ABOUT THE SOCIETY FOR CONSERVATION BIOLOGY

SCB is a global community of conservation professionals with members working in more than 100 countries who are dedicated to advancing the science and practice of conserving Earth's biological diversity. The Society's membership comprises a wide range of people interested in the conservation and study of biological diversity: resource managers, educators, government and private conservation workers, and students.

SCB publishes the flagship peer-reviewed journal of the field, *Conservation Biology*, and the cutting-edge online journal, *Conservation Letters*. The Society provides many benefits to its community, including local, regional, and global networking, an active conservation-policy program, and free online access to publications for members in developing countries. SCB also administers a postdoctoral program, the David H. Smith Conservation Research Fellowship Program, sponsored by the Cedar Tree Foundation.

ASSESSING THE RELATIVE IMPORTANCE OF LANDSCAPE AND HUSBANDRY FACTORS IN DETERMINING LARGE CARNIVORE DEPREDATION RISK IN TANZANIA'S RUAHA LANDSCAPE

Leandro Abade

WILDCRU - UNIV. OXFORD

David Macdonald, WILDCRU - UNIV. OXFORD ; Amy Dickman, WILDCRU - UNIV. OXFORD

Tanzania's Ruaha landscape, centred around Ruaha National Park (RNP), is an international priority area for large carnivores, supporting >10% of the world's lions (*Panthera leo*) and globally significant populations of leopards (*Panthera pardus*), spotted hyaenas (*Crocuta crocuta*) and other carnivores. However, Ruaha's carnivore populations cause intense conflict with local people, mainly due to livestock depredation, and are exposed to alarming rates of retaliatory killing, especially on village land adjacent to RNP. Depredation risk is likely to be influenced by both habitat features and livestock husbandry, but the specific environmental risk factors, and relative importance of habitat and husbandry, have never been assessed in this landscape. Here, we assessed which ecogeographic variables (EGVs) were associated with depredation risk for grazing livestock on village land, and generated a predictive map of large carnivore predation risk, based on species distribution modelling algorithms (SDMs). Secondly, we investigated the relative influence of husbandry and EGVs on depredation risk of enclosed stock, based on a generalized linear model. Grazing livestock predation risk was higher closer to rivers, and in areas of lower elevation and low percentage of tree cover, with 41% of the area mapped as high-risk. For enclosed stock, predation risk was mostly influenced by low percentage of tree cover and increased rainfall, with no discernible influence of current husbandry, which suggests that traditional husbandry was insufficient to outweigh the innate predation risks associated with high-risk landscape areas. Adopting new husbandry methods, such as specialised

guarding dogs and fortified livestock enclosures, could be valuable for reducing depredation and carnivore killing in the Ruaha landscape.

USING LANDSCAPE AND BIOCLIMATIC FEATURES TO PREDICT THE DISTRIBUTION OF LIONS, LEOPARDS AND SPOTTED HYAENAS IN TANZANIA'S RUAHA LANDSCAPE

Leandro Abade

WILDCRU - UNIV. OXFORD

David Macdonald, WILDCRU - UNIV. OXFORD ; Amy Dickman, WILDCRU - UNIV. OXFORD

Tanzania's Ruaha landscape is an international priority area for large carnivores, supporting over 10% of the world's lions and important populations of leopards and spotted hyaenas. However, lack of ecological data on large carnivore distribution hinders the development of effective carnivore conservation strategies in this critical landscape. Therefore, the study aimed to: (i) identify the most significant ecogeographical variables influencing the potential distribution of lions, leopards and spotted hyaenas across the Ruaha landscape; (ii) identify zones with highest suitability for harbouring those species; and (iii) use species distribution modelling algorithms (SDMs) to define important areas for conservation of large carnivores. Habitat suitability was calculated based on environmental features from georeferenced presence-only carnivore location data. Potential distribution of large carnivores appeared to be strongly influenced by water availability; highly suitable areas were situated close to rivers and experienced above average annual precipitation. All three species showed relatively narrow niche breadth and low tolerance to changes in habitat characteristics. From 21,050km² assessed, 8.1% (1,702km²) emerged as highly suitable for all three large carnivores collectively. Of that area, 95.4% (1,624km²) was located within 30km of the Park-village border, raising concerns about human-carnivore conflict. This was of particular concern for spotted hyaenas, as they were located significantly closer to the Park boundary than lions and leopards. This study provides the first map of potential carnivore distribution across the globally important Ruaha landscape, and shows that SDMs can be effective for understanding large carnivore habitat requirements in poorly sampled areas. This approach could have relevance for many other important wildlife areas that only have limited, haphazard presence-only data, but which urgently require strategic conservation planning.

UNDERSTANDING AND OPERATIONALISING CORAL REEF RESILIENCE IN THE MALDIVES, INDIAN OCEAN

Ameer Abdulla

IUCN Maldives Marine Projects

Patrik SVENSSON, IUCN Maldives Marine Projects ; Gabriel GRIMSDITCH, IUCN Maldives Marine Projects ; Agnese Mancini, IUCN Maldives Marine Projects ; Fathimath NISTHARAN, IUCN Maldives Marine Projects

Although calls for networks of representative marine protected areas have been frequent and global in the past two decades, progress towards on-the-ground protection in developing countries has faltered severely due to lack of financial resources, technical capacity, institutional will, and stakeholder collaboration. Establishing networks of marine managed areas (MMAs) that may or may not include protected, no-take zones, provides more opportunities for legal designation, credible establishment and effective and comprehensive management of marine resources than strict MPAs or individual, un-linked MMAs. We utilize this approach in the Maldives where coral bleaching and mortality has been severe due to the 1998 El Niño and where 106 individual island resorts provide the most extensive platform for coral reef management in the country. Ecological surveys to assess reef resilience on individual islands were used to develop house reef management plans that were endorsed by government and resort managers. Key strengths of this approach include the capacity to address local and regional scale ecological patterns, anthropogenic impacts, and management needs. In Small Island Developing States with large geographical expanses and diverse number of reefs such as the Maldives, this methodology may present the most useful approach for managing coral reefs.

A MECHANISTIC UNDERSTANDING OF BERGMANN'S RULE IN A GENERAL ECOSYSTEM MODEL

Andrew Abraham

UNEP-WCMC

Derek TITTENSOR, UNEP-WCMC ; Tim NEWBOLD, UNEP-WCMC ; Drew PURVES, Microsoft Research ; Michael Harfoot, UNEP-WCMC

Bergmann's rule has been applied to a broad range of taxa, including poikilotherms, in a number of geographic regions and predicts that body size is correlated with latitude and elevation. Mechanisms commonly considered in previous studies to explain the observed patterns in animal body size include: chance, migration ability, predation, thermoregulation, resource availability, habitat availability and starvation resistance. It is most likely that the observed clines arise from synergistic interactions between several of these mechanisms. However, despite over 160 years of scientific research, both the generality and the underlying mechanism(s) of this ecogeographic principle remains disputed. In this paper we describe the use of a General Ecosystem Model, the Madingley model (Harfoot et al., 2014), to test for the existence of broad-scale interspecific patterns of body size

in terrestrial endotherms and ectotherms. We then utilize this model to investigate the above hypotheses and identify the primary mechanism(s) driving the emergent geographic patterns of terrestrial animal body size. Harfoot, M. et al. (2014) Emergent Patterns of ecosystem structure and function from a mechanistic general ecosystem model, PLoS Biology.

DO ESTIMATES OF LANDSCAPE RESISTANCE REFLECT ANIMAL MOVEMENT?

Briana Abrahms

University of California-Berkeley

Sarah SAWYER, USDA Forest Service ; Neil R. JORDAN, Botswana Predator Conservation Trust ; John, W. MCNUTT, Botswana Predator Conservation Trust ; Alan M. WILSON, University of London Royal Veterinary College ; Justin, S. BRASHARES, University of California-Berkeley

Evaluation and maintenance of landscape connectivity is essential to the conservation of genes, species, and habitats. Currently, estimating landscape resistance with resource selection functions is widely used to focus connectivity planning on areas where animal movement is predicted to occur. Yet, the extent to which animal behavioral state (e.g. foraging, resting, commuting) influences resource selection has largely been ignored. Recent advances in GPS technology can fill this gap by associating unique behavioral modes with location data. Here, we review resistance surface modeling studies to determine the extent to which existing connectivity models incorporate behavioral state. We evaluate: 1) the incorporation of an individual's behavioral state in development of resource selection functions; 2) the integration of behavioral influences into landscape resistance development; and 3) the validation of modeled connectivity with behavioral data. Our review suggests that most connectivity studies conflate resource selection with movement behavior, which may result in misleading estimates of landscape resistance. We then present a case study on African wild dogs (*Lycaon pictus*). Using high-resolution GPS and activity data, we develop resistance surfaces for all available location data ('full model') and alternatively for location data specific to when the study animals were traveling ('movement-only model'). Finally, we compare model predictions of connectivity with actual dispersal data. Results show that including only movement data when creating resistance surfaces reveals strikingly different patterns of connectivity than the full model. As expected, the movement-only model was a better predictor of observed dispersal patterns. Successful application of resistance surface modeling for connectivity planning therefore requires explicit examination of the behavioral contexts in which movement decisions are made.

REDUCING EMISSIONS FROM THE FORESTS UNDER REDD+: A CASE STUDY STATE FORESTRY DEPARTMENT OF PAHANG, MALAYSIA EXPERIENCE

Abdul Khalim Abu Samah

Forestry Department Peninsular Malaysia

Mohd Paiz KAMARUZAMAN, State Forestry Department Of Pahang ; Norhaidi YUNUS, State Forestry Department Of Pahang ; Ismail PARLAN, Forest Research Institute Malaysia (FRIM) ; Samsudin MUSA, Forest Research Institute Malaysia (FRIM)

Abstract Forestry has been recognised as amongst potential sector for climate change mitigation. REDD Plus mechanism has been identified under the UNFCCC to provide financial incentives to allow developed countries to offset their emission through deforestation and forest degradation and enhancement of carbon sequestration, conservation and sustainable management of forests in the developing countries. Malaysia recognises that REDD Plus has potential to raise Malaysia future involvement in the Climate Change mitigation programme. In order to explore Malaysia readiness in the REDD Plus engagement, Malaysia has embarked a pilot REDD+ projects, with financial support from the International Timber Trade Organization (ITTO) entitled Reducing Forest Degradation and Emissions Through Sustainable Forest Management (SFM) In Peninsular Malaysia. The project is jointly conducted by Forest Research Institute Malaysia (FRIM), State Forestry Department of Pahang and Forestry Department of Peninsular Malaysia. The project site which is located in the State of Pahang with main objective to determine carbon emissions from forest degradation activity in logged over forests and the assessment of the contribution of sustainable forest management practices to reduce emissions from forest degradation. Financial evaluations of the improved management practices will also be undertaken to provide avenues for assessing PES. This pilot REDD Plus project has preliminary been used to assess the rate and drivers of deforestation through the use of satellite data. The combination of Landsat and SPOT satellite images coupled with Land use change maps are used to identify drivers of deforestation and further verified through ground verification. This paper will highlight the progress of implementation of this study, sharing several issues and challenges encountered and finally concluded by outlining several important future strategies as an important way forward in the REDD Plus engagement.

LANDSCAPE DYNAMICS ACROSS SPECIES IN MEDITERRANEAN OAK FORESTS: ANTHROPOGENIC VERSUS ENVIRONMENTAL DRIVERS

Vanda Acácio

Instituto Superior de Agronomia (University of Lisbon)

Francisco MOREIRA, Instituto Superior de Agronomia (University of Lisbon) ; Filipe DIAS, Instituto Superior de Agronomia (University of Lisbon) ; Filipe Xavier CATRY, Instituto Superior de Agronomia (University of Lisbon)

Forests and woodlands dominated by oaks (*Quercus* spp.) have high conservation value across Europe. Global change seems to be negatively affecting oak ecosystems, through land use change, climate change and spread of exotic pathogens, and a drastic decrease in oak forest area is predicted, especially for sub-Mediterranean oaks. In Mediterranean Europe, oak forests and woodlands are very abundant and provide important ecosystem services. In particular, land cover in mainland Portugal is dominated by Mediterranean evergreen oaks (cork oak and holm oak) in the south. Deciduous sub-Mediterranean oaks occur in a much smaller extent in the north of the country. We used data from forest inventories for mainland Portugal for 1966 and 2006 and biophysical, climatic and anthropogenic variables to model oak landscape dynamics in a period of 40 years. General trends show that although overall persistent, oak ecosystems have been changing to shrublands, agriculture and other forest types in distinct proportions across oak species. For all oak species, shrub encroachment occurred with increasing fire frequency and change to croplands was more likely with decreasing slope. Shrub encroachment in former cork oak forests and woodlands occurred in regions of lower maximum temperatures, with higher fire frequency, population loss, and distant from roads, indicating land abandonment in marginal areas. Holm oak forests and woodlands were more persistent where temperatures were highest; changes to other land covers occurred in less warm areas but where temperatures have increased, maybe indicating that holm oak although well adapted to hot climate in its core area of distribution may not be as well adapted to variations in temperature in marginal areas. Deciduous oak forests and woodlands were less persistent in areas with higher temperatures and with increasing very warm periods, indicating that this oak group is more likely to become affected by forecasted climatic changes.

ILLEGALIZING A TRADITIONAL FISHERY IN THE BOHOL SEA: MARINE SPECIES CONSERVATION POLICY MARGINALIZING THE MARGINALIZED

Jo Marie Acebes

Ateneo de Manila University

The world's marine and coastal resources are threatened by the increased exploitation of fisheries and habitat degradation. Of particular concern are large marine vertebrates with k-selected life history strategies given to their vulnerability to overexploitation. A common fishery management strategy is the implementation of fishing bans to protect species or taxonomic groups such as cetaceans and elasmobranchs. In the Philippines, all species of cetaceans, the whale shark

(*Rhincodon typus*) and the giant manta ray (*Manta birostris*) have been protected since the late 1990s. The prohibition on the hunting of these species impacted the livelihoods of thousands of fishers in the country in varying degrees but some more so than others, such as those in the Bohol Sea who have depended on the fishery for over a century. This paper presents the case of the large marine vertebrate hunters of the Bohol Sea wherein fishers were excluded from the decision-making and managing process of the fishery. Key informant interviews, archival research and policy reviews were conducted in four study sites. Conservation policies such as these have socio-cultural and economic implications on fishing communities often taken for granted by policy makers and managing bodies. Many fishing communities are marginalized and with increasing protection on marine resources, these communities are marginalized further by depriving them access to all their traditional target species. However, some defied the fishery policies and contested its legitimacy. These communities remain as the center of Mobulid ray fishery in the Bohol Sea. This fishery remains so poorly understood. The lack of real co-management systems results in implementation problems and the non-compliance to fishery policies. In order to make existing and policies for this type of fishery work, there is a need to redesign management strategies and strengthen stakeholder support and cooperation through co-management.

APPLICATION OF PROCESS BASED MODELS FOR MAPPING FRESH WATER SERVICES IN CAMBODIA

Natalia Acero

Conservation International

Leonardo SÁENZ, Conservation International

There is a growing need to understand the links between ecosystem services and the goods they provide to people. Tools to assess freshwater services and to identify their spatial flows by linking them with multiple water users, especially under data-poor environments, are required. There are many hydrological or ecosystem services tools that could be used to map water-related services, but there is a gap on how to integrate them with an ecosystem services framework to provide performance metrics in order to prioritize and spatially identify the distribution of actual services based on use and demand from multiple beneficiaries. This paper seeks to describe the application of WaterWorld, a policy support system, spatially explicit, self-parameterizing (utilizes remotely sensed and globally available data sets for application) physical based model for mapping fresh water services. Through a case study in Cambodia, we explore the spatial distribution of three freshwater ecosystem services: quality, quantity and flow regulation and their actual provision to different beneficiary groups: drinking water for cities, hydropower production and agricultural irrigation. As a result we mapped

a fresh water services on a national level, based on WaterWorld hydrological modeling, with a spatial resolution of 1km and baseline representing the mean water balance for 1950-2000. We identified spatial connections that facilitate service flows and highlighted ecosystems important to ensure continued benefits from freshwater services. This result offers an important basis for an exhaustive assessment of freshwater services in the country and is focused to support conservation and sustainable development policies.

CHANGES IN AMPHIBIANS' DIVERSITY ACROSS LANDSCAPES MODIFIED BY HUMANS IN NORTHEASTERN COLOMBIA

Aldemar Acevedo

University of Pamplona

Orlando ARMESTO, University Simon Bolivar ; Monica

MARTINEZ, University of Pamplona ; Diego CARRERO, University of Pamplona

The Neotropics are well known for harbouring high levels of biodiversity and endemism especially in the Andean region, considered of high value for conservation. However, there are communities of species that occur in a mosaic of habitats where increasing human activities such as deforestation, expansion of agriculture and climate change, have clearly modified the composition, diversity and distribution of wildlife. In this study we evaluated changes in amphibians' diversity across landscapes modified by humans, aiming to find the possible causes that have driven the biodiversity loss. We sampled in northeastern Colombia from 2011 to 2014 in 15 localities including different biomes (tropical dry forest, Andean forest, High Andean forest and Paramo). We estimated Shannon index of richness and diversity and applied multiplicative diversity partitioning (Alpha and Beta) to landscapes and types of biomes. We reported 59 species of amphibians (12 families, 3 orders). The highest diversity was found in the Andean forest and tropical dry forest; however, such biomes also presented the highest level of transformation into secondary forest, pasture and other types of vegetation, with modifications of more than 40%, which resulted in 60% of species showing significant decrease in their populations. Paramo and tropical dry forest showed the highest number of endemism with 3 and 5 species; nevertheless, the transformation of habitat in such biomes was estimated between 40% and 60%. The general decrease of amphibians' diversity in modified habitats can be explained as a consequence of the low adaptability and high sensitivity to changes in landscape in the majority of amphibian species. Therefore, we hypothesize that high rate of fragmentation could accelerate processes of local extinction. We recommend to plan and establishing zones that promote higher connectivity between forest fragments and the design of monitoring plans of the species reported in the study area.

THE EFFECT OF FISH DISPERSAL CAPACITY ON YIELDS FOR TERRITORIAL USE RIGHTS IN FISHERIES: CASE STUDIES OF CHILE, MEXICO AND JAPAN

Erendira Aceves-Bueno

UCSB

Jorge CORNEJO-DONOSO, UCSB ; Steve GAINES, UCSB

Territorial Use Rights in Fisheries (TURFs) have existed for centuries, and most of them have been established within the boundaries of traditional fishing grounds. However, TURFs are gaining more widespread attention as a potential tool for fisheries management in new sites around the world. This growing popularity belies the fact that there are still unresolved questions about the most effective TURF designs. One of the key questions is the role of TURF size on their efficiency both from ecological and social standpoints. Larger TURFs decrease the spillover of adults and larvae to surrounding areas and thereby create greater incentives for TURF owners to take actions that enhance yields in the future. This study explores the expected effect of TURF size on yields for TURF systems in Chile, México and Japan. We calculated the expected effect of larval dispersal and adult movement on yields for TURFs in each system with and without cooperation among neighboring TURFs. Our results show that the analyzed TURF systems fall into three main categories a) TURFs that have an adequate size to reduce the effect of the expected adult movement and larval dispersal, b) TURFs that are large enough to reduce the effects of the estimated adult movement, but are too small relative to the effects of the expected larval dispersal c) TURFs that are too small to reduce the effects of both the expected movement of adults and larval dispersal. We found evidence that under the last condition strong cooperation among TURFs occurs. These analyses improve the existing theoretical framework for TURF design. They also provide empirical evidence that complementary management tools can arise when natural and social constraints prevent the construction of TURFs of an optimal size.

IMPORTANCE OF MONITORING METHODS IN A RESTORATION PROGRAM OF AN ENDANGERED DIADROMOUS FISH: CASE STUDY ON ACIPENSER STURIO SUSTAINED POPULATION

Marie-Laure Acolas

IRSTEA

Romarc LE BARH, IRSTEA ; Eric ROCHARD, IRSTEA

Acipenser sturio is a critically endangered species, the last natural reproduction occurred in 1994 in the Gironde (South West France) and a captive broodstock was constituted. Since 2007, the species benefits from a European recovery plan enhanced by national action plans; since then the population is sustained through stocking (>1.5 million juveniles released).

This is a long-lived species with late maturation that need long-term measures and associated monitoring to evaluate the efficiency of the stocking practice and the functionality of the population currently rebuilding. Monitoring a migratory species in the wild is a challenging task because movements between key habitats are frequent during the life cycle so either the monitoring covers all environments with substantial resources, either it needs to take place in an environment representative of the population functionality (i.e. growth or breeding habitat). Methods and tools involved in the monitoring need to be non-invasive with respect for the species endangered status. Several stakeholders are usually implied in a recovery plan but who is in charge of the monitoring depends of the local context: scientists or/and local managers? In our case study, monitoring undertaken on the long run consists of (1) incidental capture declarations by fishermen in the whole distribution area, the data gathered being coordinated either by representative of professional fishermen and scientists (2) scientific sampling with a consistent protocol in a key habitat, the estuary, relatively convenient to sample thanks to a specific methodology. Short term studies can be added to answer specific questions on life history traits using ad hoc tools (i.e. telemetry to assess migration pattern). Data interpretation called different disciplines such as behavioural science, population dynamics which illustrates the multidisciplinary of conservation biology.

101-TEMPORARY STREAMS: CURRENT MANAGEMENT CHALLENGES AND PROMISING SOLUTIONS

Vicenç Acuña

ICRA

Albert RUHÍ, Global Institute of Sustainability, Arizona State University ; Margaret PALMER, National Socio-Environmental Synthesis Center

Temporary streams are not only very common in arid landscapes, but make up the majority of river networks. Temporary streams support high biodiversity, and especially in arid landscapes have a crucial role on regional biodiversity. In fact, temporary streams contribute to the regional diversity through the aquatic biota, as well as through the terrestrial biota relying on them. Furthermore, temporary streams drive connectivity for terrestrial species at the regional scale. Temporary streams provide valuable goods and services, especially in arid landscapes through the provision of recreational and aesthetic information values. However, temporary streams are being buried or degraded at alarming rates owing to development, hydrologic alteration, disposal of waste water, etc. Temporary streams are also highly vulnerable to climate change, as predictions suggest that arid regions will receive less total rainfall and with higher inter- and intra-annual variation. The most important management challenge

is however that temporary streams are often managed as if they were permanent and, sometimes are even managed as terrestrial ecosystems. Proper management of temporary streams is only possible if good information on the spatial extent and status of temporary streams is available, but this is often not the case. Another current constraint for managers is the usual undervaluation of the ecological and economic values of temporary streams, given that these values are not widely understood by the public, landowners, producers, developers etc. Promising solutions for the current management challenges include that temporary streams (aquatic and associated terrestrial habitats) should be legally defined as part of the river network, and policies to protect them must recognize that flow intermittency per se is not a stressor but a natural component of the flow regime of many streams.

