently, there has been a growing

recognition of the importance of understanding and managing the linkages between natural capital and human well-being. However, so far, there is very limited understanding of how policy intervention affects natural capital and then influence human well-being. Particularly, it is due to lack of quantitative indicators of natural capital and human well-being as well as systematical causal inference of underlying mechanisms. Moreover, although spatial autocorrelation is a well-known issue, previous impact evaluation research seldom takes it into consideration. Here through an international collaborative project, we assembled remotely sensed data, geographic information, and socioeconomic data to construct indicators of natural capital and human well-being in Cambodia, Southeast Asia. We then constructed spatially explicit causal inference models to test a number of hypothesized causal mechanisms of policy intervention on natural capital and human well-being. Our results identify multiple pathways through which protected areas affect natural capital and human well-being. Our results also confirm that spatial autocorrelation significantly affects model parameters and cannot be ignored. This study laid a theoretical and methodological foundation for future research and practice on understanding and managing natural capital for human well-being.

SYMPOSIUM (ID 108) DEMONSTRATING EFFECTIVE BIODIVERSITY CONSERVATION OUTCOMES WITH THE USE OF GEO-TECHNOLOGIES IN PARAGUAY AND THE AMERICAS

A. Alberto Yanosky
Guyra Paraguay

Satellite remote sensing has been crucial in Paraguay and from Paraguay to the region, to monitor biodiversity conservation outcomes. Monitoring through remote sensing has allowed decision makers in Paraguay to advance the conservation of biodiversity from identification of key sites for conservation, evaluate their human-induced land use changes and natural changes and provides co-benefits for local people and climate change adaptation and mitigation. Among the several aspects to measure advances in biodiversity conservation, some of them are related to land use changes. Monitoring Important Bird and Biodiversity Areas, and the methods and its application has been extended beyond the boundaries of Paraguay into the Americas (for important sites for waterfowls, for mangroves, for Amazonian sites, and particular sites of conservation investments). The monthly report for the Gran Chaco, the ecoregion with the highest rates of deforestation, have been linked to strong communicational campaigns which have permitted to put in place conservation actions. Selection of sites for key environmental services, methods of identification of sites by high value conservation forests and areas, impact of climate change in ecosystem services, are

among the many information outputs which were linked to implementation of activities to conserve biodiversity. This work done by a private conservation institute (Guyra Paraguay) has been done in close cooperation with sub-national, national and international public and private institutions. It is of an unprecedented type the way of advancing biodiversity conservation using GIS through satellite data collected, the ease of access to such data, and a model of policies that have promoted free and open data in the country. This is a prominent example of the increased dialogue between the remote sensing/data providing community and conservationists.

CLIMATE-SMART GRASSLANDS MANAGEMENT: ADAPTING TO CLIMATE VARIABILITY, REDUCING VULNERABILITY OF PRODUCERS, AND CONSERVING BIODIVERSITY IN URUGUAY

A. Alberto Yanosky
Guyra Paraguay
Holger KRAY, World Bank

Uruguay is known for its grass-fed beef production on a landscape with diverse grasses and gentle hills where trees or shrubs are only seen in rocky and hilly areas. The basis for its world famous beef-production economy can be traced to the early 1600s when 100 livestock heads were introduced to Uruguay's extensive grasslands and the national herd has since grown dramatically. In this rural landscape, a convergence of different animals and plants makes Uruguay a country of globally significant biodiversity with approximately 14 million hectares of savannah—the dominant landscape where livestock have adapted. Due to now hundreds of years of extensive and increasingly intensive livestock production, the rich biodiversity found in Uruguay is becoming more and more threatened. Over the past ten years, the country has experienced extreme floods and droughts, increasing both in intensity and frequency, when compared to historical records. Repeated and severe floods and droughts have had a strong negative impact on rural livelihoods and production levels. Uruguay has sought to develop strategies and mechanisms to responsibly capitalize on its natural resources in the pursuit of market opportunities presented by increasingly aware and demanding consumers. Uruguay has successfully demonstrated improvements in NRM and climate change adaptation practices for the most vulnerable production systems of Uruguay. Uruguayan family farmers adopted economically, climate-smart and environmentally sustainable practices. These interventions have integrated soil, water, and biodiversity management through implementation of 5,300 on-farm sub-projects covering over 880,000 hectares of agricultural landscapes throughout the country (5% of Uruguay's productive area). Natural grasslands management and biodiversity mainstreaming have proven to be crucial for

reducing vulnerability and promoting adaptation strategies under a “responsible and biodiversity-friendly producer.”

SPATIAL DISTRIBUTION OF PARROTFISHES ON CORAL COMMUNITIES IN THE GULF OF THAILAND AND THE ANDAMAN SEA

Thamasak Yeemin

Marine Biodiversity Research Group, Faculty of Science, Ramkhamhaeng University
Pitakphong SUANTHA, Marine Biodiversity Research Group, Faculty of Science, Ramkhamhaeng University ; Watchara SAMSUVAN, Marine Biodiversity Research Group, Faculty of Science, Ramkhamhaeng University ; Kanwara SANGMANEE, Marine Biodiversity Research Group, Faculty of Science, Ramkhamhaeng University ; Juthamart PUTTHAYAKOOL, Marine Biodiversity Research Group, Faculty of Science, Ramkhamhaeng University ; Montaphat THUMMASARN, Marine Biodiversity Research Group, Faculty of Science, Ramkhamhaeng University ; Makamas SUTTHACHEEP, Marine Biodiversity Research Group, Faculty of Science, Ramkhamhaeng University ; Wichin SUEBPALA, Marine Biodiversity Research Group, Faculty of Science, Ramkhamhaeng University

Scleractinian corals are recognized as ecosystem engineers in tropical coral reef ecosystem, providing a structural complex habitat which harbors the highest biodiversity in marine ecosystem. Parrotfishes are an important group on coral reefs because of their roles on grazing and bioerosion. They can feed on macroalgae which are the most important space competitors of scleractinian corals. Some parrotfish species have been reported to feed directly on living corals. Overfishing causes significant decline of parrotfish on many coral reefs worldwide. Degradation of coral reefs, caused by coral bleaching events has been showed to affect reef fish communities. In the present study, we examined spatial distribution and abundance of parrotfish on coral communities in the Gulf of Thailand and the Andaman Sea following the severe coral bleaching event in 2010. Parrotfishes were quantitatively observed using a visual census technique in belt transects, 50 m x 5 m for each at nineteen study sites. The dominant parrotfishes were *Chlorurus capistratoides*, *C. sordidus*, *C. strongylocephalus*, *Scarus ghobban*, *S. niger*, *S. prasiognathos*, *S. quoyi*, *S. rivulatus*, *S. rubroviolaceus*, *S. scaber* and *S. tricolor*. The parrotfishes were more abundant at the study sites in the Andaman Sea, in a range of 68 – 121 individuals/250m². The densities of parrotfish in the Inner and Eastern Gulf of Thailand were very low. The present study provides important data on status of parrotfish abundance in Thai waters and highlights the importance of basic biology of parrotfishes for coral reef fisheries management.

ASSESSMENT OF THE STATUS OF FISHERIES RESOURCES WITHIN THE DAWASAMU DISTRICT QOLIQOLI IN FIJI.