CONCENTRATION OF OCEAN CHLOROPHYLL-A ALONG THE MIGRATION ROUTE EXPLAINS THE POPULATION SIZE OF FRANKLIN'S GULLS (LEUCOPHAEUS PIPIXCAN) AND ELEGANT TERNS (THALASSEUS ELEGANS) IN CENTRAL CHILE

María Paz Acuña RUZ

Geomatics and Landscape Ecology Lab, University of Chile
Hector Jaime HERNÁNDEZ PALMA, Geomatics and Landscape Ecology Lab, University of Chile ; María Angélica VUKASOVIC FLORES, Wildlife Ecology Lab, University of Chile ; Cristián Fernando ESTADES MARFÁN, Wildlife Ecology Lab, University of Chile

Monitoring migratory bird populations over large geographic areas and extended periods of time can be a difficult and resource-demanding task. Because satellite technology offers a relatively inexpensive and verifiable means to gather environmental information at multiple spatial and temporal scales, it can become a very useful tool for the latter, provided that relevant relationships between populations and remote sensing data are found. The interannual variation in abundance and movements of long-distance migratory birds often depend on both local factors and those operating on a larger scale (e.g. climate, food production in the oceans). In this study we show how the distribution of two long-distance migratory birds depends on variables at continental scales. Using census data for three estuaries in central Chile (Itata, 36°23'S, 72°51'W; Mataquito, 35°07'S, 72°10'W; and Reloca 35°43'S, 72°35'W) from 2006 to 2014 (10 campaigns/year) we modeled the variations in summer (December-January) population sizes of the long-distance migrants *Leucophaeus pipixcan* and *Thalasseus elegans* in relation to physical variables along the Pacific coast of South America, such as the ocean temperature and chlorophyll-a concentration (MODIS/Aqua Ocean Color sensor), used as proxies for food availability. The best

models included a significant negative effect of chlorophyll-a concentration during the winter (June-July) in the coast of Northern Perú. Considering a time lag associated to the transformation of phytoplankton into seagull food, the latter result suggests that the primary productivity in the migration route may determine how far South will these species travel in search of food. These models allow us to reasonably predict the number of individuals who come to the coast of central Chile every summer approximately five months in advance, constituting a valuable tool to understand and manage the populations of migrant waterbirds.

THE EFFECTS OF HUMAN INFLUENCED STAND CHARACTERISTICS ON THE UNDERSTORY VEGETATION IN HUNGARIAN OAK DOMINATED FORESTS

Réka Ádám

Hungarian Academy of Sciences Centre for Ecological Research [INSTITUTE] Eötvös Loránd University
Péter ÓDOR, Hungarian Academy of Sciences Centre for Ecological Research ; János BÖLÖNI, Hungarian Academy of Sciences Centre for Ecological Research

The uniform shelterwood system changes the natural structure and species composition of European temperate forests, creating homogenous stand structure, lower mixture ratio, more closed canopy and removed shrub layer in some cases. In our study we assessed the main factors influenced by human activity which affect the species composition of herbs and tree seedling assemblages. 332 sampling plots were selected in 40-160 year old, recently managed, formerly managed and abandoned *Quercus cerris* and *Q. petraea* dominated stands in North Hungary. Understory was surveyed in 28 0.5 m² sized circular subplots in each plot, where presence/absence data of species was recorded. Potential explanatory variables were the distance from forest edge and the nearest settlement, stand age, canopy closure, mixture ratio, diameter diversity of the overstory and density of low and high shrub layer. To explore the relationship between assemblages and explanatory variables we used Redundancy Analysis (RDA). Light-demanding herbaceous species (e.g. *Campanula persicifolia*, *Hieracium murorum*, *Poa nemoralis*) and sessile oak seedlings preferred oak dominated stands with opened canopy. Shade-tolerant and general forest herb species (e.g. *Fragaria vesca*, *Geum urbanum*, *Melica uniflora*) occurred in forests far from settlements where rich shrub layers, heterogeneous stand structure, high mixture ratio can be found. Seedlings of most shrub and some tree species (e.g. *Ligustrum vulgare*, *Prunus spinosa*, *Sorbus torminalis*) preferred rich shrub layers, while the seedlings of most frequent associate tree species (*Acer campestre* and *Fraxinus excelsior*) occurred in formerly managed or abandoned forests, with diverse overstory, away

from settlements. As a conclusion, to conserve our forest plant species we have to regard oak forests as complex habitats, where patches with rich shrub layer, heterogeneous stand structure and tree species composition, and the oak dominated, opened patches are also essential.

MEETING GLOBAL CONSERVATION TARGETS: CREATE NEW PROTECTED AREAS OR MANAGE EXISTING ONES?

Vanessa M. Adams

University of Queensland

Hugh P POSSINGHAM, University of Queensland

Protected areas are a central mechanism for conserving global biodiversity. However, there is debate around the extent to which protected areas contribute to the conservation of biodiversity solely through their establishment, highlighting the importance of active management within protected areas. Given limited conservation funds and shortfalls in funding for basic protected area management needs, a critical question is whether conservation funds are best spent on purchasing land for further expansion of the protected area system or managing existing established protected areas to an acceptable standard. We use a dynamic habitat model to integrate these two actions. In contrast to current conservation spending which is focused on protected area expansions, it can be optimal to manage the existing protected areas prior to purchasing new reserves. The relative priority of protected area expansion and management is influenced by the relative costs and rates of degradation associated with habitat clearing (addressed by protection) and other threats such as animal poaching (addressed by management). We develop an easy to interpret heuristic that integrates these factors and can be applied to the range of biodiversity threats faced by protected areas. Lastly we present an example of its application.

SETTING CONSERVATION MANAGEMENT THRESHOLDS USING A NOVEL PARTICIPATORY MODELLING APPROACH

Prue Addison

Australian Institute of Marine Science

Kelly DE BIE, University of Melbourne ; Libby RUMPF, University of Melbourne

We introduce a participatory modelling approach for setting management thresholds, which represent when management intervention is required to address undesirable ecosystem changes. This approach was designed to assist when management thresholds: must be set for environmental indicators in the face of multiple competing objectives; need to incorporate scientific understanding and value judgments; and, are set by participants with limited modelling experience. The approach was tested in a workshop, where participants

set management thresholds for the alga, *Hormosira banksii*, to address the threat of trampling by visitors to an intertidal marine protected area. The approach involved trading-off the environmental objective, to maintain the condition of intertidal reef communities, with social and economic objectives to ensure management intervention was cost-effective. Ecological scenarios, developed using scenario planning, were a key feature that provided the foundation for where to set management thresholds. The scenarios represented plausible future states of *H. banksii* that may occur under increased threatening processes. Participants defined four discrete management alternatives to address key threats, and estimated the consequences of alternatives on objectives under each ecological scenario. Weighted additive model outputs express uncertainty, which can be explored and used to inform where to set management thresholds. This approach encourages a proactive form of conservation management, where management thresholds and associated management actions are defined a priori for ecological indicators, rather than reacting to unexpected ecosystem changes in the future. We discuss the application of this approach to protected area adaptive management, in particular the Reef 2050 Long-Term Sustainability Plan, which is the most recent government initiative designed to guide adaptive management of the Great Barrier Reef World Heritage Area over the next 35 years.

PREFERENCE OF LOCAL INITIATIVES IN CONSERVATION OF NATURAL RESOURCES AT YAKARI GAME RESERVE

Bola Adeleke

Redeemer's University

Local conservation initiatives had been in use by conservators since early 1990s. The major aim is to replace the state-driven conservation methods with locally driven ones. Local conservation initiatives largely originate from the rich culture of communities surrounding the protected area. Through a discourse analysis, semi-structured interviews were held with eleven groups of key informants. Ten of the communities surrounding the Game Reserve were selected through a random sampling technique. Structured questionnaires were administered to 350 community residents selected through purposive sampling technique to determine the implications of local initiatives in conservation compared with state-driven conservation. The result analysed mainly through descriptive method revealed that local initiative driven conservation technique leads to less conflict between protected area and communities; and better conservation output. Majority agreed however that integration of state-driven conservation methods and local initiative driven method would be most applicable. The role of NGOs collaborating with the park system in integrating procedure was emphasised.

DYNAMICS OF THE PARASITIC (VARROA DESTRUCTOR) IN COLONIES OF APIS MELLIFERA INTERMISSA IN THE MEDITERRANEAN CLIMATE OF ALGERIA

Noureddine Adjlane

University of Boumerdes, Department of Biology, Algeria
Nizar HADDAD, National Center for Agriculture Research and Extension, Bee Research, Unit.P.O. Box 639- Baq?a 19381, Jordan,

Population dynamics of *Varroa destructor* were studied for two years (March 2012–March 2014) in 12 *Apis mellifera intermissa* colonies located in Blida (center of Algeria).. The number of bees, the amount of open brood and capped, daily natural mortality, level of infestation of adult bees and level of infestation of the brood, was monitored. The brood cycle and behavior of reproduction in *Apis mellifera intermissa* is set by exceptional and seasonal contrasts in climate: dry summer (June to September), with an almost complete stop brood. Autumn, relatively wet causes a second peak of activity and brood development. The values of the infestation rate of brood and bees show two peaks in August (29 % and 12.5%), this period when there is less of bees and brood in the colony. In all colonies, the population of *Varroa* presented during the spring curve of exponential growth, which is explained by the continued presence of brood. In the growth phase, followed by a collapse of populations of mites, which in our experimental conditions, occurred from early summer, along with a weakening of colonies phase. Successive brood cycles allow the population growth of *Varroa*, while the absence of brood during the summer months has the opposite effect of reducing populations of *Varroa*. It appears that the level of *Varroa* infestation in colonies varies according to climatic conditions (seasonal) and internal conditions of each colony. In Mediterranean climates of Algeria, the milder winter climatic conditions and the possibility to collect food resources during a considerable part of the winter account for the permanent brood-rearing activity of honey bee colonies, which is relevant for the intrinsic growth rate of *Varroa* in these regions.

DETERMINATION OF TRACE METALS LEVELS IN SEAWATER AND ZOOPLANKTON IN THE MOROCCAN ATLANTIC COAST

Imane Afandi

In the marine environment, trace metal elements were mainly found as metal cation form in the dissolved, colloidal and particulate fractions. Their toxicity is largely related to their concentrations in the dissolved and particulate phases of seawaters. However, this micropollutants are accumulated in marine organisms of higher trophic level including zooplankton community. Zooplankton are very abundant and play a very important role in the marine food chain. Therefore, they can contribute to the transfer of trace metals to higher trophic levels due to their significant capacity to bioaccumulate metals from their food, as well as from seawater. The Moroccan Atlantic coast; which represents our study area; is mainly influenced by upwelling and anthropogenic micropollutants input. These two factors contribute to increasing the availability of trace elements in surface waters, thus they promote their availability for zooplankton. For this reason, this work aims to ascertain the level of trace metals in water (Cd, Pb and Cu), in particulate matter and zooplankton (Zn, Mn, Pb, Cu, Cd, Cr, Co, Ni, Fe and Ba), along the southern area of Atlantic coast off Morocco. Seawater and zooplankton samples were collected in December 2013, at 28 stations; from Sidi Ifni to the south of Dakhla (23  40'N); and all stations were located on transects perpendicular to the coast. The analysis of trace elements in dissolved phase is performed by chrono-potentiometry, and then the concentrations of trace elements in particulate phase and zooplankton were determined by inductively coupled plasma mass spectrometry. In the three compartments, the results showed that the concentrations of trace metals are increasing going from the north to the south part of the study area. We also noticed a variation in levels of contamination between the three compartments, thus the highest concentrations are recorded in zooplankton community.

PRELIMINARY STUDY OF TOMATO ROOT EXTRACT AS A POTENTIAL ECOLOGICALLY-FRIENDLY FUNGICIDE AGAINST TWO DECAY FUNGI IN WOOD

Adewale, Opeyemi Agbo-Adediran

DEPARTMENT OF FORESTRY TECHNOLOGY, FEDERAL COLLEGE OF FORESTRY

Abiodun, O OSO, DEPARTMENT OF SILVICULTURE, MINISTRY OF FORESTRY

Many wood species in Nigeria have good utilization potentials and under proper conditions, they would give centuries of service; however no timber species is immune to deterioration and disintegration if sufficiently exposed to long period of atmospheric conditions and different wood rotting organism. For most wood decaying fungi, wood offer abundant food reservoir, fungi cause more loss of wood than other biotic agents. Bamboo, an important group of woody- stemmed perennial plant and substitute for timber species was used to determine the fungicidal effect of tomato root extract against two decay causing fungi in wood. This investigation used extract of *Lycopersicon esculentum* root as test preservative agent against two decay fungi in the test blocks of *Bambusa vulgaris*. Five levels of the extract were formulated -0%, 25%, 50%, 75% and 100%. The test blocks were incubated with *Podoscypha bolleana* and *Lenzites palisoti* for twenty- one days after dipping inside the test preservatives at different concentration. The results obtained showed that *Podoscypha bolleana* exclusively caused more loss at 18.15% while *Lenzites palisoti* caused 17.65%. it was also observed that the untreated test blocks yielded more weight loss than the treated and the weight loss progressively became lower as the concentration increased. The data were analyzed using two- way analysis of variance and it was revealed that there was no significant difference between fungi and the extracts at 0,05% probability level. It was however recommended that active fungi-toxic ingredient in tomato roots should be identified and isolated for effective development and use as an eco- friendly wood preservative as conventional preservatives have adverse effects on users and environment alike.

BIODIVERSITY, BIOPIRACY AND BENEFITS TO THE INDIGENOUS PEOPLE IN CAMEROON

Agejo Ageh

University of Yaounde2

An almost unprecedented amount of discussion has been stimulated on the merits and demerits of genetic engineering of crop plants, and has divided both the public and scientific communities. The arguments for and against genetic engineering are invariably based on visions of the new technology from widely different ethical perspectives. Fundamental issues of man's relationship with nature and the environment, and theological matters are issues of concern. The genetic engineering of living cells, plants, animals and human beings has brought ethical concerns and issues to conservation of biodiversity. Agricultural productivity depends in part on the availability of biodiversity for the development of improved cultivars. Until the 1970s, biodiversity was considered to be part of the "common heritage of indigenous people." Under this regime, biological resources are treated

as belonging to the public domain and are not owned by any individual, group, or state. The paper will address the link between biodiversity and biopiracy its benefit to indigenous people in Cameroon. Whether biopiracy is an antithesis to the conservation of biodiversity? The paper will examine biodiversity conservation, national and international legal framework relating to biopiracy activities if they are beneficial. It will also highlight the on-going debate in the areas of environmental protection, exploitation, risk, benefit sharing and acceptance, and intellectual property rights. The paper will end with a conclusion and some recommendations.

PHENOTYPIC DIVERSITY OF PHILIPPINE ABACA (MUSA TEXTILIS L. NEE)

Catherine Hazel Aguilar

University of the Philippines- Los Banos

Januar AUJERO, Polytechnic College ; Florence ZAPICO, Mindanao State University

Abaca or Manila hemp is a close relative of banana that is cultivated for the fibre that can be extracted from its stalk. In Southern Mindanao in the Philippines, three abaca strains viz. Maguindanaon, Tangongon, Bongolanon are cultivated by farmers under diverse ecological conditions in the mainland. For this study, In situ characterization was done using six quantitative and twenty five qualitative morpho-agronomic traits. The dendrogram generated from cluster analysis showed the formation of two main clusters and highlighted the morphological divergence of 2 Maguindanaon strains from the remote uplands of Tboli. This divergence is further supported by purplish sap color of these varieties in contrast to the white sap color of other varieties. Morphological homogeneity was, however, noted for the first cluster implying uniformity for traits evaluated. These results imply low variability for the crop and this could have disastrous consequences vis a vis its survival in the field amidst threats posed by viral infestation, habitat degradation and global climate change. Interventions should therefore be undertaken to conserve remaining abaca population stands and to infuse new genes to the narrowing genepool of the crop.

49-FROM POLLINATION TO PLANT OFFSPRING QUALITY: WHAT IS LEFT AFTER SEX IN FRAGMENTED HABITATS?

Ramiro Aguilar

Instituto Multidisciplinario de Biología Vegetal

Lorena ASHWORTH, Instituto Multidisciplinario de Biología Vegetal ; Mauricio QUESADA, Centro de Investigaciones en Ecosistemas, Universidad Nacional Autónoma de México

Sexual reproduction in flowering plants represents a key process for their long-term population viability as it provides the opportunity to maintain or to increase genetic diversity and

thus the evolutionary potential to adapt to new and changing environments. Moreover, sexually produced seeds represent an independent dispersal phase of a new unique genotype readily to colonize new habitats. To accomplish sexual reproduction, plants need mobile vectors to transport pollen grains to conspecific stigmas, which may be a risky endeavor in current changing landscapes scenarios. The loss and fragmentation of habitats by human activities are pervasive phenomena in terrestrial ecosystems and represent today the main driving forces behind biodiversity loss. Due to the key importance of angiosperm diversity for ecosystem functioning, much research has been conducted over the past several decades to assess the effects of anthropogenic habitat loss and fragmentation on the processes and interactions involved in sexual plant reproduction. Here, by means of separate meta-analyses, I present estimates of overall habitat fragmentation effects on bee pollinator fauna, pollination, plant fecundity, plant genetic diversity and offspring quality across an extensive sample of angiosperms worldwide. By estimating fragmentation effects on each of these processes, from pollination to offspring quality production, we may be able to detect the critical or more vulnerable steps in sexual plant reproduction. Finally, I explore how certain life history and ecological traits of plants can moderate the magnitude of fragmentation effects. The global response patterns observed here are important for plant conservation, as they imply that first-hand information on certain plant traits may allow us to rapidly detect potential reproductive susceptibility to habitat fragmentation.

A COMPARATIVE ANALYSIS OF TOURISM ORIENTED MODELS FOR CONSERVATION AND DEVELOPMENT; LESSONS FROM UGANDA

Wilber Ahebwa

Makerere University

*Chris SANDBROOK, United Nations Environment Programme
World Conservation Monitoring Centre*

Striking a balance between biodiversity conservation and community development remains a key challenge facing the developing world. Reflecting the neoliberal rhetoric of market engagement to conserve nature, nature based tourism was incorporated as a crucial conservation and development tool in Uganda. Proponents of this approach argue that it offers 'win-win' outcomes for conservation and development by generating tangible benefits (employment, income, local markets, catalysing local enterprises, donations etc) that compensate for costs and create incentives for communities to conserve. Private-Community Partnership (PCPs) and Direct community engagement in enterprises have been the main models applied to enable tourism to work for community development and hence an incentive for conservation. In the current paper, we analyze and compare the introduction, implementation and implications of these two models in

Uganda. We demonstrate that while the PCP model leads to an enhanced flow of revenue for community projects, it is also associated with a number of problems including unequal sharing of generated profits leading to huge leakages from the local economy, the creation of conflicts among the community, limited community engagement, and hence low levels of buy in by the majority of community members. On the other hand, the direct community engagement model is more engaging to communities, creates more linkages within the local economy, and creates a sense of ownership, but generates less revenue for sharing schemes. We conclude that if inherent governance issues, market challenges and skills gaps were addressed, the direct community engagement model would be a more effective tool for delivering conservation benefits to communities. Key words: Private-Community Partnerships, Conservation enterprises, Uganda, Wildlife

FROM RHETORIC TO REALITY: INTEGRATING IMPACT EVALUATION IN THE DESIGN, IMPLEMENTATION AND ADAPTIVE MANAGEMENT OF MARINE PROTECTED AREAS

Gabby Ahmadi

World Wildlife Fund

Louise GLEW, World Wildlife Fund ; Mikaela PROVOST, World Wildlife Fund ; Helen FOX, Rare ; David GILL, National Socio-Environmental Synthesis Center ; Ismu HIYADAT, Conservation International ; Sangeeta MANGUBHAI, Wildlife Conservation Society ; PURWANTO, The Nature Conservancy

Impact Evaluation is gaining momentum in the conservation sector and has already generated novel insights into ecological impacts of terrestrial protected areas - though it has yet to be applied to Marine Protected Areas (MPAs). Marine conservation strategies often allocate considerable resources towards MPA establishment with the expectation they will provide fisheries as well as biodiversity benefits. While the "reserve effect" has been robustly shown, generating a sufficient evidence base to inform marine conservation efforts across geographies and scales will require the sector to mainstream impact evaluation techniques, bridging the current mismatches between and evaluation. Here, we describe integration of impact evaluation in an ongoing monitoring program in a network of MPAs in the highly biodiverse Bird's Head Seascape (BHS) in West Papua, Indonesia. Specifically we (1) highlight the challenges of implementation 'on the ground' and in a marine system; and (2) the transformation of an existing monitoring program into an impact evaluation appropriate design. Insights from the BHS suggest that impact evaluation can be embedded within performance measurement systems, enabling ecological monitoring efforts to simultaneously inform adaptive management and conservation policy.

DEVELOPING BANGLADESH'S FIRST "WALL-TO-WALL" FOREST COVER AND FOREST COVER CHANGE MAP

Imran Ahmed

Bangladesh Forest Department

Matt HANSEN, University of Maryland ; Peter POTAPOV, University of Maryland ; Karl WURSTER, US Agency for International Development (USAID)

An important component of forest management and monitoring for REDD+ and other programs is the monitoring, reporting, and verification of forest cover and forest cover change. In Bangladesh, a "wall-to-wall" map of forest cover change has never been completed. To address this data gap, USAID is funding a forest cover change map through the U.S. government SilvaCarbon program. The Bangladesh forest cover product is a joint USAID-SilvaCarbon-Bangladesh Forest Department project whose goal is to map the spatiotemporal dynamics of forest change in Bangladesh through the use of multi-temporal satellite data. The series of multi-temporal data from the Bangladesh project is a useful contribution to many environmental and planning projects including the Bangladesh REDD+ program. The Bangladesh forest cover products and publications made use of an automated "wall-to-wall" remote sensing method, developed jointly by South Dakota State University and the University of Maryland, and incorporated thousands of Landsat ETM+ images. Given the landscape heterogeneity of Bangladesh the team acquired and pre-processed RapidEye imagery to systematically validate the Landsat-derived product. This project demonstrates how a global forest product can be adapted to create important national and subnational forest cover and forest cover change maps at low cost, and that can be used as a basis for other national forest monitoring systems and other forest management and monitoring practices. The forest cover change maps is a foundational piece of future work that adds additional information regarding forest structure and biomass, in particular for mangrove forests of the Sundarbans, where field measurements have already been carried out.

WIDESPREAD SPECIES ARE RELATIVELY UNINFORMATIVE IN CONSERVATION PLANNING

Munemitsu Akasaka

Tokyo University of Agriculture and Technology[INSTITUTE]

The University of Queensland

Richard FULLER, The University of Queensland ; Taku KADOYA, National Institute for Environmental Studies[INSTITUTE] University of Guelph ; Taku FUJITA, The Nature Conservation Society of Japan

Considerations of efficient resource allocation are essential not only during prioritizing a set of conservation actions, but also

when planning for data collection. Costs may vary with the type of information collected. For example, distribution records of species with small geographic range sizes are more costly to obtain on a per capita basis, while those of larger-ranged species are relatively less costly. Here we investigate the relative influence of small and large range size species distribution data in spatial prioritization. We assessed how the number of species meeting conservation targets increased with the cost of records used for selecting areas to be conserved, using a simulation process that for each species sequentially selected areas for conservation to meet a species-specific representation target. We used the latest database on the distribution of threatened plants in Japan, which has records at 10 km x 10 km spatial resolution for 1630 species. We discovered that entering species into the model in rank order from small to large range size always outperformed a model where species were ranked in the opposite order. Moreover, the former always had lower total area needed to meet the conservation targets. Similar results were obtained using the Marxan optimization algorithm, and results are problem driven by a smaller mean overlap among species' distributions with smaller range size. Results suggest that distribution records of large-range species are of less importance than smaller-ranged species, hence, in limited budgets, their omission would not significantly change the outcome of the conservation prioritization process.

TRADE IN ENDANGERED SPECIES OF WILDLIFE: A CASE OF LAGOS, NIGERIA

Excellence Akeredolu

UNIVERSITY OF LAGOS

Elizabeth EHI-EBEWELE, Federal Ministry of Environment ; Joshua UZU, UNIVERSITY OF LAGOS

Trade in endangered species of wildlife constitute a potential threat to biodiversity conservation in Lagos Nigeria. The market growth for bush meat and wildlife trophy collection is gradually leading to a decline in animal population. A 4-month survey was carried out in four black market sites predominantly known for ivory and wildlife trade namely: Ikorodu, Oyingbo, Lekki and Badagry to investigate the activities of illegal wildlife traders in Lagos, Nigeria. The study showed that bush meat and ivory trade flourishes in some parts of Lagos State alongside with woodwork and beadwork as cover ups in hotels where they are easily accessible to foreign buyers. Ivories are sold secretly to customers in order to avoid arrest. Skins of python, Leopard, antelope and monitor lizards which artisans use in design of shoe, belts, bag are available in Lekki, Oyingbo and Badagry market while head of primates such as monkey, gorilla and chimpanzee are also displayed in Ikorodu market without impunity. Endangered species of birds such as grey parrot and many others are sold along the Lagos bar beach in amount ranging from \$32 to \$133. Tusks of elephants, warthog and rhinoceros are traded

in disguise as souvenirs like combs, key holders, bangles, rings, and cigarette holder, animal and human figurine for easy patronage and smuggling. The study identified Lagos as both the local and international trade route for illegal wildlife trade as foreign syndicates easily smuggle wildlife exploiting the porosity of the sea ports and border towns in Lagos state. The study concluded that illegal ivory and wildlife trade is real in Lagos and requires urgent attention as most animals sold in Lagos market do not comply with the convention of international trade in endangered species (CITES) as animals listed in appendix 1 and 2 are still sold without fear of punishment.

HUMAN-TIGER CONFLICT IN SUNDARBANS, BANGLADESH: UNDERSTANDING PATTERNS AND PROCESSES

Mahbub Alam

WildTeam

Alam HAWLADER, WildTeam ; Md. Mizanoor RAHMAN, WildTeam ; Nasir UDDIN, WildTeam ; Md. Khairul ISLAM, WildTeam ; Sobahan TALUKDER, WildTeam ; Rezvin AKTER, WildTeam ; Iqbal HUSSAIN, WildTeam ; Adam BARLOW, WildTeam ; Christina Greenwood BARLOW, WildTeam ; Md. Anwarul ISLAM, WildTeam ; Prakash Kant SILWAL, WildTeam ; Sandeep SHARMA, Smithsonian Institution ; Sumaiya FIROZE, United States for International Development

Sundarbans, the largest contiguous tract of mangrove forest in the world, is also infamous as the human-tiger conflict capitol. This region has seen some of the most intense forms of human-tiger conflict, mainly in the form of human injuries and fatalities inside the forest, and stray tiger incidents and livestock depredation outside the forest. The loss of human life leads to increased hardship for already desperately poor local people and causes negative attitudes towards tigers, who are also at the margin of extinction-vortex due to various anthropogenic threats in this unique habitat. We collected and analyzed the human-tiger conflict data for a period of seven years (2008-2014) from Bangladesh Sundarbans. We present an exploratory analysis of this data followed by a spatial analysis to identify the patterns of conflict hot-spots. After this we explored various ecological and socio-economic factors in and around Sundarbans to get a better understanding of the cause of human-tiger conflict. We also present the community based efforts practiced by WildTeam to reduce and mitigate human-tiger conflict in this region.

IDENTIFICATION OF GEOPHYSICALLY DIVERSE LOCATIONS THAT MAY FACILITATE SPECIES' PERSISTENCE AND ADAPTATION TO CLIMATE CHANGE

Christine Albano

Conservation Science Partners

Brett DICKSON, Conservation Science Partners

Conservation of geophysical diversity has been proposed as a strategy for conserving species diversity and facilitating adaptive capacity of species in the face of changing climate. Existing protected area networks may not correspond to the most geophysically diverse places because they have typically not been selected on this basis. Our objectives were to characterize geophysical diversity across the southwestern United States, assess the sensitivity of our results to methodological choices, and assess the degree to which the existing protected areas network in this region captures geophysically diverse places. We classified the region into geophysically distinct units (land facets) on the basis of topographic and edaphic variables. We calculated land facet diversity on the basis of multiple classification methods, thematic resolutions, and spatial scales (i.e., spatial grain and neighborhood size), assessed the sensitivity of land-facet diversity estimates to these methods, and integrated the results to provide a multi-scaled estimate of geophysical diversity. We used Gap Analysis to assess the protected status of particular land facets and lands with high land-facet diversity. Land facet diversity estimates were more sensitive to spatial scale than to methods used, but results based on different methods or spatial scales typically were highly correlated. Our results indicated several key gaps exist in the southwestern protected areas network, particularly in productive soil types at middle elevations. Our analytical approach can provide guidance for identifying and prioritizing locations that may facilitate species' capacity to adapt to global climate change.

CURRENT AND POTENTIAL DISTRIBUTION OF THREATENED AMPHIBIANS FROM THE EASTERN CORDILLERA IN COLOMBIA AND ITS IMPLICATIONS FOR CONSERVATION

Monica Albornoz

University of Pamplona

Aldemar ACEVEDO, University of Pamplona

Colombia is considered a megadiverse country in terms of amphibians; nevertheless, very few studies have concerned their natural history, distribution, ecology and diversity, and all of them have overlooked the assessment of levels of threat. We analysed historical occurrence records of 60 species of amphibians listed under any category of threat from the Eastern Cordillera of Colombia, a region with severe lack of information regarding diversity and conservation status. We determined the current distribution and conservation status using GIS to associate layers of land cover, land use, as well as presence and absence of protected areas. To obtain the potential distribution of the species we applied the maximum entropy algorithm for distribution models, using 19 climatic

variables. The majority of threatened species of amphibians belong to the families Craugastoridae and Bufonidae; moreover, the latter has the most of species in the category CR. The analysis of protected areas resulted in only 20 species occurring in at least one area under protection, specifically in 8 out of 20 natural parks and 8 out of 111 natural reserves, which contrasts with the remaining 40 species that occur in areas highly affected by vegetation loss, especially the middle and southeastern regions of the cordillera where more than 60% of the original forest has disappeared. Estimation of potential distribution showed that mean annual temperature along with mean values of precipitation are the variables that better describe the obtained models, with which the northeastern resulted in the region that presented favourable climatic conditions and also the highest number of protected areas that could support remaining and emerging populations of amphibians. Therefore, we identify the necessity of establishing monitoring programs that run periodically, as well as implementing ecological restoration and promoting sustainable land use, in order to identify and propose priority conservation areas.

CAN SATELLITE-DERIVED ECOSYSTEM FUNCTIONAL TRAITS ANTICIPATE SPECIES SHIFTS?

Domingo Alcaraz-Segura

University of Granada

Angela LOMBA, Universidade do Porto ; Rita SOUSA-SILVA, Katholieke Universiteit Leuven ; Diego NIETO-LUGILDE, University of Maryland ; Paulo ALVES, Universidade do Porto ; Damien GEORGES, Université Joseph Fourier ; Joana VICENTE, Universidade do Porto ; João HONRADO, Universidade do Porto

In a world facing rapid environmental change, anticipating potential impacts of habitat change on biodiversity is of utmost relevance. Remote sensing-based Ecosystem Functional Attributes (EFAs), such as primary production dynamics, are promising predictors for Species Distribution Models (SDMs) by offering an integrative response of vegetation performance to environmental drivers and changes. This way, species responses can be linked to pressures on ecosystem functioning. In addition, biodiversity monitoring may benefit from considering EFAs since they show a quicker response to environmental changes than structural or compositional attributes (e.g. land-cover or species richness). Our objectives were to assess whether the performance of SDMs improves with the inclusion of remote sensing-based EFAs, and whether observed trends in EFAs can be used as early-warnings of potential species range shifts. Four sets of models were compared for 41 threatened and rare plant species in the Iberian Peninsula with these combinations of predictors: 1) only climate, 2) climate and land-use, 3) climate and EFAs, and 4) only EFAs. For sets 1-3, SDMs were fitted considering 2001 as baseline, and projected under scenarios of climate change for 2020. Changes in EFAs

during 2001-2013 were used to explore whether the range shifts predicted by the climate-based models (set 1) for 2020 could be anticipated by using the 2001-2013 trends in the EFAs-based models (set 4). We demonstrated, based on a large number of plant species covering all IUCN categories, a positive effect of remote sensing-based EFAs on SDMs performance and on their effectiveness to anticipate species responses to environmental changes. Our approach highlights the potential role of EFAs in the early-warning of range shifts as well as the detection of short-term fluctuations in suitable conditions, thus improving the overall effectiveness and utility of biodiversity monitoring for policy and management applications.

24-NAVIGATING GOVERNANCE NETWORKS FOR COMMUNITY-BASED CONSERVATION IN A MULTI-LEVEL WORLD

Steven Alexander

University of Waterloo

Mark Andrachuk, University of Waterloo ; Derek Armitage, University of Waterloo

Community-based conservation initiatives are embedded in multi-level governance networks with diverse and emerging actors. While network governance can facilitate coordinated action, social learning, and experimentation, conservation actors need to be critical and reflect upon the broader social, institutional, and relational context in which they work. Here, we identify and outline five 'waypoints' intended to help conservation actors 'know their networks' and to consider more systematically the relational ties and network structures that influence conservation efforts. The waypoints we highlight provide a reference for how conservation initiatives are framed, the network dimensions that may be of interest, choices available to analyze networks, and the embeddedness and nestedness of networks. At each waypoint there are certain decisions to be made, and these decisions lead towards certain analytical pathways. This is not to suggest that there is a singular pathway that must be followed. Rather, we emphasize that choices at each waypoint have implications on the types of networks that are perceived, which in turn reveal certain aspects of the social relationships that affect community-based conservation initiatives and influence desired conservation outcomes.

IMPOVERISHED BIRD FUNCTIONAL DIVERSITY IN TROPICAL FOREST FRAGMENTS ON HUMAN-MODIFIED LANDSCAPES

Eduardo Roberto Alexandrino

Escola Superior de Agricultura Luiz de Queiroz

Alex Augusto Abreu BOVO, Escola Superior de Agricultura Luiz de Queiroz ; Marcelo MAGIOLI, Escola Superior de Agricultura Luiz de Queiroz ; Daniela Tomasio Apolinario LUZ, Escola

Superior de Agricultura Luiz de Queiroz ; Katia M P M B FERRAZ, Escola Superior de Agricultura Luiz de Queiroz ; Cagan H. SEKERCIOGLU, University of Utah

Tropical forests are considered a key component to maintenance of Earth biodiversity. However, much of tropical wooded biomes were converted to human-modified landscapes (HML), which generated small and isolated forest fragments surrounded by agricultural matrix. Considering the growing interest by ecologists to assess the potential ecological services provided by these fragments in HML, we evaluated the current bird functional diversity (FD) in eleven Atlantic Forest fragments in southeast Brazil. Three large fragments (230, 251 and 1451ha) are protected, while eight small have no protection (3 -115ha). We considered bird data from our one year of complete sampling (mist nets and point counts) in the small fragments and recent data of bird monitoring in the larger ones (data published in literature). Habitat preference, foraging guilds, foraging strata, sensitivity to disturbance and body mass were used as traits to calculate FD. We found higher FD values in the large fragments and low values in the small fragments, which resulted FD values highly correlated with fragment size (adjusted- $R^2 = 0.9457$, $F = 175.1$, $p < 0.001$). The absence of some specialist/sensitive species, e.g. large frugivorous and understory insectivorous, explains the low FD values in the small fragments. Since HMLs are commonly found in many parts of the Brazilian Atlantic Forest domain our results warn for a birds' functional impoverishment in the small fragments. Although the use of functional traits improves the bird assemblages' assessment in fragments, they are not being considered by managers in conservation plans of HMLs.

ECOSYSTEM SERVICES, INCOME AND HUMAN WELL-BEING AMONG RURAL COMMUNITIES

Amanda Alfonso

Universidad de Chile

Javier A. SIMONETTI, Universidad de Chile ; Francisco Zorondo-Rodríguez, Universidad de Chile

Land use changes impact on both ecosystem services and income, key factors on human well-being. To understand the weight of each factor on well-being among rural poor communities, we evaluated the (dis) similarities of the associations between variation of well-being against changes on the provision of ecosystem services and changes on income. We used empirical data from rural households from Pelluhue district, central Chile. Landscape in Pelluhue changed since 70s, currently being dominated by monoculture plantations of Monterey pine. The introduction of pine plantations triggered a decrease of water and fruit provision for local people. Among 77 rural households -most of them under poverty line-, we evaluated their perceptions of i) variation of well-being (outcome variable), and changes on ii) water provision, iii) fruit

provision, iv) surface of native forest, and v) household income (explanatory variables). We prompted informants to compare current conditions with those of 2 decades ago. Answers were reported using a Likert scale. We ran multivariate regressions to test associations between outcome and explanatory variables. We found that a decrease on well-being is associated to a decrease on both of surface of native forest available (coefficient=0.11, $p=0.04$) and the quality of water provided by them (coefficient=0.15, $p=0.05$). No association was found between variation of well-being and change on provision of fruits and quantity of water. Variation on well-being was not associated to changes on income, at least at the levels they have change over the last 20 years. Our results suggest that human well-being of poor rural communities are more affected by changes in ecosystem services than variation in income. (Funded by Fondecyt N 3140487)

THREATS TO BIODIVERSITY IN PAKISTAN: A CASE STUDY OF RARE AND ENDEMIC PLANTS IN CHITRAL VALLEY

Haidar Ali

University of Swat

Muhammad QAISER, University of Karachi

Biodiversity loss is a global issue but the reasons responsible may be addressed on local scale. Likewise, health of any ecosystem can be analyzed by the richness of its rare and endemic taxa. Out of total of 4758 vascular plants documented in Flora of Pakistan, 400 are endemic, among which 52 are endemic to Chitral valley. Upon critical analysis of the population size, Extent of Occurrence (EOO) and Area of Occupancy (AOO) for three consecutive years, 52 plants are assessed, according to the IUCN Red List Categories and Criteria. As a result, 4 taxa are categorized as Critically Endangered, 11 are Endangered, 12 are Vulnerable and 25 are data deficient. The reasons of endangerment of these rare and endemic plants of Pakistan include population pressure, poverty, lack of land use plans and lack of enforcement of the existing rules. Majority of these rare and or endemic plants (i.e. 65%) are used traditionally for various ailments. These plants are mostly collected by children, lacking proper knowledge regarding pre and post harvest methods, as a result major portion of the collected plants are wasted. Mainly nomads, Ajars and Gujors (nomad tribes), are the resource users, because, they are now exploiting the habitats of these high altitude plants, whereas, previously they were residing at lower altitudes. In addition rapid infrastructural development (roads, buildings), pollution, the destructive activities of massive influx of Afghan refugees also contribute in threatening the resources. It is expected that the present data will provide a comprehensive understanding of the most critical factors currently influencing depletion of rare and endemic plant

species and aid in improving the effectiveness of mitigation measures to reduce them.

A COMPARATIVE ASSESSMENT OF CLIMATE CHANGE EFFECT ON SOME OF THE IMPORTANT TREE SPECIES OF HINDU-KUSH HIMALAYAS, USING PREDICTIVE MODELLING TECHNIQUES

Kishwar Ali

The University of Reading, UK

Hussan Ara BEGUM, Department of Botany, Abdul Wali Khan University

A comparative assessment of the effect of global climate change on some the ethno-medically and socio-economically important tree species was carried out in the Hindu-Kush Himalayan mountains. The primary study site chosen was the Swat Valley of Northern Pakistan, which is a unique biodiversity hotspot supporting some important ethnomedicinal plant species. The species assessed for the future climate change effects were: *Acacia modesta* Wall., *Abies Pindrow* (Royle ex D.Don), *Pinus wallichiana* A. B. Jackson, Royle and *Taxus baccata* L. The Maximum entropy (MaxEnt) modelling technique of species prediction and distribution was used, applying HADCM3 (Hadley Centre Coupled Model, version 3) which is a coupled atmosphere-ocean general circulation model (AOGCM) and A2a global climate change scenario. Results suggest that by the year 2080, there will be a significant change in the distribution and density of these species. It was found that *Acacia modesta* will have significantly higher density, expanding to the southern and central parts of the Valley, i.e. the lower basin of Himalayas. The remaining three species have produced opposite results to *Acacia modesta*, as they will significantly reduce in their density and restrict in their distribution in the Valley. The results show that all species will have altitudinal movement to the northern cooler climatic regions of the Himalaya/Hindu-Kush. Results related to the validity of the models indicate "good model" for all species in both present and future predictive models attaining very high AUC values, i.e. 0.989, 0.98, 0.95, and 0.961 for training data for *Acacia modesta*, *Abies pindrow*, *Pinus Wallichiana*, and *Taxus baccata*, respectively. These changes will alter the socio-ecological environment of the fragile Himalaya-Hindu-Kush Mountains which can ultimately result in food and medicine scarcity.

MORPHOMETRICS AND URBAN ADAPTATIONS OF ASIAN PIED MYNA (STURNUS CONTRA) IN RAWALPINDI CITY, PAKISTAN

Sakhawat Ali

Institute of natural and management sciences

Naeem Akhtar ABBASI, Environmental Biology and

Ecotoxicology Laboratory, Department of Environmental

Sciences, Faculty of Biological Sciences, Quaid-e-Azam University, Islamabad ; Riffat Naseem MALIK, Environmental Biology and Ecotoxicology Laboratory, Department of Environmental Sciences, Faculty of Biological Sciences, Quaid-e-Azam University, Islamabad ; Muhammad RAIS, Department of Wildlife Management, PMAS- Arid Agriculture University ; Sajid MEHMOOD, Department of Zoology, Hazara University ; Nouman KHALIQUE, Department of Wildlife Management, PMAS- Arid Agriculture University ; Naveed Ahmed QURESHI, Department of Wildlife Management, PMAS- Arid Agriculture University

Asian Pied Myna (*Sturnus contra*) was first reported in Pakistan at Changa Managa forest plantation in Kasur District in April 1982. Recently, a shift in the populations of pied myna (*S. Contra*) from rural to sub-urban and urban habitat has been noticed. Present study was designed to investigate the extent of expansion of population of pied myna in urban areas of Rawalpindi. For this purpose we conducted rekey surveys to find the potential habitat of pied myna (*S. contra*) and identify its seasonal population trends in the city. A total of five different sampling sites were identified for survey and periodic monitoring. Total these sites mainly consists of human settlement areas where marshes formed by the sanitation water. Point count method was used to estimate the population at selected site and observation was made through binocular (250x) for a period of a whole year. A high concentration of *S. Contra* was observed during the month of November (12.08 ± 1.01), December (12.08 ± 1.01), January (12.08 ± 1.01) and February (12.4 ± 1.16) suggesting some migratory influx during winter months. The average observed population of pied myna was (9.46 ± 0.86) throughout the city. During the whole study period, a stable population of 3-4 pairs at each study site was observed at sites which prefer to developed nest on electric and telephonic poles, feed upon dumped house garbage and animal dungs. Average morphometrics of ten captured individual was as: total length ($23.83 \text{cm} \pm 0.23$), tail length ($7.13 \text{cm} \pm 0.13$), beak length ($2.63 \text{cm} \pm 0.04$), and average weight ($82 \text{g} \pm 1.73$). It is predicted that alongwith feeding and nesting opportunities, marshy vegetation in urban open spaces and hiding places developed in urban construction which provide cover attracts *S. Contra* to adopt in urban environment and it may extends with urban expansion in the coming years.

DO SEX DIFFERENCES INFLUENCE THE ACCURACY OF POPULATION VIABILITY ANALYSIS? THE EXAMPLE OF SURVIVAL RATES IN SPARROWHAWK (ACCIPITER NISUS) IN TWO POPULATIONS IN THE UK.