David Yeeting

University of the South Pacific
Cara MILLER, University of the South Pacific ; Stacy JUPITER, Wildlife Conservation Society

Increasing population size and high levels of unemployment are some of the factors placing increased pressure on local fisheries resources in many Pacific Countries, including Fiji. In turn, important coastal ecosystems including coral reef ecosystems and near-shore habitats are coming under increasing demand to meet both subsistence needs and to supply urban markets. In response to this dilemma, strategies for sustainable management, community participation and engagement, and local livelihood support have been explored through such avenues as ecosystem-based management regimes and locally managed marine area designation. A key tool for effective implementation of such approaches however is a well-informed understanding of the marine resources within the given area of concern, identification of key habitats, an overview of current fishing practices (including relative effectiveness and specificity), as well as insight into the reliance and use of fisheries resources. This present study undertook a multi-pronged approach to assess marine resources within the Dawasamu District. In the first instance a thorough meta-analysis of all available data was undertaken to provide a baseline level of information as well as potential guidance for how to synergize the typically variable types of data that is available to review fisheries resources within local fishing grounds in Fijian waters. Secondly, a catch-per-unit effort survey undertaken, collected data on biomass, diversity, distribution and habitat of community catch. A second component of this data collection focuses on the effectiveness and specificity of different gear types and methods used. The third area of investigation of this study includes socioeconomic surveys of coastal villagers to assess the relative importance of fisheries resources within households in the Dawasamu District.

EFFECT OF FOREST PATCH ISOLATION AND FOREST PATCH SIZE ON NATURAL FOREST ARTHROPOD DIVERSITY WITHIN KWAZULU-NATAL TIMBER PRODUCTION AREAS

Inam Yekwayo

Stellenbosch University
James PRYKE, Stellenbosch University ; Francois ROETS, Stellenbosch University ; Michael SAMWAYS, Stellenbosch University

South African natural forests are highly fragmented naturally, surrounded by a matrix of grassland. Recent human

development has isolated these patches further and in some cases reduced them in size. Small patches are thought to be adverse for forest specialist species due to the decreased forest interior and increased edge habitat. Here we determine the impact of forest patch isolation and patch size on arthropod diversity. Forty sites were selected with ten in large (≥ 100 m) patches that are isolated (> 500 m) from other patches; ten large patches that are near (< 100 m) to other patches; ten small (≤ 50 m) patches that are isolated; and finally ten were selected that were small patches that are near other patches. Arthropods were sampled using pitfall traps, leaf litter sampling (Berlese funnels) and active searches. The only pairwise difference observed were small-isolated patches having significantly higher species richness and abundance compared to small-near patches. Assemblage composition between forest patches of different patch size revealed significant differences between all pairs. This study indicates that patch isolation does not affect arthropod diversity in large forest patches since there were no differences in species richness between large-isolated and large-near forest patches and also no differences were observed in assemblage composition between large-isolated and large-near patches. This suggests that the size of the patch is more important for natural forest arthropods than isolation. These forests have been naturally isolated for millennia and this has probably led to species evolving to this fragmented network of forest patches. In transformed landscapes this remain true, provided that the size of the natural forest patches remain large enough (and intact) to overcome anthropogenic pressures. Conserving large patches should be the conservation priority for indigenous forests in this landscape.

DEVELOPMENT AND VALIDATION OF THE TAIWAN CHILDREN'S ENVIRONMENTAL ACTION INDEX

Chiung-Fen Yen

Providence University, Taiwan

Chia-Ling CHIANG, National Dong Hwa University ; Li-Hua HOU, Providence University, Taiwan ; Tsung-Wei YAO, Providence University, Taiwan ; Chiu-Ju SU, Providence University, Taiwan ; Joel J. MINTZES, California State University

One of the principal objectives of environmental education is to encourage and support environmentally responsible behavior. In this study, we used Smith-Sebasto and Fortner's Environmental Action Internal Control Index as a framework to develop and validate a useful instrument for assessing environmental attitudes and behavior among elementary and middle school children in Taiwan. We dubbed a new instrument the Taiwan Children's Environmental Action Index (TCEAI) which addresses relevant and significant environmental issues in the Taiwanese context. This instrument was field tested and revised to insure that the instrument conformed to the reading level of test subjects. Subjects of the study were students attending elementary school, grades five ($n=65$) and

seven ($n=80$) and middle school, grade nine ($n=71$). Responses to the experimental instrument were factor analyzed that generating a principal component solution with Varimax rotation and Kaiser normalization. Our findings suggest that the TCEAI displays substantial internal consistency (Cronbach's $\alpha=.92$), moderately positive correlations with self-report measures of environmentally responsible behavior ($R = .35$ to $.46$, $p < .01$). No differences were found among students by gender or age. These findings suggest that the new instrument has substantially favorable psychometric characteristics and may be a valuable tool for use in elementary and middle school classrooms in Taiwan. Currently we are developing teaching modules that address each of the four factors identified in the rotated factor matrix. The module on conservation, for example, introduces students to the importance of habitats to the survival of plants and animals. In future work, we plan to develop revised versions of the instrument to accommodate aboriginal and tribal students in order to broaden its scope and applicability.

POTENTIAL OF RETENTION TREES IN PRESERVING LICHEN DIVERSITY IN MANAGED NORTHERN BOREAL FORESTS

Anna-Liisa Ylisirniö

University of Lapland

The role of retention trees in preserving diversity of old-growth forest lichens was studied in northern boreal spruce forests in NE Finland. Five study sites were established in each of the following categories: 1) 10-12 year old clear-cuts with few retention trees (old logging methods), 2) 7-8 year old clear-cuts with many retention trees (new logging methods), 3) old-growth forests. The occurrence of 14 old-growth forest indicator lichens was investigated from 30 deciduous trees and snags on each site. The species richness of indicator lichens was significantly higher on the old-growth forest sites than in the clear-cuts, regardless whether there were many retention trees or few ($t = 3.578$, $p = 0.013$). The number of lichen records was significantly higher on the old-growth sites compared to the clear-cuts with few retention trees ($t = 2.917$, $p = 0.035$), but the difference to the clear-cuts with many retention trees was not significant ($t = 2.222$, $p = 0.71$). The species found in clear-cuts (one *Leptogium* and two *Nephroma* species) were mainly growing on aspen (88% of the records), the rest were found on goat willow (9%) or birch (3%). On the old-growth sites the observed nine species were mostly growing on goat willow (51%) or birch (39%); only 10% occurred on aspen. All the *Chaenotheca* species which are old-growth forest indicator lichens growing on birch were lacking from clear-cuts, as were species *Lobaria pulmonaria* and *Arthonia incarnata*. The results indicate that the ability of retention trees to maintain lichen diversity is limited, especially for species which prefer closed

canopy and humid microclimate. The survival of lichen species on retention trees in the long run needs further studies, because increased desiccation and solar radiation in the clear-cuts may affect populations in delay.

SYMPOSIUM #151_CONTEXT DEPENDENT EFFECTS OF BIODIVERSITY LOSS ON DISEASE

Hillary Young

UC Santa Barbara

Large wildlife are being systematically lost across the world. These reductions lead to profound shifts in the ecology of entire communities and ecosystems, and often have major consequences for prevalence and transmission dynamics of many diseases. However, the effects of these large wildlife declines on disease likely hinges upon both underlying, and often changing, abiotic properties of these systems as well as on the types of secondary anthropogenic changes associated with wildlife loss, and the pathogens considered. This has made it difficult to predict impacts or guide management, and led to the suggestion that the relationship is idiosyncratic. Here we will present results from a regional study across East Africa, which seeks to understand how environmental and human context mediates the impact of large wildlife loss on disease. Our results find that environmental and human context is indeed critical in determining the impacts of large-wildlife decline on disease dynamics. While general relationships that ignore context may remain elusive, by incorporating context predictive power for biodiversity disease relationships can be greatly increased.