Alix Aliaga

University of Southern Denmark

Fernando COLCHERO, University of Southern Denmark ; Owen JONES, University of Southern Denmark ; Dalia A. CONDE, University of Southern Denmark

Understanding how survival differs between sexes and among populations of the same species is fundamental for wildlife conservation and management. Demographic studies of wild populations have been challenged by the scarcity of long-term datasets and the difficulty of ageing individuals in the wild. Nevertheless, it is important to understand how differences in survival between the sexes and among sites contribute to overall population growth and species survival. In this work, we focus on sex and site differences in survival for the sexually dimorphic Eurasian sparrowhawk (*Accipiter nisus*) in two Scottish populations. Our dataset was obtained from the Long-term Individual based Time Series (LITS) project and collected by the British ornithologist, Ian Newton. It has the advantage of being a long-term study with a large number of individuals with age and sex information. We used BaSTA (Bayesian Survival Trajectory Analyses) to compare survival rates when we account for sex and site differences. Our preliminary results show that there are age-specific survival differences among sexes and location. Based on these results we test how the accuracy of a Population Viability Analysis (PVA) changes when we account for sex- and site-differences in survival. Although this is a study from only one species, we consider that it is fundamental to further explore how the accuracy of PVAs can change if we incorporate sex differences in demographic behaviour, which can be key for the management of species with sexual dimorphism.

HOW CAN AGRI-ENVIRONMENT SCHEMES COMPLEMENT SEMI-NATURAL HABITAT IN PROTECTED AREAS?

Jamie Alison

University of Liverpool

Simon DUFFIELD, Natural England ; Michael MORECROFT, Natural England ; Rob MARRS, University of Liverpool ; Ilik SACCHERI, University of Liverpool ; Jenny HODGSON, University of Liverpool

Protected areas may be the most important conservation investment to reduce the rate of biodiversity decline. They ensure the persistence of large areas of semi-natural habitat (SNH), and generally support higher abundances of species than the surrounding landscape. In many parts of the world agri-environment schemes (AES) are also implemented to make agricultural land less hostile for wildlife; this process is sometimes referred to as "softening the matrix". Recent research has made it clear that biodiversity responses to AES are mixed across different taxa and regions. The impact of AES management is also dependent on the landscape context. To target AES effectively we need to know whether improvements

over their conventional counterparts are greater when they are well connected to SNH in protected areas. We have tested whether connectivity to SNH improves the effectiveness of AES using a novel field study in north-west Hampshire, UK. Moth surveys were carried out on calcareous grassland reserves and on four ~3km transects running into the arable matrix, sampling both AES and conventional arable field margins. Whilst arable farming clearly decreases macro-moth abundance, our results show substantial overlap between communities on SNH and those on surrounding arable land. We find that a certain proportion of species particularly benefit from SNH, and that connectivity to SNH dictates the effectiveness of AES management for these species. We conclude that to maximise the abundance of specialist macro-moths, investment into AES margins would be optimally allocated close to patches of SNH. However, allocating AES in such a way would not be without its costs. Interestingly, agricultural land at high connectivity to SNH, whether AES or not, is associated with an increased abundance of both specialist and non-specialist insect species. Agricultural management should therefore be considerate of this fact.

HIGH ELEVATION ENDEMICS AND CLIMATE CHANGE: THE FUTURE OF RARE LICHENS IN THE SOUTHERN APPALACHIANS

Jessica Allen

The New York Botanical Garden/The City University of New York Graduate Center

High elevation species worldwide are increasingly threatened by mountain top extinction. The southern Appalachian Mountains, one of the most biologically unique and diverse region of North America, is no exception. An increasingly large body of literature is emerging that documents this pattern. Mountain top extinction in this region warrants considerable attention as it is a threat to many biological communities and species. Lichens, symbioses between fungi and algae, are particularly abundant and diverse in the southern Appalachians, including a number of species that are narrowly endemic to the high elevations. In this study, I documented the current distributions of nine endemic lichens throughout the high elevations in the southern Appalachians and used niche modeling to predict how much suitable habitat will exist within their current ranges by 2050 and 2070. Considerable data exist for lichen distributions in one small area of the southern Appalachians, the Great Smoky Mountains National Park (GSMNP), so I performed a focused inventory of the target species in high elevation ridges outside of GSMNP. To conduct the modeling in Maxent I used the resulting localities from my field work and locality data from collections held at The New York Botanical Garden. During my field work I located at least one previously undocumented population of each target species on high elevation ridges outside of GSMNP. Regardless

of the climate model and carbon dioxide concentration used, the Maxent models predict little to no suitable habitat for all species within their current ranges by 2070. The implications of these results and future research directions in light of them will be discussed.

TRAGEDY OF THE EXCLUDED: DEFINING AND ASSESSING RESOURCE ACCESS IN MARINE CONSERVATION

Margaret Allen

University of Washington

A commonly observed paradox in conservation is that restriction of people's access to nature and natural resources may protect ecosystem health, but sometimes decreases the wellbeing of local people and can invite conflict and reduce people's willingness to protect resources. At a middle ground between complete protection and unrestricted commercial use is ecosystem-based management (EBM), which strives to maximize the overall wellbeing of both people and ecosystems. An important domain of human wellbeing to track for the purposes of EBM is resource access, or the ability to gain and maintain uses and benefits of the natural environment. Access does not simply refer to the physical and legal ability to benefit from resources; it can also depend on political power, social capital, and economic capacity. Understanding who is allowed to use what, in what ways, and when also reflects other related dimensions of wellbeing, such as food security, meaningful livelihoods, fairness, and sovereignty. This paper reports on the results of a systematic process to identify indicators of resource access to inform US marine and coastal management. Based on a comprehensive literature review, 82 candidate indicators were evaluated according to predefined screening criteria. Top scoring indicators include objective and subjective measures of shoreline access, fishing permits and landings, and access to seafood markets. This working selection of indicators may be used to inform a range of EBM goals, from biodiversity conservation to poverty alleviation. The related literature suggests that measuring these indicators alone will not lead to better marine management, however; local communities must be involved in defining and implementing what counts as secured rights and access to natural resources, and how this relates to their own wellbeing and sustainable marine conservation.

194 TRAGEDY OF THE EXCLUDED: DEFINING AND ASSESSING RESOURCE ACCESS IN MARINE CONSERVATION

147 SYSTEMATIC MONITORING AND REPORTING OF ESSENTIAL BIODIVERSITY VARIABLES ON NEW ZEALAND'S PUBLIC CONSERVATION LAND

Robert Allen

Landcare Research

Peter BELLINGHAM, Landcare Research ; David Forsyth, Arthur Rylah Institute for Environmental Research ; Andrew GORMLEY, Landcare Research ; Sean HUSHEER, New Zealand Forest Surveys ; Catriona MACLEOD, Landcare Research ; Norman MASON, Landcare Research ; Adrian MONKS, Landcare

Research ; Sarah RICHARDSON, Landcare Research ; Elaine WRIGHT, Department of Conservation

There is considerable interest in designing and implementing monitoring systems that can report on the status and trend of Essential Biodiversity Variables at large spatial scales (e.g. nationally). The New Zealand Department of Conservation (DOC) began implementing systematic monitoring and reporting of some Essential Biodiversity Variables on New Zealand's public conservation land (~30% of New Zealand's land area) in 2011. DOC's Biodiversity Monitoring and Reporting System (BMRS) reports on three components of ecological integrity: indigenous dominance, species occupancy, and ecosystem representation. Building on a carbon monitoring network established in New Zealand during the early 2000s, the BMRS involves monitoring at plots on an 8-km grid superimposed over New Zealand's public conservation land, including North, South and Stewart Islands and offshore islands. The monitoring gathers information on five measures: Size-class structure of canopy dominants; Representation of plant functional types; Distribution and abundance of exotic weeds; Distribution and abundance of exotic pests; and Assemblages of widespread animal species - Birds. There are 1311 plots, with 20% monitored annually on a rolling five-year cycle. This presentation will highlight key steps in the design and implementation of the BMRS, and demonstrate how the data can be used to report annually on the trend and status of New Zealand's biodiversity.

THE ROLE OF SCALE AND SPATIAL PATTERNS IN PEOPLE'S ATTITUDES AND PERCEPTIONS OF PROTECTED AREAS

Teri Allendorf

University of Wisconsin-Madison
Volker RADELOFF, University of Wisconsin-Madison ; Nicholas KEULER, University of Wisconsin-Madison

Social dimensions of protected areas are an important aspect of protected area success. However, it is difficult to capture social dimensions of protected areas at the broad scales at which conservation planning is typically conducted. Our goal was to identify spatial patterns in people's attitudes toward protected areas across a range of scales. We sought to understand at which scale people's attitudes differ and to uncover patterns in people's relationships with protected areas. We conducted 3573 interviews in 140 villages in the vicinity of three protected areas in Nepal and four protected areas in Myanmar. We identified at which spatial scale the amount of variability in attitudes and perceptions of benefits and problems of the protected areas was largest. Our results showed that negative perceptions, such as problems with wildlife and natural resource extraction, varied the most among villages, our finest scale. In contrast, positive

perceptions, which included benefits such as conservation and ecosystem services, recreation and aesthetics, and extraction, tended to vary the most between countries, our broadest scale. Protected area benefits and problems associated with protected area management varied the most among protected areas, our intermediate scale. These results suggest that systematic patterns in park-people relationships exist at broad scales and that interventions to improve the park-people relationship may be most effectively targeted at different scales. For example, positive perceptions may be fostered with interventions at the national level, such as national media campaigns or national educational curricula, while negative perceptions may be most effectively mitigated through interventions targeted at specific villages and conflicts.

THE ROLE OF AGENCY IN STRUCTURING COLLABORATION NETWORKS IN NATURAL RESOURCE MANAGEMENT

Jorge G. Álvarez-Romero

ARC Centre of Excellence for Coral Reef Studies, James Cook University [INSTITUTE] National Environment Research Program Northern Australia Hub, Charles Darwin University
Vanessa ADAMS, ARC Centre of Excellence for Coral Reef Studies, James Cook University [INSTITUTE] Research Institute for the Environment and Livelihoods, Charles Darwin University [INSTITUTE] National Environment Research Program Northern Australia Hub, Charles Darwin University [INSTITUTE] School of Biological Sciences, The University of Queensland ; Katie MOON, Institute for Applied Ecology/Institute for Governance and Policy Analysis, University of Canberra ; Örjan BODIN, Stockholm Resilience Centre, Stockholm University ; Michaela SPENCER, Research Institute for the Environment and Livelihoods, Charles Darwin University ; Deborah BLACKMAN, School of Business, University of New South Wales

Collaborative networks are widely suggested as a key factor affecting the success of natural resource management (NRM) and conservation projects. However, our knowledge of the factors affecting their formation and structure is limited. Collaboration can emerge from the need to achieve common goals (e.g. reduce soil erosion), but also as a consequence of stakeholders being brought together by having different (even conflicting) stakes in a common resource (e.g. farmers and conservationists). The way in which different stakeholders engage with each other (or not) can be examined as social networks. Social network analysis can be useful to study social relationships and interpreting their implications for NRM, but implicitly assumes that individuals have a level of choice (agency) in establishing relationships. Yet, such interactions are not always chosen voluntarily, thus demanding the study of agency and its relation to the structure of social networks. Our study explores the role of agency and the nature of

relationships in NRM collaboration networks in northern Australia. We identified and mapped five types of collaboration networks among organizations, and assessed organizational characteristics that drive the formation of collaborative ties. We used repertory grids to characterize organizations and explain their relationships and position in those networks where agency seems to be prevalent. We found that agency was present in some networks and identified attributes of organizations (e.g. transparent, responsive) associated with the choice to collaborate with them. Through the integration of both analytical methods, we were able to better understand the relationships among NRM organizations, and identify collaboration types which are positively associated with individual agency and those which likely do not. Our study presents a novel approach that responds to increasing calls for rigorous investigations of the nature of relationships within social networks.

DELTAMETHRIN INDUCED CYTOTOXICITY AND OXIDATIVE DAMAGE TO THE FRESHWATER CILIATE PARAMECIUM TETRAURELIA

Rima Amamra

Laboratory of Cellular Toxicology, BADJI MOKHTAR UNIVERSITY

Mohamed Réda DJEBAR, Laboratory of Cellular Toxicology, BADJI MOKHTAR UNIVERSITY ; Ouisse MOUMENI, Laboratory of Cellular Toxicology, BADJI MOKHTAR UNIVERSITY ; Amel ALAYAT, Laboratory of Cellular Toxicology, BADJI MOKHTAR UNIVERSITY ; Hadjer OTMANI, Laboratory of Cellular Toxicology, BADJI MOKHTAR UNIVERSITY ; Sana BENOSMANE, Laboratory of Cellular Toxicology, BADJI MOKHTAR UNIVERSITY ; Marwa BENAMARA, Laboratory of Cellular Toxicology, BADJI MOKHTAR UNIVERSITY ; Houria BERREBBAH, Laboratory of Cellular Toxicology, BADJI MOKHTAR UNIVERSITY

The problem of environmental contamination by the excessive use of organics cannot be neglected. Extensive application is usually accompanied with serious problems and health risk. It is established that many chemicals, in common use, can produce some toxic effects on biological systems through their mode of action or by production of free radicals that damage all cell compounds. Deltamethrin, a widely used type II pyrethroid insecticide, is one of the most common contaminants in freshwater aquatic system. In this study, we investigate the effects of deltamethrin exposure on the induction of cytotoxicity and oxidative damage to the freshwater ciliate *Paramecium tetraurelia*. After the exposure of paramecium cells to the insecticide, we followed up the growth kinetics, generation time and generation number. Also, we studied the variation in biomarkers of stress such as: Malondialdehyde (MDA), glutathione (GSH), glutathione-S-transferase (GST) and catalase (CAT). Moreover, respiratory

metabolism was monitored. Our results showed a significant decrease in the proliferation of cells correlated by the decrease in generation number and the increase in generation time. Also, we noted an inhibition in the percentage response. Deltamethrin exposure has led to a lipid peroxidation supported by a significant increase in (MDA) level which might be associated with decreased level of (GSH). (GST) and (CAT) activities, antioxidant enzymes, were significantly induced. The response was concentration dependent. A strong disturbance in respiratory metabolism was observed. In summary, deltamethrin is highly toxic to the freshwater ciliate *Paramecium tetraurelia*. Exposure to low concentrations showed significant adverse on growth accompanied with the induction of oxidative damage supported by the alteration of respiratory metabolism. Keywords: Deltamethrin; *Paramecium tetraurelia*; Contamination; Lipid peroxidation; Oxidative stress; Respiratory metabolism.

SPATIAL AND TEMPORAL CHANGES IN THREATS TO STEPPES IN TURKEY

Didem Ambarli

Duzce University

Ozge BALKIZ, Nature Conservation Centre ; Aydan OZKIL, Nature Conservation Centre

To halt loss of biodiversity, it is vital to identify and describe threats accurately. This study reveals a good example of dynamic nature of threats to steppes of Anatolia, Turkey that are used by various ways and intensities for thousands of years and suffering from tragedy of commons at the same time. Information from various sources have been collated to gather information about threats such as literature on pollen records, historical books, census data, questionnaires and field survey data. Among various types of threats have been identified, grazing and ploughing were found to be the most prominent threats. But their patterns and intensities have changed in space and time as land abandonment and a major change in the use of freshwater resources for agriculture have taken place in the recent decades. In addition, there are novel threats such as residential development, afforestation in roadsides, village vicinities and eroded hillsides; mining and road constructions in remote hills. Furthermore, the future effects of climate change are being questioned as experiments around the world are implying that semi-arid regions came out to be less resistant. The perception of threats is also subject to change in terms of the profession questioning. There is a big difference in identification of threats between academicians doing research on steppe biodiversity and officers actually protecting it: officers of Department of Nature Conservation and Natural Parks do not see climate change, development and afforestation as major threats but poaching, overgrazing due to transhumant grazing, mining and agricultural pollution are their main concern. We propose to develop a national project

to foster steppes as conservation targets and conduct a large scale field survey supported by other information sources to understand the true extent and magnitude of threats to steppes, as the first step to conserve steppes.

FEEDING ECOLOGY OF EURASIAN LYNX FROM MEDITERRANEAN TO CAUCASIAN ECOSYSTEM: SPECIALIST DIET AND IMPLICATIONS FOR CONSERVATION

Huseyin Ambarli

Wildlife Ecology and Management, Faculty of Forestry, Duzce University

Eurasian lynx (*Lynx lynx*) is one of the most widespread, but the least studied felid species in Turkey. I studied its diet by collecting scats in two different ecosystems of Turkey from Mediterranean and Black Sea, and conducted camera trap studies from 2007 to 2013 to assess the species status. Scat samples (n=101) were washed, identified with frequency of occurrences by reference samples previously collected. I found that Eurasian lynx main prey was brown hares and occurrences decreased from 95% in Mediterranean to 75% in lesser Caucasia. The number of prey items gradually increased through southern to northern ecosystems. In northern study area diet shifted to the small mammals, avian species and carnivore species including lynx. The detection rates of brown hares also sharply decreased by camera traps at the northern ecosystem that complied with shifting of prey items because there are more predators in lesser Caucasia compared to Mediterranean ecosystem. Although Eurasian lynxes feeds mainly on roe deer in Europe, their foraging adaptability provided to survive in different ecosystems by feeding with smaller mammals and bird species in Turkey. The study showed that Eurasian lynx diet is mainly specialist diet similar to Iberian lynxes, and revealed its status in Turkey. Therefore, any conservation program of Eurasian lynxes in south western Asia should also include the status of brown hares, and impact of hunters on them to implement effective conservation plans.

PECULIAR REPRODUCTION IN IBERIAN LYNX (LYNX PARDINUS): WHAT STANDS BEHIND CORPORA LUTEA PERSISTENCE?

Olga Amelkina

Leibniz Institute for Zoo and Wildlife Research
Lina ZSCHOCKELT, Leibniz Institute for Zoo and Wildlife Research ; Stefanie KOSTER, Leibniz Institute for Zoo and Wildlife Research ; Rodrigo SERRA, Iberian lynx conservation breeding program ; Arne SÖDERBERG, National Veterinary Institute ; Beate C BRAUN, Leibniz Institute for Zoo and Wildlife

Research ; Katarina JEWGENOW, Leibniz Institute for Zoo and Wildlife Research

The Iberian lynx is considered the most endangered felid in the world with roughly 300 individuals left in the wild. To support and restore its populations, a breeding program has been initiated, coupled with extensive research on lynx reproduction. Studies revealed that lynx genus presents a peculiar reproduction pattern, not found in any other mammalian species studied so far – corpus luteum (CL), a transient gland which supports pregnancy via progesterone secretion, persists in the ovary for over two years. We hypothesize that persistent (per) CLs ensure monoestrus in lynxes. Therefore, if a pregnancy fails to occur with the first mating, Iberian lynx is physiologically excluded from the breeding pool till the next year. As such reproductive characteristic can greatly reduce the success of breeding programs, it is essential to gain a profound knowledge on the mechanisms behind perCL. To do so, we studied the expression of potential luteotropic and luteolytic factors in perCL of Iberian and Eurasian lynxes, as well as in CL of domestic cat to establish a common luteal course in felids. Investigated factors included agents of programmed cell death (apoptosis: Bcl-2, Bax, caspase-3, Fas, tumor necrosis factor alpha and its receptors) and commonly luteotropic prolactin with its receptor. Samples were obtained after ovariectomy (two Iberian lynxes, health reason; domestic cats, shelters and clinics) or postmortem (Eurasian lynx, roadkill and hunting). We revealed the presence of pro-apoptotic factors (Bax, caspase-3, Fas) in perCL, contrary to their morphological persistence. Here, Bcl-2 might be the factor to rescue perCL from regression. Moreover, prolactin was still present in perCL of lynxes outside the breeding season. We propose prolactin as an essential factor that secures CL persistence in lynxes. The study was funded by DFG (Je163/11-1) and DAAD (A/10/86242). Iberian lynx samples were provided by Environmental Council of the Government of Andalusia and ILCBP.

DEMOGRAPHY OF EPOMOPHORUS GAMBIANUS IN GHANA

Kofi Amponsah-Mensah

Department of Animal Biology and Conservation Science, University of Ghana

Andrew CUNNINGHAM, Institute of Zoology, Zoological Society of London ; James WOOD, Disease Dynamics Unit, University of Cambridge ; Yaa NTIAMOA-BAIDU, Centre for African Wetlands, University of Ghana

Epomophorus gambianus is a widespread African fruit bat with ranges throughout much of West Africa and is reported to roost in loose colonies of a few individuals in a variety of habitats. The species is hunted as bushmeat within Ghana and other parts of West Africa. A variety of zoonotic viruses have been reported from the species, thus making it a potential public health

risk. Despite this, the population dynamics and demographic parameters of the species are largely unknown. The study involved mapping of the distribution of *E. gambianus* in Ghana, estimation of birth rates, population structure, survival probability and colony size changes. A total of 29 colonies of *E. gambianus* either isolated or sympatric with other species have been identified, the largest comprising ca. 5000 bats in the Ve-Golokuati town (Volta Region) which was the focus for the detailed demographic studies. The initial population of this colony declined over the 21-month study period to between 2000-3000 individuals, with peak numbers occurring in March and September. Data from the 1,702 individuals captured showed no significant variation in age categories, but the population was significantly male dominated (58.5% males; $\chi^2 = 49.4$, $df=1$, $p=0.05$). Pregnancy occurred between October-February and May-August with peaks in January and July. Based on an assessment of the proportion of adult females pregnant in each breeding period, birth rate is estimated to be 1.8 young per female per year. Attempts to estimate survival probability using Capture-Mark-Recapture (CMR) with PIT tag marking technique were unsuccessful, as recapture rates were too low (~2% of marked individuals) to provide any robust estimation. Future studies will focus on trying other methods like radio tracking to provide further understanding of movements and changes within the population.

STILL SPOTTED? SETTING A GLOBAL BASELINE FOR THE LEOPARD, PANTHERA PARDUS

Corey Anco

Fordham University

Joseph LEMERIS JR., Duke University ; Andrew JACOBSON, Zoological Society of London ; Luke DOLLAR, National Geographic Society

A basic tenet of leopard biology, its secretive and solitary nature, cuts both ways in its conservation. The leopard is a remarkable felid with the greatest known range of any cat and, appropriately, a wide habitat tolerance. The leopard can survive from tropical forests to deserts, sea level to 5,000 m on Mt. Kilimanjaro, and from undisturbed forests to urban parks in megacities. While the shy habits of the leopard certainly assist in survival, it also complicates biological study and baseline knowledge on its population and distribution. While the leopard is listed as "near threatened" by the IUCN, its overall population is declining and there are nine recognized subspecies, some of which are critically endangered. We gather an unprecedented volume of current and historical information on leopard distribution and status to create the first global map of historical leopard distribution. Additionally, we provide an updated current global range map depicting areas with known resident populations or fragmented, transient ones. This enables the first comprehensive estimate of range loss for the leopard. However, global, and in many cases, even

regional population estimates are still impossible given current data limitations. Although we are unable to provide updated population and distributional information for some regions, we assess leopard status throughout the world. In addition, we assess the quality of population and range information. Scientific and conservation focus on leopards is increasing yet still patchy; we aim to provide a comprehensive, global baseline that will stimulate and prioritize future research and conservation effort.

VITAL SIGNS: SUSTAINING ECOSYSTEM SERVICES IN THE CONTEXT OF AGRICULTURAL INTENSIFICATION AND CLIMATE CHANGE

Sandy Andelman

Conservation International

Agricultural intensification is critical to meeting the growing demand for food. Agriculture is also the greatest threat to nature, but sustained agricultural production also depends on essential ecosystem services nature provides. Two thirds of the world's arable land not currently in agriculture is in Sub-Saharan Africa, so the world is focused on Africa as the world's next breadbasket. To prevent unintended consequences of increased agricultural intensification for biodiversity and ecosystem services in Africa, a broader, more holistic approach to agricultural development and management is needed. This requires that the set of metrics used to measure and track the success of agricultural development expands from a narrow, sector-specific set (e.g., crop yield, household income) to an integrated set that reflects the interconnectedness of food security, water security, climate security, ecosystem health and human wellbeing. The Vital Signs system has a statistical sampling frame that integrates biophysical and socioeconomic domains. It spans all of the scales that are critical for agricultural decision making, from a household, to a farm, a landscape, to a nation. The system provides a strategic set of metrics that can quantify, effectively and efficiently, over time, the critical tradeoffs and synergies among ecosystem services, livelihoods and agricultural production. These tradeoffs are illustrated using the Vital Signs resilience index and data from the Southern Agricultural Growth Corridor of Tanzania. The index provides novel insights into which types of landscape interventions have the greatest likelihood of sustaining both crop production and ecosystem services in the face of increasing climate variability and shocks. The system has already been adopted by three African countries - Tanzania, Ghana and Uganda - and is poised to expand further, with potential to fill the data gap for tracking the Sustainable Development Goals in developing countries.

CONSERVING NATURE'S STAGE: A GEOPHYSICAL APPROACH FOR IDENTIFYING CLIMATE RESILIENT SITES IN THE SOUTHEASTERN US

Mark Anderson

The Nature Conservancy

Melissa CLARK, The Nature Conservancy; Arlene OLIVERO, The Nature Conservancy; Analie BARNETT, The Nature Conservancy

In light of climate change, conservationists need planning methods designed to conserve the maximum amount of biodiversity while allowing species and communities to rearrange in response to the climate. We developed such an approach for the Southeast US. First we identified the abiotic factors correlated with species diversity patterns and stratified the region into 29 geophysical settings (combinations of bedrock, soil, and elevation zones). Next, within each geophysical setting we located sites that had two key characteristics: 1) relatively complex topography and large elevation ranges that increased the number of available micro-climates, 2) highly connected natural cover that allowed species to access the local climates. The former was estimated using a 30 m landform model and spatial estimates of wetland density. The latter was estimated using a resistant kernel model applied to a landcover based resistance layer. We scored sites based on these components and hypothesized that the high-scoring sites will maintain their existing species longer relative to other sites of the same geophysical setting. Using overlays on the high-scoring sites, we tabulated the degree of rare species capture (65%) and overlap with conservation sites chosen for their high quality biodiversity features (47%). The correspondence between the biodiversity sites and the high scoring geophysical sites reveal places likely to be important to both current and future diversity.

WOOD-INHABITING BEETLES IN LOW STUMPS, HIGH STUMPS AND LOGS ON BOREAL CLEAR-CUTS: IMPLICATIONS FOR DEAD WOOD MANAGEMENT

Jon Andersson

Department of Wildlife, Fish, and Environmental Studies

Joakim HJÄLTÉN, Department of Wildlife, Fish, and Environmental Studies; Mats DYNESIUS, Department of Ecology and Environmental Science

The increasing demand for biofuels from logging residues requires serious attention on the importance of dead wood substrates on clear-cuts for the many forestry-intolerant species. In particular, the emerging harvest of low stumps motivates further study of these substrates. On ten clear-cuts we compared the species richness, abundance and species composition of saproxylic beetles hatching from low stumps, high stumps and logs of Norway spruce. By using emergence traps we collected a total of 2,670 saproxylic

beetles among 195 species during the summers of 2006, 2007 and 2009. We found that the species assemblages differed significantly between high stumps and logs all three years. The species assemblages of low stumps, on the other hand, were intermediate to those found in logs and high stumps. There were also significant difference in species richness between the three examined years, and we found significant effect of substrate type on richness of predators and fungivores. As shown in previous studies of low stumps on clear-cuts they can sustain large numbers of different saproxylic beetles, including red-listed species. Our study does, in addition to this fact, highlight a possible problem in creating just one type of substrate as a tool for conservation in forestry. Species assemblages in high stumps did not differ significantly from those found in low stumps. Instead logs, which constitute a scarcer substrate type on clear-cuts, provided habitat for a more distinct assemblage of saproxylic species than high stumps. It can therefore be questioned whether high stumps are an optimal tool for nature conservation in clear-cutting forestry. Our results also indicate that low stumps constitute an equally important substrate as high stumps and logs, and we therefore suggest that stump harvesting is done after carefully evaluating measures to provide habitat for saproxylic organisms.

SHORT-TERM RESPONSE TO STUMP HARVESTING BY THE GROUND FLORA IN BOREAL CLEAR-CUTS

Jon Andersson

Department of Wildlife, Fish, and Environmental Studies

Mats DYNESIUS, Department of Ecology and Environmental Science; Joakim HJÄLTÉN, Department of Wildlife, Fish, and Environmental Studies

We conducted a study in the Southern and Middle Boreal zone in northern Sweden to examine whether stump harvesting causes extra soil damage compared to conventional forestry and if stump harvesting affects the assemblage, species richness and occurrence of individual species of vascular plants and bryophytes in boreal clear-cuts. We recorded the occurrence of all species of bryophytes, vascular plants and the cover of soil disturbance in 50 X 50 cm sample plots on 20 clear-cuts, 22 - 49 months (mean 32 months) after clear-cutting. All clear-cuts were slash harvested and scarified and half of the clear-cuts were in addition stump harvested. The added effect of stump harvesting was assessed by comparing stump harvested clear-cuts with clear-cuts that had not been stump harvested. We found that the additional use of stump harvesting caused an increase in the cover of soil damages compared to conventional harvesting with only slash harvesting and scarification. Also, we found significant negative effects of stump harvesting on the plot occupancy (number of 0.25 m² plots occupied in each clear-cut) of four species of the most common boreal plant species (the mosses

Hylocomium splendens and *Pleurozium schreberii* the dwarf shrubs *Vaccinium myrtillus* and *Vaccinium vitis-idaea*). *V. vitis-idaea* had almost 80% lower plot occupancy in the stump harvested clear-cuts than in the controls. Some species did also respond positively to stump harvesting. Our results show that harvesting of low stumps can have both negative and positive short-term effects on certain common species of vascular plants and bryophytes. However, the relatively modest increase of soil damage caused by stump harvesting in contrast to the heavy impact on e.g. *V. vitis-idaea* suggests stumps, with their slightly elevated sockets, may contribute to the survival of at least some plants during the clear-cut phase.

SOCIAL SCIENCE PERSPECTIVES IN ECOSYSTEMS MANAGEMENT AND CONSERVATION IN KENYA

Dymphina Andima

Kenya Agricultural and Livestock Research Organization

Social sciences as a discipline and ecosystems management involves working with people and communities in order to assess levels of ecosystems management and empower them with knowledge and skills for better conservation of natural resources. However, there are challenges faced in the process of the introduction of better management practices in ecosystems conservation due to various factors such as slow or lack of adoption, perceptions and attitudes, group management and establishment of by-laws at the local level for ecosystems management. A qualitative baseline survey conducted in neighbouring communities of 2 river catchments in Southwest Kenya shows that ecosystems management and conservation depends on several factors such as labour allocation by gender, access and control over resources as well as the extent at which farmers know and practice ecosystems management such as soil and water conservation, planting trees, riverbank, water sources and wetland protection, establishment of indigenous tree nurseries and planting trees. The results indicate that in 6 demarcated blocks, surveyed, 90 percent of the farmers knew and were practicing soil and water conservation measures in 2 blocks as compared to 0-30 percent of the same farmers who knew and were practicing riverbank, water sources and wetland protection. In terms of labour allocation, River bank, water sources and wetland protection was the domain of male adults and male children throughout the year across the 6 blocks and agroforestry practices were done by all gender in one of the blocks as compared to the others. Fuelwood and energy saving was practiced by Female adults and sometimes female children. However, access and control over resources such as land was a male domain across the blocks. The current knowledge and practice by farmers in ecosystems management and conservation can be exploited to achieve maximum farmer benefits both socially and economically.

PROMOTING BAMBOO UTILIZATION FOR RESOURCE CONSERVATION IN THE COASTAL STRIP OF SOUTHERN NIGERIA

Elizabeth Andrew-Essien

University of Calabar, Calabar

Esekong ANDREW, University of Calabar, Calabar ; Enoabasi ANWANA, University of Uyo

The consequences of climate-change induced trends on the vulnerable coastal fringes of Africa remain critical with particular reference to human security and livelihood options. This paper seeks to evaluate the distribution and value-awareness of bamboo as a natural resource for human development in diverse sectors. Adopting a comparative format, three Local Government Areas are delineated from Cross River and Akwa Ibom states respectively, for study to examine the awareness level of communities to the potential multiple use values of bamboo as a natural resource that can be sustainably managed for ecological and human benefits. Using purposively designed semi-structured checklist for the focus group discussions with bamboo cultivators, construction engineers, craftsmen, traders and other end-users, the study obtains, respondent's perspectives on the use value of bamboos, the benefits and challenges that surround livelihood security development in the face of other competing available options. Findings indicate a wide level of awareness to the multiple-use values and potentials of bamboo within the area to improve and sustain livelihoods. The challenges indicated include, amongst others, low economic value and pricing of bamboos, including the dearth of appropriate technology to effectively harness the benefits to be derived from the resource. Recommendations include intensive education on the multi-use value of bamboos, regulated harvesting systems to prevent premature harvesting and wastage, recycling of cut-off particles to limit waste and proper finishing of ornamental bamboo products to up-grade the economic value. Key Words: Climate Change, conservation, ecology, bamboo, challenges

76-EVALUATING THE BIODIVERSITY IMPACTS OF COMMUNITY CONSERVATION PROGRAMMES IN MADAGASCAR

Herizo Andrianandrasana

Durrell Wildlife Conservation Trust[INSTITUTE]Biodiversity Institute, Department of Zoology, University of Oxford
Richard LEWIS, Durrell Wildlife Conservation Trust ; Lance WOOLAVER, Durrell Wildlife Conservation Trust ; Anselme TOTO VOLAHY, Durrell Wildlife Conservation Trust [INSTITUTE]Durrell Wildlife Conservation Trust ; Bellarmin RAMAHEFASOA, Durrell Wildlife Conservation Trust ; Bary Jean RASOLONJATOVO, Durrell Wildlife Conservation Trust ; Robert BOUROU, Durrell Wildlife Conservation Trust ; Fidy Bruno RALAINASOLO, Durrell

Wildlife Conservation Trust ; Ony RABEARIVOLOLONA, Durrell Wildlife Conservation Trust ; Richard YOUNG, Durrell Wildlife Conservation Trust

Improving management of natural resources in Madagascar is challenging since conservation NGOs have to use much of their time to mitigate human pressures and improve local communities' wellbeing. People rely heavily on natural resources for their survival and the government has limited resources to enforce laws. Impacts of conservation actions are poorly understood and their measurement is rarely chosen as a priority. Since 1997, Durrell has developed and implemented a widely known community-based conservation programme in 109 villages from 6 of its 9 key sites in Madagascar. This programme includes regular participatory ecological monitoring and weekly village patrols carried out by 461 local monitors. The community based conservation project aimed to save some of the world's rarest species and their threatened ecosystems. However at the same time they addressed social issues at the local level and tried to improve human wellbeing conditions by focussing on improvement of primary education, social cohesion and public health and reduction of inequality. We performed a 30 years retrospective evaluation (1982-2013) of the effectiveness of Durrell's community conservation projects by comparing key environmental and social indicators between the 109 project villages and 109 control villages. These indicators include threat indicators such as fires, forest loss, forest fragmentation and invasion of exotic plants and biodiversity features such as area of good quality habitat and species density. Results of the studies will inform about the success of each conservation strategy and inform decision making through the regional development plan. Findings also will help clarifying the role that can be played by the community approach in the creation of protected areas targeted by the government.

110-COMMUNITIES COUNT: PARTICIPATORY ECOLOGICAL MONITORING APPROACHES IN ACTION IN MADAGASCAR

Herizo Andrianandrasana

Durrell Wildlife Conservation Trust [INSTITUTE] Biodiversity Institute, Department of Zoology, University of Oxford
Richard LEWIS, Durrell Wildlife Conservation Trust ; Richard YOUNG, Durrell Wildlife Conservation Trust ; Andry TOTO VOLAHY, Durrell Wildlife Conservation Trust ; Bellarmin RAMAHEFASOA, Durrell Wildlife Conservation Trust ; Robert BOUROU, Durrell Wildlife Conservation Trust ; Bary Jean RASOLONJATOVO, Durrell Wildlife Conservation Trust ; Fidimalala Bruno RALAINASOLO, Durrell Wildlife Conservation

Trust ; Ony RABEARIVOLOLONA, Durrell Wildlife Conservation Trust ; Lance WOOLAVER, Durrell Wildlife Conservation Trust

Since 2001 Durrell Wildlife has developed the participatory ecological monitoring approach with the local communities and regional public services to annually collect data on key species, habitats and the threats to the biodiversity. This is being done in the wetlands of Lake Alaotra and the dry forests of Menabe in areas where the local communities have been given the legal rights to environmentally manage the neighbouring natural habitats (public-domain lands). The results of the monitoring are used in an environmental inter-village competition whereby prizes (development projects) are distributed to participating communities. Between 2007 and 2009 we compared the effectiveness of community led monitoring and the rigorous scientific monitoring and we did not find any significant difference on key indicators. In 2011 the participatory ecological monitoring approach has been expanded to become the largest village patrol project in the country. We engaged 461 local monitors known as local foresters committee to collect biodiversity and pressures data in three more key conservation sites: Nosivolo River, Manombo rainforest and Baly Bay National Park. Local foresters committee are composed by 6 volunteers per village. Thanks to supports from the Regional Environmental service, those local monitors received technical training about data collection and reporting system. They were given uniform, camera, telephone and simple equipments to facilitate their work. A large public meeting attended by local authorities, regional Forests and Fishery services and partners, followed by a traditional communal meal has been organised every three month in each village to discuss results of monitoring and link to decision making. Our work has shown that participatory ecological monitoring is a feasible and advantageous approach to reinforce conservation actions in developing countries like Madagascar.

ID 38: CHANGING THE INCENTIVES FOR BUSHMEAT HUNTING IN NORTHEASTERN MADAGASCAR

Danamona Andrianarimanana

University of California-Berkeley
Christopher Golden, Wildlife Conservation Society/Harvard School of Public Health

Wildlife consumption can be viewed as an ecosystem provisioning service because of wildlife's ability to persist under sustainable levels of harvest. Using longitudinal survey methods, micro-economic analytical techniques, and robust epidemiological study designs to determine the health and economic value of subsistence wildlife harvest, we can begin to understand incentives for bushmeat hunting. Heightened monitoring and enforcement of hunting could increase the costs of harvesting and thus elevate the price and reduce

consumption of wildlife. Effective monitoring would incur a 66% reduction in the biomass of wildlife consumed. Increased enforcement would therefore be beneficial to biodiversity conservation but could limit local people's food supply. On average, the value of wildlife provisioning represented 57% of annual household cash income in local communities from the Makira Natural Park and Masoala National Park. In past work, we have demonstrated a nearly 30% increase in the incidence of anemia given loss of access to wildlife resources. In our current work, we will be investigating the value of wildlife to micronutrient status (vitamin A, vitamin B12, iron, zinc and fatty acid profiles). Ongoing interventions in our landscape include sustainable chicken husbandry promotion and mobile health clinics to simultaneously address the challenges of food security, lack of health care infrastructure and trends in environmental degradation from agricultural extensification and wildlife harvest.

THE CHALLENGE OF ADDRESSING WILDLIFE AND HUMAN DEMANDS: INCORPORATING MAMMALS CONSERVATION AND BIOFUELS DEVELOPMENT IN LAND USE PLANNING.

Cintia Camila Silva Angelieri

University of São Paulo

Marcelo Pereira SOUZA, University of São Paulo

The increased demand for the conversion of natural habitats to agricultural areas is a major threat to biodiversity and part of this demand is due to the necessity of energy generation by biofuels. Therefore, it is challenging to address wildlife conservation in a climate changed world demanding for food and energy. It is especially challenging to deal with mammals that require large territories. This study considered Species Distribution Models (SDM) techniques associated with decision-support tools to address land use planning in the most human modified landscape in Brazil (São Paulo State, Southeast, Brazil). Three endangered large mammals (i.e. Puma concolor, *Leopardus pardalis* and *Chrysocyon brachyurus*) occurrence records (2001-2012) and environmental variables (bioclimatic, topographic and landscape related) were modeled using Maximum Entropy algorithm (Maxent 3.3.3.k) and SDMtoolbox (ArcGIS 10.1). The decision-support tool Zonation has been successfully applied in a multi-species spatial prioritization approach to identify priority areas for conservation in the study area. Zonation will be also applied by March 2015 to evaluate conservation options under two realistic biofuel scenarios in the central region of São Paulo State (Tietê-Jacaré watershed): 1. current land use scenario and 2. next future land use scenario (GEOMOD model applied projecting sugarcane expansion by 2019). The results will explicitly show the overlap of areas proposed for biofuels development with areas of high conservation priority. It is important to identify land use planning opportunities

and conflicts in the study area. Also, it might serve as a model to guide similar process for others species and other environmental impacts world-wide. This study makes an important contribution to land use planning for conservation, dealing with threats and their likely impacts on biodiversity through explicit incorporation of uncertainty into decision-making process.

HABITAT CONSERVATION PRIORITY: A FLORISTIC APPROACH APPLIED TO MEDITERRANEAN WETLANDS

Claudia Angiolini

University of Siena

Daniele VICIANI, University of Florence ; Gianmaria BONARI, University of Siena ; Lorenzo LASTRUCI, University of Florence

Finding strategies to produce priority lists for conservation purposes is a very important issues, particularly in biodiversity "hot-spots" such as the Mediterranean basin, where biodiversity loss is a critical threat. A relevant recognition of plant communities importance for conservation purposes was established with their inclusion into the "Habitats Directive" (HD; 92/43 EEC), that relates habitat typologies to plant community syntaxonomical units. Thus, the use of plant communities as a proxy for habitats, ecosystems or ecological communities can provide a solid base to perform conservation priority lists. However, habitat definitions in HD lead to several inaccuracies in local habitat characterizations because of its central-northern European focus. Several wetland plant communities (and their corresponding habitats), rare in the Mediterranean basin, are not included in the HD. This study aims to propose some criteria and a procedure to assess the conservation importance of habitats. It deals with plant community types at the alliance level as promising units for setting conservation priorities. The main criteria used are distribution/abundance of vascular plant species of conservation interest and their greater or lesser fidelity to a plant community, considered as a key driver to set alliance value. Multivariate methods was applied and a quantitatively synthetic floristic index was set up. We tested this procedure in an important wetland area of central Italy, where a large amount of botanical data were available. Our investigations highlighted: i) the higher conservation values of some alliances not listed in the HD, bringing to light various gaps in current conservation laws affecting Mediterranean wetlands; ii) that habitats widely distributed in other biogeographical areas may have a great conservation importance, underestimated in the Mediterranean region; iii) the necessity to consider regional singularities when setting conservation priorities.

COLLAPSE OF GREY PARROT (PSITTACUS ERITHACUS) POPULATIONS IN GHANA

Nathaniel Annorbah

Manchester Metropolitan University

Stuart MARSDEN, Manchester Metropolitan University; Nigel COLLAR, BirdLife International

The Grey Parrot (*Psittacus erithacus*), listed as Vulnerable on the IUCN Red List, is undergoing rapid population declines in most of its range owing to capture for trade and habitat loss. The status of the species is not well known in Ghana. We sought to 1. assess the distribution and abundance of the species across Ghana, 2. repeat surveys at roost sites identified two decades ago, 3. gauge people's knowledge and perceptions of the decline and the possible reasons for this, and 4. examine the trade and other factors that may have contributed to the population decline. A random sample of 48 10x10km² cells were surveyed for 3-5 days each across c.50,000km² of Ghana's forest zone between April 2012-June 2014. Searches were conducted for 40 of 60 previously surveyed roosts. Extensive interviews were conducted to sample knowledge and perceptions on GP, its trade and population declines. Thirty-two groups and 103 individual GPs were recorded in 13 (27% of) cells. Mean group size was 3.2 (maximum group size = 12). Mean encounter-rate across all sites was 0.047±0.14 (SD) groups/hr. No active roost found but GP encountered in five roost areas, with 51 sightings in one site. Only 18 individuals were recorded in three roost areas that harboured 700-1200 birds each two decades ago. Of 866 interviewees, 31% had not sighted parrots in the last six years. On population trends, 94% of interviewees indicated declines in the last 5 years and 99%, the last 10 and 20 years, respectively. GPs in Ghana have suffered catastrophic declines in merely two decades, owing to past excessive offtake from the wild for the bird trade, and persistent habitat loss and degradation. Parrots are now prone to widespread local extinctions and an ultimate nationwide extinction if trends continue. Major livelihoods have been lost through collapse of the trade.

BIODIVERSITY CONSERVATION AND ANTI-DIABETIC PLANTS USED BY THE TRIBAL COMMUNITIES OF ANAMALAI HILLS COIMBATORE DISTRICT, SOUTHERN WESTERN GHATS OF TAMIL NADU, INDIA.