76-USING THE IUCN RED LIST INDEX TO EVALUATE THE IMPACT OF A CONSERVATION ORGANIZATION

Richard Young

Durrell Wildlife Conservation Trust

Carl JONES, Durrell Wildlife Conservation Trust ; Andrew TERRY, Durrell Wildlife Conservation Trust ; Vikash TATAYAH, Mauritian Wildlife Foundation ; Stu BUTCHART, BirdLife International

Global and project-level biodiversity indicators have received considerable attention, but indicators of the conservation actions and impacts of programmes and institutions appear to be under-developed. The IUCN Red List Index (RLI) has potential to be a useful indicator at an organisational-level to evaluate long-term impact of conservation on the extinction risk of species, thereby supporting institutional decision-making and communications. However, it has not yet been tested for its utility in tracking changes in extinction risk of a set of species targeted specifically by an individual conservation agency. In this talk, I examine the feasibility of using the RLI as one metric of the conservation impact of the Durrell Wildlife Conservation Trust, a conservation charity

which runs multi-decadal programmes on a modest number of globally threatened terrestrial vertebrate species. Of 17 target amphibian, bird and mammal species, eight underwent improvements in Red List category (reductions in extinction risk) owing to conservation. This drove a 67% increase in the value of the Red List Index between 1988 and 2012. This contrasts with a 23% decline in a counterfactual RLI showing projected trends if conservation had been withdrawn in 1988. For organisations that target sets of species with circumscribed geographic distributions and that are regularly assessed by the IUCN Red List, the RLI is a useful indicator for measuring and demonstrating long-term conservation impact to technical and non-technical audiences.

NONINVASIVE GENETIC TRACKING OF ASIATIC BLACK BEARS (URSUS THIBETANUS) AT ITS RANGE EDGE IN IRAN

Gholam Hosein Yusefi

CIBIO/InBio - Research Center for Biodiversity and Genetic Resources[INSTITUTE]Mohitban Society[INSTITUTE]Biology Education Center, Uppsala University

Leili KHALATBARI, CIBIO/InBio - Research Center for Biodiversity and Genetic Resources[INSTITUTE]Mohitban Society ; Vania COSTA, CIBIO/InBio - Research Center for Biodiversity and Genetic Resources ; Hadi FAHIMI, Mohitban Society ; Mohammad E SEHHATISABET, Department of Environment ; Albano Gonçalo BEJA PEREIRA, CIBIO/InBio - Research Center for Biodiversity and Genetic Resources

The Iranian population of the Asiatic black bear, *Ursus thibetanus*, is the westernmost peripheral population of the species as well as one of the most threatened one. In the remote mountainous areas of the southeast Iran this bear suffers from critically low population size, pronounced decline and isolation. Unlike other populations in Asia, little data exist on this peripheral population in general and, in particular, its genetic status still is uninvestigated. Here we report the first genetic analysis of the Iranian black bear using mitochondrial and microsatellite markers via noninvasive samples (feces). Further, phylogenetic relationships among Asiatic black bear populations using published sequences and sequences in this study were assessed. The results reveal the absence of mtDNA variability in the studied population, yet all samples from 5 geographically separated areas had the same, unique haplotype. Also low levels of nuclear genetic diversity were found among Iranian black bears ($HE = 0.57$ across 7 microsatellite loci in overall samples), with lower levels of microsatellite differentiation ($F_{st} = 0.07$) between black bears from the 2 source areas (northern vs. southern groups). The mitochondrial phylogeny from median-joining network, neighbor-joining tree and Bayesian phylogenetic analyses revealed that Iranian black bears are highly distinct from the

other populations from East Asia. Our findings suggest that Iranian black bears represent separate Evolutionary Significant Unit (ESU), and support their designation as a separate subspecies. Although preliminary, the results bring important new information on the genetic status of Iranian black bears and also provide a baseline for future monitoring of this endangered bear.

A NOVEL APPROACH FOR ASSESSING SHIFTING CULTIVATION DYNAMICS IN A REGIONAL CONSERVATION HOTSPOT - INSIGHTS FROM NORTH-EASTERN MADAGASCAR

Julie Gwendolin Zaehring

University of Bern

Sandra ECKERT, University of Bern ; Cornelia HETT, University of Bern [INSTITUTE] Ministry of Natural Resource and Environment (MoNRE) ; Bruno RAMAMONJISOA, Departement des Eaux et Forêts de l'Ecole Supérieure des Sciences Agronomiques (Université d'Antananarivo) ; Peter MESSERLI, University of Bern

The north-eastern escarpment of Madagascar has been deemed a global hotspot of biodiversity due to its high levels of endemic species being heavily threatened by accelerated deforestation rates and landscape changes. The main concern for conservation of the remaining humid primary forests is the shifting cultivation practices of local smallholder farmers for rice production. According to the mainstream narrative, human population growth leads to a shortening of crop-fallow cycles and thus to the accelerated conversion of forests to agricultural land. However, little is currently known about the dynamic changes between forest and shifting cultivation systems at the regional level. Existing land cover change analyses in this area have so far only focused on binary forest to non-forest changes and have therefore failed to account for the dynamic nature of the change processes between forest and different agriculture land use systems. This can be partly explained by the significant challenge to delineate shifting cultivation systems on land cover maps using traditional remote sensing classification approaches. To address this gap we therefore applied a novel GIS approach, that was originally developed for the assessment of shifting cultivation dynamics in Laos and has so far never been applied elsewhere, to map shifting cultivation of different crop-fallow lengths as well as permanent agriculture land use at the regional level. Change analyses of land use maps between 1995 and 2011 allowed us to comprehend the general trends of land use trajectories and their spatial variation. This more detailed understanding of land use change dynamics is key to plan for successful interventions to slow forest loss while at the same time improving local livelihoods. We further believe that this approach holds great potential for conservation monitoring in this resource-rich but poverty-prone conservation hotspot.

CONSERVATION IMPLICATIONS OF FLOODS, FOREST MANAGEMENT AND LAND USE FOR SAND LIZARD POPULATIONS

Anamarija Zagar

CIBIO Research Centre in Biodiversity and Genetic Resources, InBIO

Marijan GOVEDIC, Center for cartography of fauna and flora ; Nino KIRBIS, Herpetological Society - Societas herpetologica slovenica

In Slovenia the sand lizard (*Lacerta agilis*) has a distinct distribution pattern concentrated in river valleys. We have conducted an extensive field sampling using transect line visual surveys at three main rivers in the country: Sava, Drava and Mur. Our main aims were to understand the spatial and habitat use of sand lizards on river banks and their proximity, and to analyse the effects of three major factors: floods, habitat type and forest management. Transects were located inside different flood zones (exceptional, occasional and frequent flooding) and outside the flooded area. Habitat types present at all three sites were forest, forest edge and open areas. Three river sections differed in the intensity of river-bank regulations done by people in the past and in the dominant land use of areas next to the river. Results showed that floods had positive effect on the spatial distribution of the sand lizard at all three rivers. We argue that via exclusion of potential competitors and predators, floods improve the conditions for sand lizards, which seemingly have an ability to survive floods in the flooding zone. Important factor further explaining the distribution in all study sites was the habitat type. Sand lizards preferentially selected edge habitats, such as forest edge or other border habitats between different vegetation. Additionally, at Mur river, we observed a rapid population boom after forest clear-cuts were created. However, rapid population decline followed after the site was again overgrown by dense *Populus* plantation. This suggests that forest management practices can have strong short-term effects on the population dynamics of sand lizards. Long-term effects still need to be studied.

BIODIVERSITY UNDER THE LIGHT OF AGRICULTURAL LAND ABANDONMENT. INTERACTIONS, IMPLICATIONS AND THE NEED TO PRESERVE RURAL MOSAICS

Sylvia Zakkak

University of Patras

Vassiliki KATI, University of Patras

Rural depopulation and agricultural abandonment are widespread in the mountainous regions of eastern and southern Europe, directly affecting landscapes and biodiversity. Our research handles this major conservation issue, attempting to assess its impact on five taxonomical groups with different

ecological demands, namely woody vegetation, ground spiders, carabid beetles passerine birds and lizards. We selected 20 sites in Pindos Mts, Greece, well-representing a gradient of land abandonment based on forest encroachment. All groups' overall species richness and abundance, apart from lizards, were adversely affected by this process. Habitats with more than 75% woody vegetation cover were relatively poor regarding spider abundance, while forest encroachment was affecting carabid beetle community composition. Typical farmland and Mediterranean shrubland bird-species diversity was also found to be negatively affected, while birds formed five distinct ecological clusters after land abandonment. Concerning lizards, despite the non-significant effects of forest encroachment, the dominance of *P. muralis* indicated a gradual lizard community shift towards species inhabiting forested habitats. At the species level no general pattern could be drawn, due to each species different ecological requirements. Our results also provide evidence for the beneficial role of low intensity grazing for spiders, while having an overall beneficial effect hampering forest encroachment. We suggest a set of 22 indicator bird species, as well as a 50% woody vegetation cover threshold, as new tools for the cost-effective designation of High Nature Value farmland and the implementation of relevant monitoring schemes, under the Common Agricultural Policy frame in Europe. In conclusion, policies towards maintaining open heterogeneous rural landscapes and the associated biodiversity should be developed, motivating traditional farming and mild grazing or logging in abandoned fields.

WALKING IN THE SUN OR HIDING IN THE WOODS? SPIDERS MAY NOT BE SO CREEPY AFTER ALL! (A CASE STUDY ON SPIDERS' RESPONSES IN GREECE)

Sylvia Zakkak

University of Patras

Konstantina ZOGRAFOU, University of Ioannina ; Vassiliki KATI, University of Patras ; Maria CHATZAKI, Democritus University of Thrace

Although in many regions, forest conservation policies are mainly addressed to prevent deforestation, there is an increasing awareness that an excess of forest cover may be problematic for some taxa. In an attempt to understand these interactions regarding the understudied group of spiders, we assess the differences in ground spider (Gnaphosidae, Liocranidae, Miturgidae and Corrinidae) diversity between open and forested habitats, in two mountainous areas in Greece: Pindos Mts. and the Dadia-Lefkimi-Soufli Forest National Park (DNP). The study sites in Pindos Mts. were placed in non-protected areas, at 500-1000m altitude, mostly covered by young forests. On the other hand, the DNP has been a reserve since 1980, located at 20-650 m altitude and covered by older forests. Sampling took place in 2011, from

May to July, in 32 sites (420 pitfall traps), representing open and closed habitats. We identified 49 species (1,662 ind.) and 45 species (851 ind.) in each area, respectively. Regardless the differences between the two areas regarding the geographical, environmental and conservation parameters, closed habitats had a consistently negative effect on both species richness and diversity. When the datasets of the two areas were treated separately, both in Pindos Mts. and the DNP the effect of canopy cover was significant in terms of species richness ($F = 4.46, P < 0.05$ and $F = 9.86, P < 0.05$) and diversity ($F = 4.50, P < 0.05$ and $F = 10.84, P < 0.05$). When the data were merged, the effect persisted for species richness ($F = 5.14, P < 0.05$), while ground spider abundance was not affected in any case. Our results are in agreement with previous findings regarding the preference of the Gnaphosidae family for open lands. Conservation measures for ground spider diversity preservation should focus on the maintenance of open, heterogeneous landscapes, either through the promotion of traditional agricultural practices, or through the enhancement of wild ungulates.

90-MOVEMENT AND EGG LAYING IN MONARCH BUTTERFLIES: WHAT HAPPENS WHEN THE MATRIX IS CLEANED UP?

Myron Zalucki

The University of Queensland

Hazel PARRY, CSIRO ; Jacinta ZALUCKI, Griffith University

Movement is the key ecological process linking individual fitness traits to the utilization of resources distributed across landscapes with population level consequences. We use various individual-based models derived from tracking of adult females to describe the host seeking behaviour over the lifetime of a "Lepidoptera" agent, which utilizes hosts both aggregated in patches and scattered across the wider landscape as a substrate for laying eggs. The models either explicitly describe movement and resources in real virtual space or simplify the process to "search and find rules". The models simulate the number of eggs laid daily and on particular patches in the landscape if movement is modeled explicitly. We examine the population consequences of different movement rules, perceptual distance (ability to find) and landscape configuration. Specifically we consider the distribution of birth to death distances and the potential population consequences of cleaning up the matrix and changing habitat configurations at a landscape scale. We relate our work to monarch butterfly (*Danaus plexippus*) population decline in agricultural landscapes, in which genetically modified crops that are resistant to herbicides ("Roundup Ready") has resulted in the decimation of milkweed (*Asclepias* sp) hosts over large areas. We make some initial (preliminary) suggestions on how monarch habitat might best be restored at a landscape scale.

LAND USE CHANGE AND THE ECONOMIC COST OF EMERGING INFECTIOUS DISEASES

Carlos Zambrana-Torrel

EcoHealth Alliance

Katherine D. LEE, University of Wyoming ; Tom HUGHES, EcoHealth Alliance ; Kris A. MURRAY, EcoHealth Alliance ; Elizabeth LOH, EcoHealth Alliance ; Jonathan H. EPSTEIN, EcoHealth Alliance ; Daniel SCHAR, US Agency for International Development ; Peter DASZAK, EcoHealth Alliance

Disease emergence is driven by socioeconomic, demographic and environmental changes, which include deforestation, agricultural expansion and both habitat degradation and fragmentation. Around 60% of all emerging infectious diseases (EID) – from HIV to Ebola - have a zoonotic origin. Over the past 70 years, nearly one-fifth of all EID were linked to some type of land conversion. Land use change leads to disease emergence by increasing opportunities for contact and pathogen spillover between wildlife and humans and by perturbing host-pathogen ecological dynamics that promote cross species transmission. Intact forests thus provide a service to human society through protection against infectious diseases outbreaks. This work aims to understand the benefits of disease regulation from intact forests by estimating the value of damages that are avoided by keeping the ecosystem intact. Our working hypothesis is that the economic costs of disease control will increase with deforestation. To test this hypothesis, we conducted a literature review to get information on revenues and operation costs for industries using land in the region, ecosystem service values –including carbon sequestration and water retention-, deforestation rates and total economic cost of a case of malaria. Our preliminary simulations estimated a \$60 trillion savings over 50 years had land been managed to mitigate disease emergence and maximize ecosystem service production. Our results could be used to define optimal land use policies by governments, private sector, and civil society stakeholders.

HARNESSING GENETIC VARIABILITY OF PHILIPPINE UPLAND RICE FOR DRY AND SALINE ENVIRONMENTS

Florence Zapico

Mindanao State University

Catherine Hazel AGUILAR, Crop Science Cluster University of the Philippines Los Banos

In the upland areas of Sarangani Province in the Philippines, tribal farmers cultivate traditional rice varieties using age-old farming methods. Field surveys have unfortunately revealed losses of these premium rice varieties due to emerging environmental and socio-political realities in the uplands. This study was thus undertaken to identify varieties which can

potentially be grown in marginally dry and saline soils. While increasing PEG and NaCl concentrations caused obvious signs of injury to all rice genotypes, considerable varietal differences were noted in the nature of responses providing evidence that these genotypes possess broad intraspecific genetic variations for drought and salt tolerance. Furthermore, G_Mlato, G_Katiil and A_Kanadal were observed to thrive relatively well despite increased salt stress and are therefore recommended for saline soils while drought-resistant A_Pilit na Bisaya, A_Pilit na di Mabal-an, A_Mayaman, A_Fitam kwat and G_Larangan consistently performed well despite water-deficit conditions and can be recommended for planting in upland areas which are perennially plagued by long dry spells. Measures should therefore be instituted to conserve these priceless genetic resources so that the province's goal of food security for the indigenous peoples will be attained.