Venkatachalapathi Arjunan

KONGUNADU ARTS AND SCIENCE COLLEGE

(AUTONOMOUS), COIMBATORE - 29, TAMIL NADU, INDIA.

Anamalai hills ('elephant hills' in Tamil), an important biodiversity conservation area in the Coimbatore district, Southern Western Ghats of Tamil Nadu, India. This paper proposed about the tribal peoples used medicinal plants for the treatment of diabetes, livelihoods and value addition survey amongst tribal communities within or adjacent to rainforest fragments five settlements of the higher ranges were selected of the 36 tribal settlements. The present study was conducted during the period of January-October, 2014. The tribal communities are Kadar, Muthuvar, Malai Malasar and Irular. The data's are collected from the tribal peoples or healers or medicinal practitioners through oral, questionnaire method and frequent field visit. Traditional medicinal practitioners known as vaidyas from the primary health care provider in tribal settlements. A total of 37 medicinal plants belonging to 25 families were identified as being used for the treatment of diabetes in Anamalai hills. The most frequently used plants are *Coccinia indica*, *Azadirachta indica*, *Trigonella foenum-graecum*, *Syzygium cumini*, *Terminalia chebula*, *Ficus racemosa*, *Momordica charantia* and *Swietenia mahagoni*. Above mentioned traditional medicinal plants are commonly used to treat diabetes. Clinical intervention studies are required to provide evidence for a safe and effective use of the identified medicinal plants in the treatment of diabetes. The over exploitation of medicinal plants in Anamalai hills should conserve through macro and micro propagation. This paper deals the biodiversity of plant which is used by tribal's communities of Anamalai hills. Keywords: Ethnobotany, Muthuvar, Diabetes, Macro and Micro Propagation, Anamalai hills and Southern Western Ghats.

REASSESSING THE CONSERVATION STATUS OF THE THREATENED FROG DENDROPSOPHUS MERIDENSIS (HYLIDAE) IN THE NORTHERN ANDES: INTEGRATING MOLECULAR ANALYSIS AND ECOLOGICAL NICHE MODELING

Luis Orlando Armesto

Universidad Simón Bolívar

Margarita LAMPO, Instituto Venezolano de Investigaciones

Científicas ; Celsa SEÑARIS, Instituto Venezolano de

Investigaciones Científicas ; Evelin QUILARQUE, Instituto

Venezolano de Investigaciones Científicas ; Aldemar ACEVEDO, Universidad de Pamplona

Dendropsophus meridensis is a treefrog endemic to the Cordillera de Mérida in the Venezuelan Andes. This species was listed as "Endangered" (EN) by the IUCN Red List because its

extent of occurrence is less than 5,000 km², although it inhabits in open areas and farms with ponds, and their populations are not affected by forest decline. However, the taxonomic status of *D. meridensis* is uncertain, as it is morphologically very similar to sister species *Dendropsophus pelidna* (sister species), which occurs in the massif El Tamá (Colombian and Venezuelan Andes). This prevents proposing action plans for its conservation. Our aim was assess the taxonomic status and geographical distribution of *D. meridensis* in order to obtain bases to reassessment the conservation status. For this, we use three molecular genes: *Cytb*, 12S and 16S; we estimated genetic divergence and structure between the populations from the Cordillera de Mérida and El Tamá. We made a species distribution modeling of *D. meridensis* in order to infer its potential geographic distribution in the Andean region. We found low levels (0.2-1% with *Cytb*, 0.2% with 12S-16S) of genetic divergence and a low level of genetic structure (34.5%) between the populations from the Cordillera de Mérida and El Tamá. The species distribution modeling predicted to the El Tamá as an environmental suitability area for *D. meridensis*. Our results suggest that *D. pelidna* is a synonym of *D. meridensis* and that the latter occurs in the El Tamá; therefore, geographical distribution of *D. meridensis* is larger than that known. The presence of this species in other areas of the Andes is not unexpected due to the characteristics of habitat where *D. meridensis* lives. Thus, we propose that the category EN for *D. meridensis* should be changed to VU (Vulnerable), as its occurrence area is greater than 5,000 km² but lesser than 20,000 km².

SYMPOSIUM NO. 90 - EXPOSURE ANALYSIS OF DIURNAL LEPIDOPTERA TO MAIZE POLLEN IN PROTECTED AREAS

Salvatore Arpaia

ENEA - Italian National Agency for New technologies, Energy and Sustainable economic development

Ferdinando BALDACCHINO, ENEA - Italian National Agency for New technologies, Energy and Sustainable economic development ; Giovanni BURGIO, Università di Bologna Alma Mater Studiorum, Dipartimento di Scienze Agrarie ; Alessandra MAGARELLI, ENEA - Italian National Agency for New technologies, Energy and Sustainable economic development ; Antonio MASETTI, Università di Bologna Alma Mater Studiorum, Dipartimento di Scienze Agrarie

Several genetically modified (GM) crops have been developed to provide protection against lepidopteran pests by the introduction of *Bacillus thuringiensis* (Bt) synthetic genes (e.g. Cry 1A- or Cry 1F- expressing maize). One of the concerns for a possible adverse environmental effect, is the threat to non-target organisms in the receiving environments where GM plants can be cultivated. In Europe direct feeding on

maize leaves by Lepidoptera larvae, other than 2 target pests, is limited to handful sporadic pest species. However, the exposure of larvae to plant products expressing Cry proteins is also possible at certain distances from cropped areas, due to pollen transportation by wind on wild host plants for larvae. In the framework of the project Life+ MAN-GMP-ITA, a possible exposure scenario for Lepidoptera living in protected areas in proximity of agricultural land, was explored in five Sites of Community Interest (SCIs) in Italy. Information collected during 2 years of samplings was stored in a database. Besides allowing the characterization of Lepidoptera fauna of the study sites, the database can support the definition of exposure scenarios based on the presence-absence of the species in each habitat during the year. When the recorded flight periods were individually overlaid with the flowering time of maize in these areas, different exposure scenarios were obtained. For instance, maize pollen production in the Po valley completely overlap with the presence of larvae of *Inachis io* L. feeding on nettles nearby maize fields. At the contrary in a SCIs in the South-East of the country where silage maize is the main product, flowering peaks are recorded in July-August when many Lepidoptera species suspend their activity. Similarly, the simulation of such scenarios for a different GM crops in the area, e.g. oilseed rape, showed different results since the early flowering of the crop indicates a possible exposure to GM tissues for only few, early active Lepidoptera.

CITIZEN SCIENCE, SOCIAL LEARNING AND TRANSFORMING EXPERTISE

Isabelle Arpin

Irstea

Taru PELTOLA, Irstea[INSTITUTE]Irstea

Citizen science (CS) is currently gaining momentum in many different research fields, including biodiversity research, boosted by novel technologies that allow new modes of participation, inviting new social groups and extending the scope of collaboration between scientists and volunteers. CS is envisioned to bring mutual gains for the participants, as well as for society at large, facilitating, for example, 'scientific literacy', collaborative skills or empowering different social groups. While such learning processes taking place on an individual, collective or societal level are claimed to have high priority in CS projects, we provide a review of the development and state of the art of CS, focusing on the learning outcomes of CS projects. We critically assess how learning has been discussed in the context of CS, and how CS projects have been designed and implemented to facilitate learning. In this context we also discuss approaches, such as public participatory GIS, which are not currently framed as CS but provide valuable experiences and methodological approaches for it. We also explore new cutting-edge collective learning processes such as Companion Modeling and Multi-Agent Behavioral Games. Through a

number of case studies in the field of biodiversity research we explore the ways in which participants are involved, new knowledge is generated, and the potential benefits derived by different groups. We conclude with recommendations for the future development of CS processes to ensure mutual learning for improved biodiversity conservation and enhancing ecosystem services and suggestions on „appropriate avenue” for future biodiversity research that is relevant for addressing social challenges of collaborative knowledge production between citizens, scientists, and educators.

EMERGENCE OF LANDSCAPE CARRYING CAPACITY FOR COMMON BUZZARDS FROM RADIO-TRACKING AND LAND-COVER MAPPING

Eduardo Arraut

Oxford University

Sean WALLS, Biotrack ; David MACDONALD, Oxford University ; Robert KENWARD, Centre for Ecology and Hydrology

Habitat destruction from landscape transformation is nowadays the main driver of terrestrial species’ extinctions. Anticipating impact of landscape structure upon animal populations can thus inform conservation. Here we present a novel modelling approach for predicting individuals’ use of space, as well as population spatial distribution and carrying capacity in real, variable landscapes. Our approach combines Resource-Area-Dependence Analysis (RADA) with Individual-Based Modelling (IBM). We call it RADA-IBM and illustrate it via modelling common buzzards *Buteo buteo* in lowland UK. Initially, to elucidate drivers of buzzard territoriality, we created three model versions that differed only with respect to which habitats individuals defend. In all models buzzards settled and incorporated habitats within parameterized foraging distances from the settling site until RADA predictions were met. When compared to a sample of radio-tracked buzzards, all models produced virtual buzzards with realistic home ranges but only one predicted an accurate pattern of home range overlap. Results from this model indicate defence of minimum areas of all habitats drives buzzard territoriality in lowland UK. This model also predicted observed population distribution and carrying capacity consistent with two independent density estimates. Additionally, it showed how variations in settling site locations and territory shapes result in the emergence of variance in carrying capacity. Our approach requires further testing, but is potentially powerful for assessing which factor or combination of factors, such as habitat distribution, climate or competition might be keeping an animal population in check. As it explicitly models landscape structure and individuals’ interactions, while requiring solely a land-cover map and individual-based behavioural observations collected by radio-tracking, it can help faster planning of, for example, landscape management or re-introductions.

SPATIAL ANALYSIS OF A POPULATION OF BOREAL FELT LICHEN ON THE ISLAND OF NEWFOUNDLAND

André Arsenault

Natural Resources Canada

The boreal felt lichen (*Erioderma pedicellatum*) is a globally rare lichen found in the Kamchatka Peninsula, Scandinavia, Alaska, Newfoundland and Nova Scotia. Although some populations have declined substantially, even to extinction in some jurisdictions, new findings in Alaska, Russia and Newfoundland have significantly increased the estimated population and geographic range. In Newfoundland, one of the epicentres for this species is on the Avalon Peninsula where there is important urban and semi-urban development. A better understanding of the ecology and dynamics of the habitat of this species is critical for land use planning to mitigate and reduce risk for this species of conservation concern. We have investigated the distribution ecology of the boreal felt lichen in a ribbed moraine landscape of the Avalon Peninsula. We have used systematic sampling of bounded plots and “walkabouts” to describe forest structure and dynamics of different ecosystem types and to examine the spatial pattern of this lichen species on individual trees and at the landscape scale. At the tree scale most of the lichen thalli were found between 1 and 2 metres in height, although some thalli could be up to 7 metres on the bole of trees. Some of the most important predicting factors for the distribution of this species include stand composition, distance to bogs, and fens, and stand age. Although the hot spots for the boreal felt lichens are not necessarily associated with old-growth gap-phase dynamics forests, they are rarely found in logged forests younger than 60 years. We will present a preliminary boreal felt lichen habitat predictive tool using a Geographical Information System (GIS) combining a number of land cover layers along with our rich field data set.

33: WHY AND HOW PEOPLE MATTER: CONSERVATION PSYCHOLOGY AND PRO-CONSERVATION BEHAVIORS

Stanley Asah

University of Washington

Many conservation problems are undeniably the result of human actions. The same is true for many conservation successes. Thus, it is not illogical to think that the *Homo sapiens* is a “cornerstone conservation species”—needs considerable attention, if we are to facilitate conservation success. Mainstream conventional thought would suggest that the condition of the environment and the desire to address that condition is the main driver of pro-environmental actions. Thence, we design educational and outreach efforts with a misplaced focus only on imparting ecological knowledge to

target audiences, expecting pro-conservation action in return. First, knowledge alone is a necessary but largely insufficient driver of action. Second, there is increasing evidence that the environment, its condition and the desire to improve that condition, in and off themselves are not sufficient reasons for people to engage in pro-conservation behaviors. Instead, people are motivated—to take action in support of conservation—by other factors many of which are social-psychological. The desire to address conservation problems motivates pro-conservation behavior only to the extent that addressing those conservation problems aligns with the actualization of social-psychological motivations. I present evidence to illustrate these points. Then I briefly present the basic tenets of conservation psychology—the science of understanding and promoting pro-conservation behaviors—and emphasize its utility for fostering biodiversity conservation stewardship. I conclude with a challenge to adopt and enhance persuasive conservation science communication—one that does not necessarily ignore the essence of conservation facts but pays due attention to what may, and how to, motivate pro-conservation behaviors.

BIOECONOMIC OPTIMIZATION OF INTERVENTIONS TO AID EVOLUTIONARY RESCUE OF A POPULATION THREATENED BY ENVIRONMENTAL CHANGE

Jaime Ashander

University of California -- Davis

Lisa THOMPSON, University of California -- Davis [INSTITUTE] Regional San ; James SANCHIRICO, University of California -- Davis ; Marissa BASKETT, University of California -- Davis

Rapid environmental changes threaten many populations of conservation concern. Biological populations and human management may both adapt in response. Human adaptation relies on changing management policy, while biological response involves phenotypic change through adaptive plasticity or genetic evolution that may rescue the population in some cases. Biological adaptation can interact with human adaptation, affecting optimal management decisions. This occurs if population phenotypes respond plastically to an environmental cue affected by environmental management. Then, changes in management alter the relative importance of plasticity and genetic adaptation in a population. We consider a situation, motivated by Pacific salmon migrating in a regulated river, where this interaction between evolutionary and management adaptation occurs and management actions are costly. We integrate evolutionary and economic perspectives by introducing a eco-evolutionary model of this situation within a bioeconomic optimization of management costs. Specifically, our model addresses the question, "what is the optimal investment in management adaptation to achieve a specified conservation goal for a population that is evolving toward a moving optimum and demonstrates an

adaptive plastic response to an environmental factor that is (partly) manageable?" We present an approximate analytical optimization of this model, as well as numerical results. The need to consider adaptation in human systems in response to climate change is well recognized, as is the potential for biotic responses. Rarely, however, has the interaction between these two types of adaptation been considered. Here we do so, using an eco-evolutionary model within a bioeconomic framework.

195 WHAT IS CONFLICT? LEOPARDS AMONG PEOPLE IN MAHARASHTRA, INDIA

Vidya Athreya

Wildlife Conservation Society - India

John D.c. LINNELL, Norwegian Institute for Nature Research ; Morten ODDEN, Hedmark University ; Sunetro GHOSAL, Stawa

When studying the interactions between humans and wildlife, conservation biologists tend to focus primarily on the negative interactions. This includes both the economic and material impacts that wildlife can have on human lives, property and livelihoods, and on the social conflicts that can arise between different stakeholders and institutions over the process of conservation. This focus on the negative leads to a failure to appreciate the far greater diversity of often nuanced interactions that occur. Our work has been conducted in an agricultural area of western India that is largely devoid of natural habitat and medium to large sized prey species and is home to almost 400 people per sq km. We have used a combination of camera trapping, faecal DNA and scat analysis, GPS telemetry and interviews to study the relationship between leopards and people in this region. The area contains a population of leopards and striped hyaena at a density of around 10 per 100 sq km. The leopards subsist on a diet of domestic dogs, cats and small livestock, and show an incredible ability to utilize this human dominated landscape. Because of their high dependence on dogs, the predation impact on livestock is low, and is spread across many households. Losses to leopards are minor compared to those from disease. Traditional livestock protection measures are widely used. No human deaths have occurred in the region for decades, although some minor attacks on people have occurred. Human attitudes towards the leopards are very diverse, but in general people are very tolerant, and we have even discovered that many local people have included the big cat god, Waghoba, into their pantheon. Our findings reveal that there is a wealth of positive and neutral interactions between people and leopards that need to be encouraged and maintained.

PATTERNS OF FISH DIVERSITY IN THE MHADEI RIVER BASIN GOA, WESTERN GHATS, INDIA

Vidyadhar Atkore

Ashoka Trust for Research in Ecology & the Environment

Jagdish KRISHNASWAMY, Ashoka Trust for Research in Ecology & the Environment ; Kartik SHANKER, Centre for Ecological Sciences, Indian Institute of Science ; Shrinivas BADIGER, Ashoka Trust for Research in Ecology & the Environment

Freshwater ecosystems provide many ecosystem services to mankind. They also harbour significant level of biodiversity and are critical for a variety of threatened species. Despite their importance, many freshwater ecosystems are threatened with extinction. River systems particularly in South Asia have become fragmented due to habitat alteration and dams. As a result of this, associated fisheries have been decimated in many developing countries affecting rural and urban livelihoods alike. Quantifying species diversity in river basins is central to biodiversity conservation. With this background, we conducted a study in the Mhadei river basin in the Western Ghats region – a global biodiversity hotspot in India. The aim was to document the patterns of riverine fish diversity and quantify associated environmental drivers of this diversity. A river stretch of 100-150 m length was identified for fish sampling. In total eleven such segments were sampled from February 2012 to April 2014. We recorded, thirty one species belonging to six orders & eight families. Of these, the family Cyprinidae was most dominant with more than twenty one species followed by Gobidae, Ambassidae, and Bagridae. *Devario malabaricus* was most dominant species followed by *Salmophasia boopis*. Species richness was higher at minimum level of inorganic nitrates and phosphates and in higher stream orders. River habitats didn't show significant relationship with and air temperature, chemical oxygen demand, free CO₂ and dissolved oxygen. The habitat guild was dominated by mid columns dwellers (64 %) followed by surface dwellers (28%) and bottom dwellers (6.30%). Similarly, feeding guild was dominated by insectivorous guild (65%) followed by algivorous (12%), carnivorous (1.5%) and omnivorous guilds (0.86%) respectively. Our study thus provides insights into patterns of fish diversity and functional guilds. Segments with the highest fish species richness should be prioritized for river management.

SPATIALLY EXPLICIT DENSITIES OF TWO GENERALIST PREDATORS AT TWO MIXED-GRASS PRAIRIE LANDSCAPE: IMPLICATION FOR QUAIL CONSERVATION IN THE GREAT PLAINS

Fidelis Atuo

Oklahoma State University

Timothy O'CONNELL, Oklahoma State University

The North American Great Plains supports multiple species of diurnal raptors that potentially rely on similar sources of food (e.g., ground dwelling birds) and nesting substrates (e.g., isolated large trees). At broad scales, these species co-occur. In this study, we endeavored to determine spatially explicit densities and resource selection by two top predatory raptors

(Red-tailed hawk and Northern harrier) in two mixed-grass prairie landscapes that are partly managed for quail recovery. We also aimed to understand the spatial scale at which these species partition habitat. From December 2012–December 2014, we conducted monthly surveys of raptors at two state wildlife management areas (separated by ~ 100 km) in western Oklahoma. Using distance sampling on line transects, we recorded 112 sightings of the Red-tailed hawk and 79 sightings of Northern harrier within core quail habitat. Overall, mixed grasses, relatively sparse ground cover, prey abundance, and more abundant canopy trees were important variables in predicting predator abundance with broad overlap between the two species at both study sites. Red-tailed hawk was the most abundant of the 2 predators at both study sites (Average density: 0.16/ha), both as a breeding resident and in reaching its highest densities during autumn and winter. Wintering densities of Northern harrier were also relatively high (Average density: 0.091/ha) at both study sites and coincided with high predation specific mortalities in quail. Although both species showed significant overlap in habitat selection at broad scale (1000 m radius), fine-scale (100 m radius) habitat use indicated greater reliance on riparian trees for Red-tailed hawk and short grasses with a low probability of tree occurrence for Northern harrier. Our analysis provides evidence for fine-scale niche partitioning among the two predators and predicts higher predation specific mortalities for quail in the winter season.

EVALUATING THE DRIVERS OF TRADE ON AVIAN BODY PARTS IN SOUTH-EAST NIGERIA: IMPLICATIONS FOR BIODIVERSITY CONSERVATION IN PROTECTED AREAS

Fidelis Atuo

Oklahoma State University

Timothy O'CONNELL, Oklahoma State University ; Peter ABANYAM, Wildlife Conservation Society

Several species of wildlife are hunted around the world for the perceived potency of certain parts of their bodies in traditional medicine and fetish practices. In Africa, many cultures require animal parts for a wide range of traditional and religious practices. This has resulted in the persecution of more than 354 bird species across the continent. In this study, we evaluated the drivers and frequency of human-related avian mortality focusing on the trade in avian body parts around major protected areas in the Cross River region of Southeast Nigeria. We identified 28 bird species from 13 families that were prevalent in regional trade. Three of the top 5 most prevalent species are listed as globally threatened under the IUCN/Birdlife threat criteria. Both knowledge of and active involvement in the trade was pervasive across the study sites and across different occupational groups. Our top model for predicting involvement in avian body parts trade identified age, income, perceived personal need for avian body parts, and number of

wives as the top socio-economic drivers of participation. The probability of active involvement in the trade decreased with age and average monthly income; an indication that younger people and villagers with low monthly income are more likely to be involved in the trade. The probability of involvement also increased with the number of wives and personal need for avian body parts. The former may be an indication of a larger household that requires more resources to sustain it; the latter likely reflects personal conviction of the efficacy of using avian body parts in traditional medicine and other cultural practices. Our study highlights the importance of targeting socio-economic factors and integrating cultural needs of the people into conservation planning aimed at reducing human-wildlife conflict in the region.

EARNING YOUR STRIPES: DOES EXPERTISE AID THE ABILITY TO MATCH BUMBLEBEE IMAGES IN IDENTIFICATION GUIDES

Gail Austen-Price

University of Kent

Markus BINDEMANN, University of Kent ; David ROBERTS, University of Kent

One element of citizen science is the collection of data by volunteers. As the discipline continues to grow so does the question of the robustness of the data collected. This study asks participants to answer whether two images of bumblebees (taken from two different UK identification guides) represent the same species. Participants varied in levels of expertise, and initial results suggest that non-expert accuracy in image matching is not significantly different to that of the experts, with the ability to correctly identify matched pairs being more accurate than the ability to identify mismatched pairs.