CONSEQUENCES OF FOREST MANAGEMENT ON THE METAPOPULATION DYNAMICS OF THE LESSER HORSESHOE BAT (RHINOLOPHUS HIPPOSIDEROS) AT THE NORTHERN EDGE OF ITS RANGE; CONTRIBUTION OF NON-INVASIVE GENETIC CAPTURE-MARK-RECAPTURE TO CONSERVATION MANAGEMENT.

Diane Zarzoso-Lacoste

Université Rennes 1, UMR 6553 ECOBIO

The lesser horseshoe bat (*Rhinolophus hipposideros*) is the Palearctic bat species which regression is best documented. During the last century, it became rare or extinct in many countries at the northern edge of its range including the Netherlands, Belgium, most of Germany and Northern France. The reasons mentioned for the decline of this forest species include pesticides, food shortage, and habitat loss. In this study, we investigated the reliability and accuracy of estimating both population size and fertility of *Rhinolophus hipposideros* by genotyping DNA from droppings collected non-invasively over two consecutive sampling sessions at twenty colonies located in a variety of managed forest habitats at the northern limit of the species distribution (Picardie, Northern France). We evaluated the strength of this non-invasive genetic

capture–mark–recapture (CMR) method by comparing the demographic data it produces to those obtained from a classical survey of these colonies realized during the same periods. We then tested for a possible effect of habitat quality, induced by different forest management strategies, on the population size and fertility of these bat colonies. Such non-invasive genetic CMR methods represent a useful tool for *Rhinolophus hipposideros* conservation since it can help to better understand the metapopulation dynamics of the species and to propose appropriate recommendations in terms of forest and land use management while maintaining ecological network between forest patches at the landscape scale.

MAPPING FOR CONSERVATION OF THE VALLEY OF THE GEYSERS (KRONOTSKY RESERVE, RUSSIA): METHODS AND CHALLENGES

Anya Zavadskaya

Kronotsky Federal Nature Biosphere Reserve
Vasily YABLOKOV, Lomonosov Moscow State University ; Daria PANICHEVA, Kronotsky Federal Nature Biosphere Reserve

The Valley of the Geysers in Kamchatka, Russia, is one of the five largest geyser fields in the world, and the only one in Eurasia. Located in Kronotsky Nature Biosphere Reserve, it remained undisturbed and pristine example of distinctive dynamic ecosystem that contains native communities of thermal bacteria, algae, lichens, mosses, red-listed endemic vascular plants and plays an important role for local population of brown bears. Outstanding esthetic values as well as the rare biological and ecological features of the Valley's ecosystem attract thousands of tourists and scientists from all over the world. However, complexity of the Valley is not yet fully understood, as prior research has focused primarily on specific species or habitats, rather than linkages between different components of the ecosystem and spatio-temporal dynamics of natural processes. The Atlas of the Valley of the Geysers – published last year – became the first attempt to show the complexity and extreme vulnerability of the ecosystem of the Valley and to put all the collected information about the area into one set of maps, understandable and useful both for public and scientists. To create the Atlas our team collected and integrated information from different databases, archives and papers, digitized and actualized existing maps, consulted specialists and rangers, and during 2009–2014 conducted their own detailed ground studies. As a result set of more than 80 full-color maps, 3D models and charts, 100 photos as well as essays by leading researchers of the area, brings together for the first time information about relief, geology, climate, landcover, vegetation, threatened plants, soils, natural dynamics of the landscape; international significance, history of discovery and modern use; recreational durability and relationships between different components of the ecosystem. The research was supported by the Russian Foundation for

Basic Research (projects 13-05-00870, 15-04-03818, 15-05-07002).

SEA TURTLE NESTING IN PERU: USING CITIZEN SCIENCE AND PUBLIC PARTICIPATION TO REVEAL OVERLOOKED NESTING ACTIVITY IN THE NORTHERN COAST

Adriana Zavala

EcOceanica
Shaley KELEZ, EcOceanica

Until 2011, Peru was not considered a nesting site for sea turtles; since 2012 we realized Olive Ridley *Lepidochelys olivacea* and Green turtle *Chelonia mydas* are nesting here on a regular basis and in increasing numbers. There are 100 km of sandy beach to be surveyed along the coast of Piura and Tumbes. Some portions of these beaches are remote, some highly urbanized and some are projected to be developed. The challenge on the developed beaches is to find the turtle reproductive activity and protect them from human threats, such as: artificial lighting, dune removal, introduction of foreign vegetation, and obstacles (beach furniture, garbage, etc.). The challenge on the remote beaches is to find the nests, needed to get the baseline data. By inspiring hotels staff and their visitors to help us we can then do the research needed to provide recommendations to the local and central government so they can manage the beaches for these threatened species. The methodology was to contact 120 hotels of the highly urbanized beaches in Piura and Tumbes to create a citizen scientist network with staff and visitors. To inspire them to help us collect data we are providing: educational presentations, posters, brochures and a turtle conservation logo for marketing. Their reporting activity will help us record nesting. Then we can evaluate and tag nesting females, mark nests and monitor their development and success. We will record all natural and human threats to females and nests. This information on nesting density, distribution, frequency, threats, and nesting and hatching success will be incorporated into the recommendations to the government to protect the southernmost nesting habitat of sea turtles in the Eastern Pacific. Our goal is to conserve sea turtles through research and protection of their nests and nesting beaches in Peru and, in the process, to involve and inspire people in our conservation effort.

ANALYSIS OF PHENOMENON OF DESERTIFICATION BY USING SATELLITE DATA IN THE NORTH ALGERIAN STEPPE

Ahmed Zegrar

Centre of Spaces Techniques

The degradation of natural resources in arid and semi-arid areas was highlighted dramatically during this century due to population growth and transformation of land use systems. The Algerian steppe has undergone a regression over the past decade due to drought cycle, the extension of areas cultivated in marginal lands, population growth and overgrazing. These phenomena have led to different degradation processes, such as the destruction of vegetation, soil erosion, and deterioration of the physical environment. In this study, the work is mainly based on the criteria for classification and identification of physical parameters for spatial analysis and multi-sources to determine the vulnerability of major steppe formations and their impact on desertification. To do this, we used satellite images Alsat-1 (2009) and LANDSAT TM (2001). These cross-sectional data with exogenous information could reduce the impact of the semi arid ecological diversity of steppe formations. This longitudinal study based on the use of remote sensing data is to analyze the evolution of steppe ecosystems. The application, through specific processes, including the supervised classification was used to characterize the main steppe formations. An analysis of the vulnerability of plant communities was conducted to assign weights and identify areas most susceptible to desertification. Vegetation indices are used to characterize the forest and steppe formations to determine changes in land use. This study will map the different components of the steppe, highlighting the magnitude of the degradation pathways, which affects the steppe environment, allowing an analysis of the process of desertification in the region.

A CREDIT POINT SYSTEM FOR ASSESSING AND ENHANCING BIODIVERSITY AT THE FARM SCALE - AND BEYOND

Judith Zellweger-Fischer

Swiss Ornithological Institute

Simon BIRRER, Swiss Ornithological Institute ; Sibylle STOECKLI, Research Institute of Organic Agriculture FiBL ; Lukas PFIFFNER, Research Institute of Organic Agriculture FiBL

In many parts of Europe, farmland biodiversity has undergone strong declines over the last decades. In recent years, a range of agri-environmental schemes have been set up to reverse the negative trend. While scientific results have repeatedly demonstrated that single measures ('options') effectively enhance farmland biodiversity, these positive outcomes did not result in a general increase at larger geographical or national scales. Instead of analysing biodiversity patterns at the plot scale, we focused on the farm level and developed a tool which assesses on-farm biodiversity as a whole. With this tool, farmers can score credit points for a total of over 30 options know to enhance farmland biodiversity. The Credit Point

System (CPS) yields a single biodiversity score for each farm. The CPS was scientifically evaluated on 133 farms in the Swiss lowland. Biodiversity was significantly positively correlated with species richness and density of plants, grasshoppers, butterflies and birds and was thus shown to be a suitable proxy of biodiversity at the farm scale. In 2010, a farming organisation for sustainable and wildlife-friendly foods set up mandatory guidelines for the enhancement of biodiversity on their producers' farms. Since then, it has become mandatory for those farms (ca. 10 000 farms managing 25% of the Swiss agricultural land) to apply the CPS and reach a minimal biodiversity score in order to remain in the label programme. Meanwhile, biodiversity scores on those farms have markedly increased, and farmers have implemented additional habitats for biodiversity. Not only the quantity but also the ecological quality of those habitats was higher in 2012 than at the outset in 2010. The uptake of biodiversity directives and the Credit Point System as an assessment tool in a label programme for sustainable and wildlife-friendly foods have opened up new perspectives towards promoting farmland biodiversity at a large scale.

EVOLUTIONARY HISTORY OF THE ENDANGERED MEDITERRANEAN TORTOISE TESTUDO HERMANNI HERMANNI: GENETIC STRUCTURE, HISTORICAL DEMOGRAPHY AND CONSERVATION ISSUES.

Saliha Zenboudji

Biogéographie et Ecologie des vertébrés (EPHE), Centre d'Ecologie Fonctionnelle et Evolutive (UMR 5175)

Marc CHEYLAN, Biogéographie et Ecologie des vertébrés (EPHE), Centre d'Ecologie Fonctionnelle et Evolutive (UMR 5175) ; Albert BERTOLERO, IRTA Aquatic Ecosystems ; Véronique ARNAL, Biogéographie et Ecologie des vertébrés (EPHE), Centre d'Ecologie Fonctionnelle et Evolutive (UMR 5175) ; Claudine MONTGELARD, Biogéographie et Ecologie des vertébrés (EPHE), Centre d'Ecologie Fonctionnelle et Evolutive (UMR 5175)

Our work focused on the genetic structure and demographic history of one of the most threatened reptile in Europe, the Hermann's tortoise *Testudo hermanni hermanni* (Gmelin, 1789). This subspecies shows a very scattered distribution in Western Europe and is classified as endangered according to the IUCN. Based on 17 microsatellite loci that were specifically developed from a pyrosequencing library, our study investigated the genetic diversity and structure of seven populations covering almost the entire subspecies range. Two major genetic groups were evidenced. The first group mainly included continental populations: Albera, Var, Italy and the northern part of the Menorca Island. The second group comprised tortoises of Corsica, Sardinia, Sicily and south of Menorca. The same dichotomy was also supported by the phylogenetic tree based on 3 mitochondrial genes (Cytb, ND4, COXI).

Temporal changes in effective population sizes as well as their demographic state revealed that all the studied populations of *T. h. hermanni* have declined. However, we observed contrasting declines in terms of time and intensity. Our work allowed to better understand the evolutionary history of the Hermann's tortoise in the occidental Mediterranean basin and to address some important issues concerning the ongoing conservation management programs. The different genetic lineages identified contribute to propose specific Evolutionarily Significant Units and Management Units. Our results have also implications concerning the restocking strategy to be adopted for the different populations of the Hermann's tortoises: is it better to preserve the genetic characteristics of the original population favoring local adaptations but thus increasing the risks of high diversity loss (especially for small and isolated populations) or to restore the genetic diversity by introducing neighboring populations (which could also include different genetic combinations)?

EVOLUTION OF SYSTEMATIC CONSERVATION PLANNING (SCP) WORK IN TURKEY - ADVANCES, ADAPTATIONS AND POSSIBLE CONTRIBUTIONS

Ugur Zeydanli

Nature Conservation Centre

Ayşe S TURAK, Nature Conservation Centre ; Didem AMBARLI, Nature Conservation Centre ; Ozge BALKIZ, Nature Conservation Centre ; Deniz OZUT, Nature Conservation Centre ; C. Can BILGIN, METU

Since its first introduction to Turkey in 2000, mainstreaming of SCP has been a slow process of overcoming impediments through an adaptive process. However, the participatory nature of the SCP processes has enabled embracing of new concepts and overcoming resistance rooted in advocates of approaches that does not involve complementarity. A recognition by the authorities of the need for more efficient conservation planning, and the effective collaboration among government bodies, university researchers and NGOs, have led to Priority Conservation Areas determined for nearly one third of Turkey. The comprehensiveness of the evaluation process has improved with each project through addition of new aspects related to persistence of biodiversity; new procedures for analysing threats and socio-economic aspects have been developed, some analyses have been adapted to local conditions due to issues on legislation, cultural, socio-economic and political characteristics, data availability and/or quality, and other limitations. As a result, the Ministry of Forestry and Water Affairs has adopted the SCP approach for determining Natura 2000 sites in Turkey. In this presentation we submit advancements in methodology, such as approach to socio-economic evaluations including conservation costs, conservation opportunities, suitability for timber production and anthropogenic threats; additional surrogates such as

ecological and evolutionary processes, wild river types, and ecosystem services; and impact of climate change. We also present details of a new procedure for analysing threats, which can be used while determining, delineating and evaluating them. The evolution of SCP in Turkey and the new tools that were developed during the process provides a model with a high potential for adoption in countries facing similar conservation constraints and opportunities.

EROSION AND DEGRADATION OF RIPARIAN FOREST CORRIDORS IN HYPER-FRAGMENTED LANDSCAPES IN THE SOUTHERN AMAZON

Barbara Zimbres

Universidade de Brasilia

Carlos PERES, University of East Anglia ; Ricardo BOMFIM MACHADO, Universidade de Brasilia

Southern Amazonian forests have succumbed to high deforestation rates in the so-called 'arc of deforestation', resulting in widespread forest loss and fragmentation. Although retaining buffer strips of riparian forests is a key goal in landscape-scale management for animal conservation, the species-specific usefulness of these riparian corridors depends on a myriad of both extrinsic and intrinsic factors. Vertebrate species responses to habitat degradation are often independent from species responses to fragmentation per se, even though these processes are associated. The conservation value of corridors is therefore determined not only by their size (width, length, area), but also their habitat quality in terms of vegetation structure. Here we explore the degree to which habitat fragmentation is linked to structural degradation in quasi-linear patches of riparian forests, which are legally protected under Brazilian legislation. We obtained structural measures across 204 sampling points nested within 39 corridors located in a highly fragmented landscape of the Southern Amazon, and compared riparian corridor width with variables that describe habitat quality: tree basal area, tree density, understory density, canopy cover, and vertical stratification profile. We also conducted a supervised classification of RapidEye® imagery with a 15-m resolution, in order to quantify overall corridor vegetation integrity based on the identification of three land-cover classes: primary forest, secondary forest, and shrubby vegetation. Although habitat loss is usually accompanied by loss in structural quality of vegetation, this is not by all means a general rule. Not all wide corridors were high-quality corridors, and vice-versa. Both corridor size and quality should therefore be considered separately when assessing overall corridor value for wildlife conservation in fragmented tropical forest landscapes.