GRAPH THEORY AND LEAST-COST PATH: HOW THEIR COMBINATION CAN IMPROVE THE ANALYSIS OF HABITAT NETWORK CONNECTIVITY AND PRIORITIZE CONSERVATION MEASURES

Catherine Avon

Irstea

Laurent BERGÈS, Irstea

The green and blue infrastructure in France is based on the conservation and restoration of ecological continuity of habitats in relation to species' biological requirements. Recent development in landscape ecology based on graph theory and species movement modelling using least-cost paths offer promising applications in terms of landscape management and biodiversity conservation. First, we present the model of potential connectivity based on graph theory and explain why it overcomes previous approaches. Then, we illustrate with an

example of connectivity analysis in the region PACA for the Red Squirrel, a forest generalist species. The models identify the landscape areas that are connected or isolated from the rest of habitat network and prioritize the importance of patches and corridors for the maintaining of global network connectivity; they also analyse how connectivity varies according to species dispersal distance. They highlight the key habitat patches and corridors that must be protected to maintain habitat network connectivity for the species. These examples clearly show that these original methods can form valuable decision support tools for the implementation of green infrastructures at different spatial scales, and also help to locate further finer-scale studies.

EFFECTS OF ENVIRONMENTAL VARIABLES ON THE SPATIAL DISTRIBUTION OF CONIFEROUS SPECIES IN THE NORTHWESTERN ALGERIA.

Faouzia Ayache

1 Department of Biology, Faculty of Natural Science and life, University Djilali Liabès, Algeria,

Mohammed BOUAZZA, Department of Ecology and Environment, Faculty of Natural Sciences, Earth Science and universe. ; M. Jaime BAEZA BERNÁ, Department of Ecology, Faculty of Science, University of Alicante

In order to assess the coniferous species-environmental relationship in the Northwestern of Algeria, we analyzed the effects of six environmental factors (continentality, altitude, exposition, mean annual precipitations, annual minimum temperatures and average annual snow days) on the distribution of five conifers species (*Pinus halepensis*, *Tetraclinis articulata*, *Juniperus phoenicea*, *Juniperus oxycedrus* subsp *macrocarpa*, and *Juniperus oxycedrus* subsp *rufescens*). The Generalized additive models (GAMs) were developed to predict the presence of these species in the study area; it were useful for estimating suitable habitats and identifying the primary factors affecting species distribution in the region. The results show that the climatic factors was the main driver determining the distribution of coniferous species in the study area especially the intensity of the cold that is a limiting factor for several plant species. These first results have provided important inputs for the management plan of coniferous species in the study area and the possible shift of the species' potential distribution in the future in cases of global warming due to climate change.

NATIONAL AND SUB-NATIONAL RED LISTS IN EUROPEAN AND MEDITERRANEAN COUNTRIES: CURRENT STATE AND USE FOR CONSERVATION

Claire-Sophie Azam

SPN

Guillaume GIGOT, SPN ; Bertrand Schatz, CNRS

Facing present statement of ongoing biodiversity loss and limited financial resources allocated to its conservation, collective tools permitting to prioritize and implement relevant operators of conservation are crucial. Red Lists (RL) have been multiplied at several scales (regional, national, subnational) during the last decades. We built here a detailed overview of the current state of national and subnational red lists (NRL and SRL) in the Europe and Mediterranean through a survey of 53 countries. We identified NRL in 41 countries and SRL in 16 countries, but with geographical and taxonomic gaps in RL coverage and with disparities in methodological approaches. Further than a statistical approach (methodology, species assessed, stakeholders, funding), we highlight the influences of the experience of stakeholders and several particular national cases. This first international review of the uses of RL in national conservation programs confirms the decisive role of NRL for conservation actions, in particular during prioritization processes. We propose a set of recommendations to increase harmonization between NRL and SRL and among neighbouring countries and to strengthen their scope for conservation.

EUROPEAN OVERSEAS, NEW FRONTIER FOR BIODIVERSITY RESEARCH?

José Azevedo

Fundo Regional da Ciência e Tecnologia
Eduard DWYER, EurOcean ; Paul HOETJES, Ministry of Economic Affairs ; Soraya SIERRA, Naturalis ; Marimar VILLAGARCIA, PLOCAN ; Philippe FELDMANN, Agence Nationale de la Recherche ; Josiane IRISSIN-MANGATA, Conseil Régional de La Réunion ; Susana FIGUEIREDO, SPI

The European Overseas Areas are strategically positioned to become a strong focus of biodiversity research in support of sustainable development. In fact, they constitute a complex geopolitical entity extending Europe's presence across the globe, incorporating all ecosystems and oceans from the tropics to the poles. Europe's overseas are mainly islands (most of them located in Biodiversity Hotspots), but also include French Guyana, one of the least disturbed areas of rain forest on Earth. Fulfilling European international commitments, such as the Convention on Biological Diversity, will require special consideration to its overseas areas. This has started to be expressed in the scope of policy instruments, such as the EU Biodiversity Strategy, and funding mechanisms, such as the LIFE+ fund, the BEST Initiative or H2020. The immense diversity of biogeographical settings and the different levels of human pressure encompassed by Europe's Overseas areas allows the testing of comparison-based hypothesis, linking patterns to processes. This unique advantage makes them an ideal setting for biodiversity research of both global significance and local relevance. Such research, however, can only be accomplished

through an extensive supporting network. This is where the European FP7 funded NetBiome partnership is making a unique contribution. NetBiome is a consortium of entities from knowledge institutions, business, government and civil society, dedicated to the mobilization of stakeholders to identify and address priority challenges in reconciling conservation of (sub)tropical biodiversity with the sustainable development of Europe's regions and territories, based on the benefits from high biodiversity. Seven international research projects are currently being funded through NetBiome, and the research recommendations under preparation will feed a second call in the near future.

A CLOSER LOOK AT BRAZIL'S FOREST CODE: ASSESSING THE NEW LAW IMPACTS

Thaís Nícia Azevedo

Earthwatch Institute

Ana Paula GIORGI, Earthwatch Institute ; Karine COSTA, USP ; Morena MILLS, University of Queensland

Recent changes in Brazil's Forest Code raise environmental concerns for biodiversity conservation worldwide. Over half (53%) of Brazil's native vegetation occurs within private properties and the Forest Code is the only law protecting native vegetation within private land, enacted to conserve native vegetation, water resources and prevent soil erosion by protecting sensitive areas. In 2012 a revision of the Forest Code downgraded native vegetation protection to favor landholders who had used their land illegally. For example, changes included amnesty to all illegal deforestation by 2008 and reduction on the required buffer zone extent nearby sensitive areas. Broad assessments have estimated that these measures decreased the total area to be restored from 50 to 21 million ha. However, broad assessments may underestimate the total area changes, considering sensitive areas buffer zones range from 5 m – 500 m. Therefore, fine scale analyses of the impacts of the changes are needed. In this study, we used high resolution imagery to undertake a fine scale analysis of the impacts of Brazil's Forest Code within a case study in Atlantic Forest. We identify areas at risk of deforestation and areas to restore in one of the world's top five biodiversity hotspots with less than 16% of its original extent. We mapped 15 watersheds (67,000 ha) in the buffer zone of a protected area under a fine resolution (1:3000). Here we present preliminary results on three different policy scenarios: i) current; ii) under the old forest code and iii) under the new forest code. Our study is the first fine-scale study to identify key areas to restore and to conserve based on the Forest Code changes. Furthermore, we expect to implement our findings through a strong stakeholder engagement effort, working close to government, landowners and other key institutions.

DESIGNATING NEW TIGER RESERVES: THE CASE OF SATHYAMANGALAM TIGER RESERVE IN SOUTH INDIA

Vinoth B

CARE EARTH TRUST

The paper describes the case of a newly declared Tiger Reserve in southern India viz. Sathyamangalam Tiger Reserve (STR) in Tamilnadu, highlighting the rationale and data that contributed to effecting the declaration. The Reserve is part of a larger composite of Protected Areas viz. Mudumalai, Bandipur and Wayanad in the Nilgiri Biosphere Reserve, and the ecological integrity of this landscape is discussed. In doing so, it demonstrates the efficacy of using what is largely considered a rudimentary method viz. line transects in estimating the population and density of three major carnivores in the landscape with their indirect evidences i.e. scats and kills, the Tiger (*Panthera tigris*), the Leopard (*Panthera pardus*) and the Dhole (*Cuon alpinus*). In addition to establishing the existence of a significant population by laying 48 transects of 930 km covering a gamut of habitats, the pilot study also demonstrates the habitat preference of the three species being clearly demarcated over an altitudinal gradient. Tiger's domination is revealed through the occurrence of 121 scats out of 220 analysed; rest of which are Leopard and Dhole. Of 27 kills observed, 14 made by Leopard, 9 and 4 by Tiger and Dhole respectively. The socio-cultural factors contributing to the use of such methods especially in wake of the apprehensions expressed by the local communities is discussed in detail.

POTENTIALS AND CHALLENGES OF INDIGENOUS KNOWLEDGE IN BIODIVERSITY CONSERVATION: CASE STUDY OF OSUN OSOGBO SACRED GROVE, NIGERIA

Folaranmi Dapo Babalola

University of Ilorin

Paxie W CHIRWA, Forest Science Postgraduate Programme, University of Pretoria

The significance of indigenous knowledge (IK) and cultural beliefs in biodiversity conservation has been emphasised. The Osun sacred grove was established on the IK of the people of Oshogbo which was passed down orally from one generation to another. Meanwhile, ecological encroachment and degradation activities posed great challenges to the sustenance of the grove and have been advancing at alarming rate. Data was collected through interview of twenty key informants in the adjoining communities and five officials in the grove. The riparian vegetation in the sacred grove is unique in the sense that it is the only remaining relic of the Nigeria rain forest ecosystem endemic to the grove. In

addition to the pressure from population explosion and urban expansion, the deforestation of the grove is resulting from farming practices going on along the boundary. About 90% of respondents informed that neglect of the local belief used to establish the grove is resulting in the encroachment activities. About 60% of the local people expressed their displeasure in the way the government is in total control of the grove and not involving the local communities. All the interviewed government officers of the grove indicated that poachers from the adjoining communities carry out illegal hunting of the wild animals in the grove and this has led to reduction and total extermination of some animals. To effectively strengthen this IK in conservation of remaining endemic biodiversity, appropriate local indigenes should be employed and fully incorporated in the management strategy of the grove; more guards are also required for patrol activities, and there is need for re-establishment of clear boundary and buffer zone to prevent encroachment and other illegal activities within and around the grove.

INTERACTIVE EFFECTS OF BUFFER WIDTH AND WETLAND HYDROPERIOD ON AMPHIBIAN REPRODUCTIVE OUTPUT

Kimberly Babbitt

University of New Hampshire

Jessica Veysey Powell, University of New Hampshire

Forest buffers are a major tool used to protect wetland-dependent wildlife. Though implemented widely, buffer efficacy is untested for most amphibian species. It is thus unclear whether buffers are sufficient for maintaining viable amphibian populations and if so, how wide buffers should be. We present evidence from a 6-year, landscape-scale experiment testing the impacts of forest clearcutting and buffer width on the reproductive output of 2 amphibian species at 11 vernal pools in the northeastern United States. We randomly assigned each pool to 1 of 3 treatments (i.e., reference, 100m buffer, 30m buffer) and used clearcutting to create experimental buffers. For each pool, we censused egg masses; catalogued all metamorphic *Ambystoma maculatum* and *Lithobates sylvaticus*; and used mixed-effects regression to assess the relative effects of treatment and pool hydroperiod on egg mass and metamorph production. Cutting exerted negative effects in both buffer treatments and on both species, but effects were stronger at 30m pools and for salamanders. For example, salamanders produced fewer egg masses over time in both buffer treatments, while frog egg mass abundance was unaffected by treatment. Also, at pools producing metamorphs, salamander metamorph abundance declined over time in the 30m treatment, but was unrelated to time since cut in the 100m treatment. Both species had complex interactions between reproductive output, hydroperiod, and buffer width. For instance, frog metamorph

snout-urodyle length increased with hydroperiod at reference pools, but decreased with hydroperiod at buffered pools, with stronger declines in the 30m versus 100m treatment. These results show that buffer width mediates the impacts of forest disturbance on the reproductive output and hydroperiod sensitivity of wetland-dependent amphibians and also suggest that short-lived, explosive breeders like wood frogs, may be more tolerant of narrow buffers than long-lived species like spotted salamanders.

MONITORING OF TRANSLOCATED POPULATIONS USING PASSIVE INTEGRATED TRANSPONDERS AND CAMERA TRAPS.

Léo Bacon

Muséum National d'Histoire Naturel

Yves HINGRAT, Reneco Wildlife Preservation

The effectiveness of conservation translocations of endangered species is conditioned by the long term survival of released individuals and their successful breeding. Yet, it remains challenging to assess translocation success in the wild. In many species, individual banding has not been proven effective for studying demographic parameters. The use of tracking methods (radio or satellite tracking) are powerful for monitoring individuals but these methods remain costly and large sample sizes are rarely available. Passive Integrated Transponders (PIT) and camera traps are appealing monitoring tools for wildlife studies. However, the pros and cons of these approaches in applied conservation remain poorly documented. We combined the use of integrated PIT technology and camera trap survey to measure the breeding success of female Houbara bustards (*Chlamydotis undulata undulata*) over 2 years, in the context of a large scale reinforcement program (99 000 released birds). We compared the outcomes of such advanced techniques with traditional field monitoring of over 7 400 nests. Results showed that antenna PIT-tag readers significantly increased the sample size of breeding females identified and monitored while camera traps improved the accuracy of nest monitoring. Our results underline the potential of these tools in the monitoring of managed populations, the measure of demographic parameters and open new routes to the development of innovative monitoring methods.

DIFFERENTIAL SPATIAL AND TEMPORAL DISTRIBUTION OF ADULT LOGGERHEAD IN WESTERN MEDITERRANEAN SEA: IMPLICATIONS FOR CONSERVATION AND MANAGEMENT

Jose Carlos Baez

Instituto Español de Oceanografía (IEO)

David MACIAS, Instituto Español de Oceanografía (IEO) ; Juan Antonio CAMIÑAS, Instituto Español de Oceanografía (IEO)

Sea turtles show relatively high fecundity and low natural mortality during the adult phase. In contrast, immature individuals (hatchlings and juveniles) present high natural mortality rates. For this reason, mortality induced by fisheries on mature phase has a higher impact on population than immature non natural mortality. Bycatch in longline fisheries is considered to be a critical global threat for loggerhead sea turtle (*Caretta caretta*), particularly important in the Mediterranean Sea. As a consequence, the most dangerous effects for loggerhead conservation in Mediterranean Sea are due to the bycatch of adult turtles. Recent studies found differences in body size of loggerhead sea turtles caught using different longline gear types in the western Mediterranean Spanish fishery. Thus the traditional surface longliners targeting swordfish (LLHB), using larger hooks than those targeting albacore tend to select larger animals. The aim of the present document is search spatial and/or seasonal trends in catches of adult loggerhead turtles in LLHB from the western Mediterranean, and model it. Loggerheads nesting reported recently in different Spanish beaches indicate the presence of adults in the study area. We analyzed the spatial and seasonal distribution of 378 loggerhead individuals caught in LLHB, with a strait carapace length size (SCR) known, of which 23 were adult specimens (i.e. SCR > 70 cm). We obtained a significant GLM model between the probabilities to bycatch a mature sea turtle in LLHB versus the independent variables: latitude, longitude, June and July. The model's goodness-of-fit was significant according to the Omnibus test (df = 4, P < 0.0001), and the model showed outstanding discrimination capacity (AUC= 0.935). According to our results, the probability to catch a mature loggerhead increases during June and July in the south of the Balearic Islands area. Conservation and management implications of our results are discussed.

EFFECTS OF HUMAN LAND-USE ON AFRICA'S ONLY FOREST-DEPENDENT FELID: THE AFRICAN GOLDEN CAT CARACAL AURATA

Laila Bahaa-El-Din

University of KwaZulu-Natal

Philipp HENSCHER, Panthera ; Rahel SOLLMANN, North Carolina State University ; Rob SLOTOW, University of KwaZulu-Natal ; David MACDONALD, Wildlife Conservation Research Unit (WildCRU) ; Luke HUNTER, Panthera

Africa's equatorial forests are threatened by widespread deforestation and bushmeat hunting and face further pressure through rapid human population growth and large-scale expansions of commercial resource extraction such as logging and mining, as well as forest clearing for plantations. Using the forest-dependent African golden cat as a case study, we assess

the effects of disturbance across a human land-use gradient. We collected camera trap data between 2011 and 2013 at five sites in central Gabon to estimate density using spatially explicit capture-recapture models. Density estimates varied from 16 individuals per 100 km² at a pristine site, and 10 – 13 per 100 km² in logging concession areas, to 4 per 100 km² in a small village hunting area. Our results suggest that while golden cat populations are largest in pristine environments, logging concessions may also play an important role in the conservation of the species, particularly as they have greater land coverage than protected areas. Post-extraction management of concession areas could help to avoid further degradation and contribute to the conservation of forest endemic species. Bushmeat hunting, particularly with the use of wire snares, poses a serious threat to the African golden cat.

CLIMATE WINDOWS: ASSESSING CLIMATE SENSITIVITY USING R PACKAGE CLIMWIN

Liam Bailey

Australian National University

Martijn VAN DE POL, Australian National University ; Nina MCLEAN, Australian National University ; Laurie RIJSDIJK, Radboud University

Global climate change is affecting species conservation and management. Although we know that climatic change affects species in different ways, it can be difficult to gain a thorough understanding of how a specific species or population may be impacted. Selecting which climate variable to investigate, the period over which climate is considered, and the way in which climate is measured (e.g. mean, maximum) can be challenging. Consequently, it has been common to simply assess the sensitivity of species to the mean climate within arbitrary climatic 'blocks' based on a priori assumptions (e.g. spring temperature); however, this rather crude approach may not provide the best representation of a species' climatic sensitivity, and using these sub-optimal climate signals will likely compromise our ability to predict future impacts of climate change. More recently, there has been an increase in the use of 'climate window analyses' that assess the sensitivity of a species in multiple possible climatic periods. This new approach allows us to test for both short and long-term climate signals, and requires fewer a priori assumptions. Here, we present a new tool kit in R statistical software that allows for easy use of climate window analyses. We provide the ability to test different aggregate statistics (e.g. mean, slope, variance), test both fixed windows (a specific time of year; e.g. first week of August) and flexible windows (the number of days before a biological response; e.g. 10 days before egg laying), and generate multiple graphical tools that aid in selecting the best climate window. We illustrate the power of our tool kit using long-term bird data. Our new tool kit will make climate window analyses more widely accessible to people investigating the

climate sensitivity of species, which will ultimately provide us with more reliable information for future species conservation and management.

DO LONG-LIVED SHOREBIRDS CHANGE THEIR NEST PREFERENCE IN RESPONSE TO EXTREME CLIMATIC EVENTS?

Liam Bailey

Australian National University

Martijn VAN DE POL, Australian National University [INSTITUTE] Netherlands Institute of Ecology (NIOO-KNAW)

One key feature of global climate change will be an increase in the frequency of previously rare climatic extremes. These extreme climatic events can have major impacts at the individual, population and community level, thus posing a major challenge for species conservation and management. Plastic change in behavioural traits may facilitate rapid species adaptation to extreme climatic events, but empirical studies are needed to assess whether such changes occur in the wild. Here, we investigate the behavioural responses of the Eurasian oystercatcher (*Haematopus ostralegus*) to rising maximum tides, using data on nest site selection covering a 20 year period. We show that the average nest elevation of the population has increased over time; however, this change appears to be driven most strongly by slower changes in habitat selection, with low elevation territories being abandoned and left unoccupied, rather than more rapid changes in individual nest site selection. Consequently, the rate of nest elevation change in *Haematopus ostralegus* is currently too slow to keep pace with rising tides. In conclusion, plastic change in nest site selection does not appear to provide a solution to rising maximum tides in this population; however, plasticity in other behavioural traits, such as nest timing, may provide an alternative mechanism for rapid adaptation to extreme climatic events and should be investigated further.

THE INFLUENCE OF PROTECTED AREA SELECTION CRITERIA ON MEASURES OF CONSERVATION EFFORT

Daniele Baisero

Sapienza Università di Roma

Carlo RONDININI, Sapienza Università di Roma

Protected areas (PA) are a cornerstone of conservation biology. They are used as indicators of conservation investment (eg: United Nations Millennium Development Goals), in explicit conservation targets (eg: CBD Aichi target 11), and to monitor species-specific conservation efforts. Furthermore, the correct assessment of the benefits that current and future PAs bring to biodiversity is a key component of systematic conservation planning. While numerous literature studies have analysed the global PA network or used PAs as a key component, these

have so far used multiple approaches to determine which PAs to include; mainly according to the IUCN PA classification system. Some published analyses only include areas that provided explicit benefit to biodiversity (i.e. classified Ia-IV), others include all PAs with an IUCN classification, or even advocate the inclusion of sites without an official IUCN category. Furthermore, since no widely adopted guideline currently exists, ulterior selection criteria such as only including national sites are occasionally applied. Consequently, the comparison of results from literature is complicated and uncertain. In order to shed light on the extent to which PA selection criteria influence our perception of the current conservation effort, we analysed the impact of using differing approaches in PA selection when measuring the global, regional and national progress towards the CBD Aichi target 11 and when measuring protection levels in mammals. We used PA records from the World Database on Protected Areas to create 12 global PA maps which include combinations along 3 common selection criteria: IUCN classification, PA nationality status, and presence of an explicit PA geometry. Results show that selection criteria may have overwhelming effects on perceived protection levels. A critical interpretation of the implications tied to each selection criteria is presented along with recommendations for key conservation analysis scenarios.

DNA METABARCODING FOR DIET AND PARASITIC ESTIMATION OF MARKHOR (CAPRA FALCONERI) IN CHITRAL, PAKISTAN

Amna Arshad Bajwa

Institute of Biochemistry & Biotechnology, University of Veterinary & Animal Sciences, Lahore, Pakistan
Saher ISLAM, Institute of Biochemistry & Biotechnology, University of Veterinary & Animal Sciences, Lahore, Pakistan ; Wasim SHEHZAD, Institute of Biochemistry & Biotechnology, University of Veterinary & Animal Sciences, Lahore, Pakistan ; Kanwal ZAHRA, Institute of Biochemistry & Biotechnology, University of Veterinary & Animal Sciences, Lahore, Pakistan

Markhor (*Capra falconeri*) population in Pakistan is facing a number of threats due to direct and indirect impact of human activities. IUCN has enlisted this wild goat as endangered. The decline might imply an intensive hunting pressure, deforestation, increasing food and habitat competition with domestic livestock. The potential impacts of intensive grazing by livestock include depletion of scarce forage, habitat degradation and reduction in breeding performance. There is a critical lack of knowledge based on molecular studies about their distribution status and needs for survival. Markhor has been found to be the definite hosts of parasitic nematodes and can be an additional cause of decreasing the population. The domestic goat is dominant livestock species, and a potential competitor with the markhor due to habitat overlap.