A RANGE-WIDE ANALYSIS OF HUMAN-JAGUAR CONFLICT

Alexandra Zimmermann

Chester Zoo

Conflict with livestock farmers is the most serious threat to the survival of the jaguar (*Panthera onca*) across its range of 19 countries of the Americas. I examined human-jaguar conflict at a range-wide scale by reviewing the state of knowledge on the topic, modeling the spatial risk of conflict across the range, and analysing a series of empirical field case studies. Findings from 43 published studies and 117 expert-described cases show that depletion of prey and poor husbandry are reported as the key reasons for depredation, regardless of ecological, cultural or socio-economic context, and that attitudes towards jaguars are not necessarily linked to losses. By combining spatial datasets with expert-based opinion, spatial patterns of human-jaguar conflicts are presented as a predictive risk map of hotspots. Around 85% of the total jaguar range, 72% of the total Jaguar Conservation Units total area and 90% of the Jaguar Corridor overlap with livestock, and 15% of the jaguar range has risk of conflict. Regions in which jaguars are repeatedly persecuted may become ecological traps and decimate local populations. An aggregate study of 17 case studies across seven countries showed that there are considerable differences in farmers' experiences and levels of concern with the issue, and that attitudes, tolerance, and social norms vary across and within communities. However, no situational factor could predict how farmers perceive jaguars and deal with depredation. The only pattern consistent across case studies was that tolerance of jaguars is most likely predicted by a factor of the perceived impact of livestock losses combined with the social influences of the community. In most scenarios, mitigation strategies must go beyond practical measures such as improving husbandry and consider also behaviour-change approaches and address underlying social issues that have shaped the conflict over time.

95-EVALUATING WHEN AND WHERE TO IMPLEMENT ROAD MITIGATION FOR WILDLIFE WITH ROADKILL MODELLING: THREE INTERNATIONAL CASE STUDIES

Fernanda Zimmermann Teixeira

Federal University of Rio Grande do Sul (UFRGS)

Kari E. GUNSON, Eco-Kare International ; Casey VISINTIN, University of Melbourne

Roads pose many threats to wildlife including mortality resulting from wildlife-vehicle collisions (WVC). Although considerable research on WVC exists, analysing and predicting risk with statistical modelling has not been fully applied in management or road planning. Models can augment these efforts by identifying or predicting high-risk areas across time and space. However, for models to be incorporated into

management practice, they must be conceptually simple, flexible to changing data, and adaptable for a range of environments or species. We present three case studies on different continents where modelling is used to describe and predict WVC risk. In Canada, road mortality is an identified threat for seven species of turtles. Two years of road mortality was documented along 100 km of highway that bisects extensive wetlands in Eastern Ontario. WVC hotspots were identified and the transportation agency is now installing permanent exclusion fencing where the highest peak of turtle mortality occurred. Subsequently, the model was extrapolated to the provincial road network and its prediction capability validated with an independent data set. In Brazil, modelling is used to identify factors related to spatial and temporal distributions of amphibian roadkill in the Atlantic Forest Biosphere Reserve. The results suggest locations and seasons for placement of mitigation. In Australia, WVC are predicted with a conceptual risk framework by modelling the magnitude of threat (vehicle presence and speed) and exposure to threat (wildlife presence) across Victoria for seven mammal species. Reported locations of WVC are used to train and validate a collision model and measure predictors influencing risk. Managers can manipulate predictor values (speed limit or traffic volume), in a simulated environment, and observe predicted collision risk on road networks. While employing different analytical mechanisms, all case studies introduce novel methods to reduce WVC.

MAPPING NATURA 2000 HABITAT CONSERVATION STATUS IN A PANNONIC SALT STEPPE WITH AIRBORNE LASER SCANNING

András Zlinszky

Centre for Ecological Research, Hungarian Academy of Sciences

Balázs DEÁK, MTA-DE Biodiversity and Ecosystem Services Research Group ; Adam KANIA, ATMOTERM S.A ; Anke SCHROIFF, YggdrasilDiemer ; Norbert PFEIFER, Department of Geodesy and Geoinformation, Vienna University of Technology

Natura 2000 Habitat Conservation Status is currently evaluated based on fieldwork; however, this is proving to be unfeasible over large areas. The use of remote sensing is increasingly encouraged but covering the full range of ecological variables by such datasets and ensuring compatibility with the traditional assessment methodology has not been achieved yet. We aimed to test Airborne Laser Scanning (ALS) as a source for mapping all variables required by the local official conservation status assessment scheme and to develop an automated method that calculates Natura 2000 conservation status at 0.5 m raster resolution for 24 km² of Pannonic Salt Steppe habitat (1530). We used multi-temporal (summer and winter) ALS point clouds with full-waveform recording and a density of 20 pt/m². Some required variables were

derived from ALS product rasters, others involved vegetation classification layers calculated by machine learning and fuzzy categorization. Thresholds separating favourable and unfavourable values of each variable required by the scheme were calibrated from 10 plots where field-based assessment was carried out. Rasters representing positive and negative scores for each input variable were integrated in a ruleset that exactly follows the Hungarian Natura 2000 assessment scheme for grasslands. Accuracy was evaluated by 10 independent assessment plots to 80% (Kappa 0.615), and the numeric score for conservation status assessed in the field was predicted by the ALS-based system with an R² of 0.97 from 20 data points. We conclude that ALS is a suitable data source for Natura 2000 assessments in grasslands, and that the national grassland assessment scheme can successfully be used as a GIS processing model for conservation status, ensuring that the output is directly comparable with traditional field based assessments.

A STRATEGIC ACTION PLAN FOR CONSERVATION AND MANAGEMENT OF THE LAST SURVIVING POPULATION OF MOROCCO'S DORCAS GAZELLE, GAZELLA DORCAS MASSAESYLA (BOVIDAE: ANTILOPINAE) IN M'SABIH TALAA RESERVE, WEST CENTRAL MOROCCO

Mohammed Znari

Cadi Ayyad University, Faculty of Science-Semlalia
Moulay Abdeljalil AIT BAAMRANE, Cadi Ayyad University, Faculty of Science-Semlalia ; Mohamed NAIMI, Cadi Ayyad University, Faculty of Science-Semlalia ; Said EL MERCHT, Regional Center of Forestry Research, Marrakech, Morocco ; Chris LOGGERS, United States Forest Service, Colville National Forest, Washington

The dorcas gazelle *Gazella dorcas* is categorized as Vulnerable on the IUCN Red List (IUCN, 2008) and is considered Endangered in Morocco (Cuzin, 2003). The species has declined precipitously throughout Morocco because of poaching and severe habitat degradation from the expansion of agriculture and increased livestock grazing pressure. Dorcas gazelles have been fully protected since 1958. In Morocco this gazelle species historically occupied the plains north of the Atlas mountains but now persists only as a remnant population, isolated within a 1,987-ha reserve established in 1952 at M'Sabih Talaa, west-central Morocco. Recent genetic analyses (Godinho et al., 2012) indicate that this population is genetically differentiated, and may be the last surviving population of Moroccan dorcas gazelle, *G. d. massaesyala*. A population viability analysis indicate that local extinction of this remnant population is imminent unless active population and habitat management are undertaken. Our recent studies established that, apart from management problems, poaching and predation by feral dogs

were the main anthropogenic factors that caused the gazelle's decline. Our researches have also shown important long-term changes in available trophic resources and the gazelle's food habits. Moreover, a fluctuating asymmetry analysis, carried out on collected skulls, was indicative of a possible environmental/genetic stress in this isolated small population. We review these findings, and based on our research results, outline a recovery strategy for the last surviving Moroccan dorcas gazelle population. So, we developed a strategic action plan for the conservation of this remnant population with a long-term vision of a viable, ecologically functional and respected population. The main goal of this plan is to improve the conservation status of this relict subspecies throughout its historical distribution range. Several well defined objectives and targets are proposed.

QUANTITY OR QUALITY, LOCAL OR LANDSCAPE SCALE - WHAT DETERMINES MULTI-TAXON SPECIES RICHNESS IN DRY GRASSLAND FRAGMENTS?

Klaus Peter Zulka

University of Vienna

Max ABENSPERG-TRAUN, University of Vienna ; Norbert MILASOWSKY, University of Vienna

The theory of island biogeography suggests that increasing the size and reducing the isolation of patches can benefit species survival in fragmented landscapes. By contrast, conservation practice has typically focused on patch quality. We compared the influence of size, isolation and quality on species richness in a set of 50 dry grassland fragments in agricultural landscapes of eastern Austria. We studied two plant taxa (vascular plants, bryophytes) and 11 invertebrate taxa (gastropods, spiders, springtails, grasshoppers, true bugs, leafhoppers and planthoppers, ground beetles, rove beetles, butterflies and burnets, ants and wild bees). We distinguished between (1) dry grassland specialists, (2) all grassland species and (3) all species. Using regression and hierarchical partitioning techniques, we found that total species richness (3) was highly influenced by spillover from adjacent biotopes. Grassland species richness (2) was determined mostly by landscape heterogeneity parameters. The area-isolation paradigm was applicable only for dry grassland specialists (1). When analysing specialists of all taxa together, species richness was significantly related to historical patch size but not to current patch size, indicating an extinction debt. At the landscape scale, the quality descriptor 'short-grass area' was a better predictor than the variable 'area of extensively used landscape elements'. 'Distance to mainland' was a good predictor for specialists of mobile animal taxa. Plant specialists showed a pronounced dependence on quality parameters at the patch scale and at the landscape scale, whereas animal specialists were influenced by patch size, patch quality, landscape quality and isolation measures. None of the taxa benefited from linear structures in the surroundings. In

conclusion, high patch quality and a network of high-quality areas in the surrounding landscape should be achieved to conserve species richness in fragmented landscapes.

ENDEMIC SPECIES PERILOUSLY RESTRICTED TO SMALL CLIMATE PATCHES

Juan Zuloaga

University of Ottawa

Jeremy T KERR, University of Ottawa

Identifying patterns of endemism and their underlying causes are essential to global prioritization of conservation efforts. Why do some areas include massive numbers of endemic species across many taxa? Do these reflect historical process related to geographic isolation and speciation or contemporary environmental factors that limit species' ranges? Preliminary studies suggest that endemism depends to some degree on late-Quaternary climate change velocity. That is, areas with low rates of climate change since the Last Glacial Maximum (e.g., mountains) shelter the most endemic species. However, this pattern can reflect contemporary climate. Here, we construct global measures of endemism for mammals relative to globally-observed climate clusters based on temperature (1°C) and precipitation (100 mm) worldwide. We calculated the area of every climate bin and the number of mammal endemic species present in each to test whether the area of climatically distinct zones globally affects numbers of endemic species. We found that small patches, irrespective of climate, tend to harbor more endemic species. The number of endemic species decreases monotonically as climatically-bounded patches increase in area. Smaller patches, housing more endemic species, are concentrated in topographically complex areas. Although underlying ecological or evolutionary processes are still debated, these findings are relevant when choosing new paths for conservation, in particular in the context of climate change. Disappearing climates will eliminate small climate patches and novel climatic conditions that replace them will preferentially generate non-analog biotic communities in regions with the highest concentrations of endemic species.

THE ROLE OF LANDSCAPE CHANGES IN SHAPING ALPINE SPECIES DISTRIBUTION

Michele Zurlo

Gran Paradiso National Park [INSTITUTE] University of Milan - Department of Biosciences

Bruno BASSANO, Gran Paradiso National Park ; Ramona VITERBI, Gran Paradiso National Park ; Cristiana CERRATO, ISAC - CNR ; Marco CACCIANIGA, University of Milan - Department of Biosciences

Ecosystems are deeply affected by the human activity and land use and land cover change is recognized as one of the most important causes of the alarming loss of biodiversity. In this

scenario is fundamental to identify the most endangered areas where developing conservation purposes. The Alpine regions are of particular interest because they are characterized by rare and fragile ecosystems with a high level of endemism well adapted to harsh condition and particular sensitive to changes. Taking in account that the landscape is the result of natural and human processes is fundamental to reconstruct what happened in the past, describe the present through monitoring activities and try to predict the future events. Therefore in biodiversity conservation the remote sensing images are useful to define the landscape structure and to evaluate its changes. Considering the importance of the scale-dependency of ecological processes, we propose a multi-temporal and scale approach to describe the landscape structures and their role in shaping Alpine species distribution. The study area is the Gran Paradiso National Park, and we will focus both on test areas and both at the landscape scale. During the first step we will set a low-cost procedure of UAV (Unmanned Aerial Vehicle) survey adapted to Alpine environment in order to obtain high temporal and spatial resolution images in test areas. In the second step we will focus on the interpretation of the aerial images already available to reconstruct the land cover changes during the last decades and we compare the results with the UAV images. In the last step the analysis will be extended to entire Park landscape using satellite data. This multiscale analysis of landscape changes allow us to study how the environmental patterns affect the animal distribution using both a multi-taxa approach and considering a single target species. These results are essential for an adaptive management, balanced in space and time.

ASSESSING THE EFFECTS OF TROPICAL LAND USE CHANGE: A CAMERA TRAPPING STUDY OF FELIDS AND THEIR PREY IN THE PIEDRAS REGION OF PERU

Samantha Zwicker

University of Washington

Kristiina VOGT, University of Washington ; Luis Enrique CUETO APARICIO, Universidad Nacional de San Agustín de Arequipa ; Jason SCULLION, McDaniel College

Previous research shows that most mammals, especially felids, are reduced in fragmented forests, particularly species averse to human-modified landscapes. Since felids are elusive, sometimes nocturnal, and usually inhabit interior forest away from human activity, they can be difficult to study through in-person field observations. One effective approach to study elusive felids is through camera trapping, where the captured imagery can be used to identify individuals of certain tropical felid species by their spots and bot fly warbles. To better understand the impacts of forest fragmentation on felids, we studied the abundance and distribution of both felids and their prey species across a modified tropical forest gradient in the Las Piedras region of Madre de Dios, Peru. The goal of this study

was to compare and relate species abundance and species diversity data for captured Peruvian mammals in response to land-use changes, specifically for jaguar, puma, margay, and ocelot. We also gathered felid home range and distribution data, and examined the relationship between felid occupancy and habitat type and felid occupancy and prey densities. Results of this research indicate healthy populations of felids compared to other Amazonian studies, and support the theory that felids are using human modified areas for both movement and habitat. In addition, we found that seasonally used and minimally fragmented forests hold abundant biodiversity and act as corridors between core habitat and protected areas for larger mammals. Given the demonstrated diversity and vulnerability of the Las Piedras region, and that it represents one of the largest unprotected and largely intact tropical rainforests in Peru, this research shows both the importance of the region in supporting robust felid populations and the urgency needed to increase the protection of the region's species and forests.