The issue of forage competition between livestock and wild herbivores has long been acknowledged as being important for conservation management. Thus there must be evidences available on food components of this wild mammal. This study will demonstrate that non-invasive fecal DNA sampling is feasible for wild goat population diet analysis and estimation of gastrointestinal parasitic load. The total extracted DNA also contains traces of food consumed by host species. Diet habit of markhor will be estimated by exploiting vascular plants specific metabarcoding markers followed by Next Generation Sequencing technologies. In addition; there is a possibility of disease transmission from livestock to the wild caprines. Similar strategy will be used for the estimation of parasitic disease load, especially nematodes, using nematodes specific primers on markhor population. The sequencing results will be analyzed by exploiting bioinformatics tools for diet and nematodes identification of markhor species. The result findings will highlight different threats and pressures faced by this species and provide recommendation for managing markhor habitat.

COMMUNITY PERCEPTION ON BIODIVERSITY CONSERVATION AND SUSTAINABLE USE OF NATURAL RESOURCE IN THE DEGRADED KAGORO-NINDAM FOREST RESERVE, KADUNA STATE, NIGERIA

Himma Bakam

Kaduna State University

Jacinta I ABALAKA, A.P. Leventis Ornithological Research Institute

Many local communities surrounding forest reserves derive their livelihood from the resources the reserves provide and that make the areas prone to pressures. Understanding community perception and attitude towards these areas is important for conserving biodiversity. This study evaluates the current management practice and the perception of local residents surrounding Kagoro-Nindam forest reserve on the conservation and sustainable use of natural resource. We collected data through structured questionnaires from 148 respondents in five villages. Majority of the respondents constituting 45% primarily have farming as occupation. Despite 91.2% of respondents supporting concept of conservation of forest resource, and 90.5% agreeing with the concept of sustainable use of natural resource, 87% of the respondents are actively involved in cutting of trees from the reserve as fuel wood for both commercial and home use. Residents are also aware of other forms of degradation in the reserve. Respondents claimed primary source of recent increase in degradation to be initiated by government who cleared forest trees for timber without replacement and protection measures. The local residents though aware of

conservation and sustainable use of resource, hold negative impression on the forest management. Knowledge of residents' perception can help during conservation actions and management decisions.

4.01 INDICATOR SELECTION FOR BIODIVERSITY MANAGEMENT: WHAT ARE WE DOING WRONG?

Payal Bal

University of Queensland

Ayesha TULLOCH, Australian National University ; Jonathan RHODES, University of Queensland

Indicators help to inform conservation practitioners about management decisions and assess the effectiveness of management. Despite widespread use of indicator species in management and the considerable amount of resources spent monitoring them, they are rarely selected under clearly defined management and monitoring objectives. This makes it difficult for indicator monitoring to report meaningfully on progress towards management targets or effectively inform management decision-making. A better alternative is a structured approach for indicator selection that explicitly links the indicator to the management objectives through the expected improvement in management performance from monitoring. We conducted a review to assess current methods proposed in the scientific literature for selecting indicator species to inform management and to evaluate its effectiveness. Decision theoretic frameworks available in the literature allow conservation practitioners and decision-makers to choose between uncertain consequences of selecting different monitoring strategies to evaluate management decisions. Taking cues from decision theory and the optimal monitoring literature, the review identifies research priorities that can pave the way for developing more effective indicator selection strategies for biodiversity management by highlighting gaps in existing indicator selection frameworks. In the face of limited resources for biodiversity conservation, this will allow us to identify cost-effective indicators for biodiversity management that are defensible and efficient.

INVESTIGATIONS ON POPULATION BIOLOGY OF EGYPTIAN VULTURE (NEOPHRON PERCNOPTERUS) IN MIDDLE AND UPPER SAKARYA REGION, TURKEY

Sunay Balaban

Anadolu University

Elif Yamaç, Anadolu University

Egyptian vulture is one of the scavenger raptor species classified as globally endangered. Especially the European population which is estimated about 3300-5050 individuals has decreased significantly in recent decades. Because of many threats like human disturbance, habitat change and poisoning, populations are still holding decline in many

countries in Europe. Although Turkey has the largest Egyptian vulture population after Spain in Western Palearctic region, there is no detailed information on the species. Determining breeding area, pair number, breeding success and threats on the population are very important for its viability. The aim of our study is to collect data on breeding success and nest characteristics of Egyptian vulture in Middle and Upper Sakarya Region, Turkey. Potential nest sites were searched between 2013-2014 in the study area. It was located 30 and 36 nests in 2013 and 2014, respectively. Totally 17 pairs were successful with 56.6% nesting success in 2013. The number of active nests were 30 and successful nests were 22 with 73.3% nesting success in 2014. Egyptian vulture is cliff nesting species. The mean nesting cliff distance between base and peak (m) was 11.8 ± 6.7 in the study area. The mean height of nests from ground (m) was 6.7 ± 4.5 . The mean nesting cavity's width, height and length (m) were 2.1 ± 1 , 1.48 ± 0.6 and 1.91 ± 0.9 , respectively. In both breeding seasons, negative anthropogenic activities were observed for some nest sites. Although we did not detect any poisoning case for this species in the study area, plenty scavengers killed because of poisoning in recent years in Turkey. Further detailed studies need to be maintained for fully understand threatens and conservation to Egyptian vulture populations in Turkey. This study was supported by a scientific research grant (1303F050) from Anadolu University Research Fund.

MULTI-ECOTYPE MIXTURES IN RESTORATION: A CASE STUDY ON ELYMUS GLAUCUS, A NORTH AMERICAN BUNCHGRASS

Jennifer Balachowski

University of California, Davis

Truman YOUNG, University of California, Davis ; Kevin RICE, University of California, Davis

Researchers and practitioners recognize the importance of using local ecotypes in ecological restoration. Because empirical data do not exist for the majority of restoration species, key issues are whether these species actually express local adaptation, and if local ecotypes alone are sufficiently genetically diverse to adapt to rapidly changing climates. The use of multi-ecotype mixtures incorporating both local and non-local ecotypes has been suggested as a technique to safeguard against climate change without resource-intensive empirical data. A concern with this technique is how individuals of different ecotypes will interact with one another when planted together, and in particular, whether these interactions influence the expression of local adaptation in the resident ecotype. Using *Elymus glaucus*, a North American perennial bunchgrass commonly used in restoration, we conducted a field experiment to test the effect of planting multi-ecotype mixtures in restoration. We reciprocally transplanted four ecotypes of *E. glaucus* without neighboring

plants, as well as with conspecific neighbors in mixtures containing only local ecotypes, ecotypes from the same broad climatic region, and ecotypes from two very different climatic regions. While we did find that ecotypic performance varied by environment (i.e., a GxE interaction), this pattern was not consistent with local adaptation for all ecotypes. For those ecotypes that did outperform others at their home-sites, the effect was not influenced by the addition of conspecific neighbors, or by the ecotypic identity of the neighbors. We conclude that multi-ecotype blends could be considered for restoration when sufficient local seed is unavailable or when future climate adaptation is a key project goal. Furthermore, given that logistic and economic constraints on native seed availability often prohibit the use of local seed in practice, we recommend further research on the efficacy of multi-ecotype mixtures.

175 IPBES - A NEW PATH TO BRIDGE THE SCIENCE-POLICY GAP

András Báldi

MTA Centre for Ecological Research

IPBES is the Intergovernmental Science-policy Platform on Biodiversity and Ecosystem Services, which is a major initiative of governments to copy the success of IPCC (the Intergovernmental Panel on Climate Change) in the topics of biodiversity and ecosystem services. Novelty of IPBES is that it goes beyond interdisciplinarity and considers different knowledge systems, that is besides the well-known academic knowledge system it involves knowledge from indigenous people, and people with traditional ecological knowledge. The integrative nature of IPBES is conceptualized in the IPBES conceptual framework, which was developed over several workshops and consultations to involve as broad range of expertise as possible. The framework puts society and institutions in the middle as it is the major target where IPBES intend to have an impact. The effect of society influences nature through direct drivers. Nature, however, can be seen in different ways. For science it is biodiversity and ecosystems, while it is a more complex system including intrinsic value for indigenous people, who call it Mother Earth. The different views are running parallel in the conceptual framework. The challenge for the future is to use this framework in the assessments, that is to incorporate information from different knowledge systems, to integrate different views and values, and to use it to effectively inform decision makers.

ANALYSIS OF AN ECOLOGICAL QUALITY INDICATOR USED ON INDUSTRIAL SITES

Pauline Balducci

EDF (Electricité de France) R&D[INSTITUTE]AgroParisTech,

UMR 8079

Violaine BROCHIER, EDF (Electricité de France) R&D ; Nathalie FRASCARIA-LACOSTE, AgroParisTech, UMR 8079 ; Agathe LE BOCCQ, EDF (Electricité de France) R&D

Companies can own substantial areas. There is a need for ecological quality assessment, in order to adapt land management to ecological or conservation issues. The composite indicator, called «Land Biodiversity Indicator» (IBF: Indice de Biodiversité du Foncier), was created during A. Lacoëuilhe's thesis (MNHN - EDF R&D, 2014). This tool enables to classify plots of land according to their ecological quality at a local scale (50 to 200 hectares). IBF includes 14 criteria assembled in three thematic: (i) "diversity/heritage" including heritage species and habitats, diversity of habitats and birds, and habitat heterogeneity criteria, (ii) "functionality" based on concepts of landscape ecology (like connectivity), and (iii) "disturbance level" integrating fragmentation, light and noise pollution, artificialisation and exotic invasive species criteria. IBF tends to show the importance of evaluating the functionality and the disturbance level to assess ecological quality of a site. IBF is still experimental. It was tested on four electricity power plant sites, located in different French geographical areas, with contrasted surroundings: woodlands, pastures, crops and industrial areas. The authors will present one application of IBF and the feedback (possibilities and limits). In order to understand the relationships among criteria, statistical approaches were used, especially correlation analysis (rho's Spearman) and hierarchical partitioning analysis. No recurrent correlation among criteria was highlighted in the different tests. Each criterion seems to bring information with no redundancy. The hierarchical partitioning approach showed that the "functionality" thematic better explains the ecological quality assessment in predominantly natural areas, whereas the "disturbance level" thematic better explains it in artificial or semi-natural areas.

MAXIMIZING THE UTILITY OF MAXENT: EXPLORING THE INFLUENCE OF BIAS MASK, FEATURE TYPES, AND STATISTICAL TEST SELECTION ON MODEL PARSIMONY

Shannon Bale

Dalhousie University

Karen BEAZLEY, Dalhousie University ; Peter BUSH, Dalhousie University ; Alana WESTWOOD, Dalhousie University ; Clara FERRARI, Paris Institute of Technology for Life, Food, and Environmental Sciences

Species distribution models (SDMs) are powerful tools used to elucidate niche requirements, predict future habitat of range shifting species, support conservation plans, and more. Maximum entropy (Maxent) is a widespread presence-only modeling technique whose popularity can be attributed to

strong predictive performance and a freely available, user-friendly software package. However, building an effective SDM is both an art and a science, and model parameterization is often rife with subjective decision-making. Maxent is particularly notorious in this regard; many Maxent studies have been criticized for applying default software settings with little justification. This criticism is well warranted, as multiple reports have shown how differing (1) background samples, (2) model 'features' (i.e. mathematical transformations of environmental data) and (3) variable reduction procedures can greatly impact results. We investigate these issues further by analyzing how bias and complexity affect the believability of model outputs for two at-risk passerines: the Canada warbler and the Rusty blackbird. Specifically, we consider the implications of (1) using different masks to account for sample bias (2) including all feature types vs. 'hinge' features alone, and (3) using area under ROC curve (AUC) statistics, training gain, or Akaike's information criterion (AIC) to select the most parsimonious model. While the choice of bias mask influenced Maxent predictions, the effects were less pronounced than in other studies. We also found that the reduced complexity achieved through the use of hinge features alone was not worth the corresponding reduction in model fit. However, the poor trade-off was only revealed by AIC. Indeed, training gain and especially AUC were poor determinants of parsimony. Our findings illustrate that there is no "one size fits all" solution to Maxent parameterization and underscore the importance of tailoring modeling choices to specific study goals.

EXAMINING THE MECHANISMS AND EVIDENCE FOR CONSERVATION ACTIONS THROUGH SCIENCE LEARNING BY PARTICIPANTS IN CITIZEN SCIENCE PROJECTS

Heidi Ballard

University of California - Davis

Tina PHILLIPS, Cornell Lab of Ornithology ; Lina YAMASHITA, University of California - Davis

Citizen science and other forms of public participation in scientific research has emerged as a major tool for studying biodiversity, engaging the public in science and igniting and supporting conservation actions. But evidence is lacking for outcomes and how participating in environmental science research and monitoring does or does not lead to science learning and environmental stewardship. To better understand the cumulative impacts of involving the public in science for conservation, we provide a comparative framework across different models of PPSR, including Contributory (participants collect data), Collaborative (participants also help design and analyze data) and Co-Created (participants work on all area of the scientific process), so projects may leverage strengths of broader and/or more intensive public participation. We examined how participation in citizen

science affects participants' perceptions of their roles in, use of, and contributions to science and conservation, particularly across different types of citizen science projects. Across diverse projects in the U.S. focused on birds, precipitation, air and water quality monitoring, pollinators and eels, we conducted 72 interviews with participants representing low, medium, and high levels of engagement, as defined by the leaders of the 6 citizen science projects. We focused analysis on understanding how their participation in citizen science helped to develop and/or reinforce specific aspects of science and environmental identity. Our initial findings indicate that depending on the quality of participation and participants' interests, the development or reinforcement of science identity is possible at all levels of engagement. Whether leading a local air quality monitoring team, or sporadically submitting monarch larvae monitoring data, many participants expressed deep feelings of empowerment and self-efficacy in their ability to contribute to and use science to address environmental problems.

SHORT-TERM ECO-PHYSIOLOGICAL RESPONSE TO TRANSLOCATIONS FROM CAPTIVITY TO THE WILD IN HERMANN'S TORTOISE

Jean-Marie Ballouard

SOPTOM

Xavier BONNET, CNRS-CEBC ; Simon DELEUZE, SOPTOM ; Elise BECK, SOPTOM ; Orianne LEPEIGNEUL, SOPTOM ; Sebastien CARON, SOPTOM

Although being commonly used in population management, translocation often suffers from a lack of feed-back, notably regarding logistical constraints associated with individual monitoring. In the case of long-lived animal, long-term studies are requiring to assess survival, reproductive and recruitment rates, of translocated and resident individuals. However considering the urgent nature of many species' situations where translocation would be appropriate, fast-assessment techniques should be tested. We assessed the eco-physiological short-term response to translocation of Hermann's tortoises (*Testudo hermanni hermanni*) directly from captivity to the wild. After being maintained in captivity 2 to 8 years, two pools of individuals were released in Spring (n=12) and in Autumn 2013 (n=12) into a natural population impacted by fire after. During the two years post-release period we radio-tracked translocated individuals (N=24) and resident tortoises (N=12) during all the activity season. Movements, behaviours, body condition, basal stress level (corticosterone) and body temperature were regularly recorded. The first year after releasing, translocated tortoise released in Autumn exhibited higher dispersion than resident tortoise and translocated tortoise released in Spring. We found no differences in thermoregulation, corticosterone level and body condition between all translocated and resident tortoises. Body condition of all tortoises increased rapidly in Spring. We found

no sign of perturbation in resident tortoises. Contrarily, resident males mated with translocated females. Survival of the three groups of tortoise was mainly affected by predation. Because tortoise adapt well to their new environment, translocations should be further tested on larger spatial and time scales to improve population restoration programs, especially in threatened species with limited dispersal ability.

91: LEOPARD RESEARCH IN SOUTH AFRICA: RESPONSIBLE SCIENCE OR ACADEMIC INDULGENCE?

Guy Andrew Balme

Panthera

Peter LINDSEY, Panthera ; Lourens SWANEPOEL, University of Pretoria ; Luke HUNTER, Panthera

Science and conservation are often driven by different agendas, partly because many researchers are reluctant to tackle applied topics perceived to be less competitive for publishing or too impractical to study. Consequently, research often fails to contribute meaningfully to conservation outcomes. We use leopards (*Panthera pardus*) in South Africa to illustrate this mismatch between research and conservation priorities. A review of the scientific literature showed that leopard studies in South Africa focused disproportionately on basic research, particularly on leopard feeding ecology inside protected areas. Academics were responsible for most articles but avoided applied studies, even though they were published in higher impact journals and took less time to undertake. An assessment of active leopard projects further demonstrated that studies were clumped in areas of low conservation concern, generally employed invasive research methodologies and often failed to publish their findings. Many projects were also funded by commercial volunteer programs with financial incentives for conducting research. We recommend that leopard researchers in South Africa and carnivore researchers more widely engage with practitioners to ensure the most pressing conservation issues are addressed. Scientists must also situate their research in a broader conservation context and evaluate the outcomes of management decisions. Finally, continued funding and permissions for research should at a minimum be contingent on research outputs being published in the peer-reviewed literature. For leopards and many species like it, the case for undertaking scientific research on basic ecology or behaviour without contributing to conservation is rapidly waning.

ADVANCING INNOVATIVE CONSERVATION TOOLS BY IMPROVING KNOWLEDGE OF DECISION-MAKING ON PRIVATE LANDS

Jessica Balukas

University of Maine

Kathleen BELL, University of Maine ; Aram CALHOUN, University of Maine ; Malcolm HUNTER, JR., University of Maine ; Dana BAUER, Boston University

Managing natural resources on private lands is a significant conservation challenge. Extensive private ownerships (e.g., over 60% of lands in USA and over 75% of France's total forest area) necessitate consideration of the effectiveness of conservation tools on these lands, and our research aims to improve conservation efforts by enhancing understanding of landowner goals and decision-making. By linking landowner survey responses with spatial data describing landscapes, we develop micro-scale, spatially-explicit models of landowner decision-making. We test the extent to which models of behavior are improved by the addition of detailed spatial data, consideration of spatial relationships, and recognition of heterogeneous landowners and natural landscapes. We combine data from a 2012 Maine landowner survey with spatial data on landscape features, human communities, land ownership, and public policies. Guided by the results of prior literature, we classified landowners using cluster analysis and developed discrete regression models of past and intended land management and development behaviors. Results suggest that landowner and landscape characteristics explain variation in decision-making and behaviors. The addition of spatial variables describing parcels and broader landscapes improves the interpretation of survey results and the fit of past and intended land management and development behavior models. Incorporating greater decision-making heterogeneity into the regression models also improves the performance of these models. Understanding how landowner decision-making varies across individual landowners and landscape settings could improve conservation policy development and implementation by helping policy-makers better integrate landowner perspectives into conservation efforts. In turn, this knowledge can potentially improve ex-ante assessment of conservation tools and ex-post compliance with voluntary and regulatory approaches to conservation.

SYMPOSIUM 134: APPLYING EMPIRICAL ESTIMATES OF MARINE PROTECTED AREA EFFECTIVENESS TO ASSESS AND IDENTIFY GAPS IN CONSERVATION PLANS

Natalie Ban

University of Victoria

Chris MCDUGALL, Haida Fisheries Program - Council of the Haida Nation and Central Coast Indigenous Resource Alliance ; Martina BECK, University of Victoria ; Anne SALOMON, Simon Fraser University ; Ken CRIPPS, Central Coast Indigenous Resource Alliance

While efforts to meet international commitments to counter biodiversity declines by establishing networks of marine

protected areas (MPAs) continue, assessments of MPAs rarely take into account measures of effectiveness of different categories of protection, or other design principles. We carried out a meta-analysis of ecological effectiveness of IUCN categories I-II (no-take), IV and VI (MPAs) compared to unprotected areas. We then applied our ecological effectiveness estimates – the added benefit of marine protection over and above conventional fisheries management – to a gap analysis of existing MPAs, and MPAs proposed by four indigenous groups on the Central Coast of British Columbia, Canada. Additionally, we assessed representation, size, spacing, and governance considerations against MPA design criteria. We then used Marxan to identify areas where gaps could be filled. We found significant differences in response ratios for IUCN Categories IV and VI MPAs compared to no-take reserves and areas open to fishing, although variability in responses was high. By rescaling the predicted ecological effectiveness ratios, we found that, compared to no-take reserves (biodiversity conservation effectiveness 100%) and open fishing areas (0% additional biodiversity contribution), IUCN Category IV had a predicted effectiveness score of 60%, ranging between 34% and 89% (95% lower and upper CI, respectively), and IUCN Category VI had a predicted effectiveness score of 24% (ranging between -12% and 72%). We found that the existing MPAs did poorly when compared against most MPA design criteria, whereas the proposed MPA network achieved many of the best practices identified in the literature, and could achieve all if some additional sites were added, as identified using Marxan. Our case study demonstrated a method for applying empirically-based ecological effectiveness estimates to an assessment of MPA design principles for an existing and proposed network of MPAs.

BIG CAT AT OUR DOOR STEP: RECOVERY AND FUTURE OF ENDANGERED LIONS IN INDIA

Kausik Banerjee

Wildlife Institute of India

Yadvendradev JHALA, Wildlife Institute of India

Asiatic lions elucidate India's conservation commitments and portray a success story. The species that once ranged from Persia to Palamau in eastern India, was almost driven to extinction by indiscriminate hunting and habitat loss. A single relict population of about 50 lions persisted in the Gir forests of Saurashtra peninsula, western India by late 1890's. With stringent protection offered by the Nawabs of Junagadh and subsequently by the State run Gujarat Forest Department, Gir lions have increased to a current population of over 400 with an annual rate of about 2%. Lions were restricted to the Gir forests (1,800 km²) till the mid-1980's, but have since dispersed to occupy over 20,000 km² of human dominated agro-pastoral landscape of Saurashtra. We herein present our 20 years' research findings on Gir lions based on radio-

telemetry to understand multiple factors responsible for the recovery and future viability of the species. Several factors were responsible for the recovery of lions in Saurashtra, there were: stringent protection from hunting, tolerant and benevolent attitudes of local communities, tolerant behaviour of lions, abundant livestock and other prey, a fair and transparent livestock predation compensation scheme and low density of lions in the human dominated landscape. The paper articulates the importance and role of each of these factors to lion recovery and future viability. Lions now occur in areas where they had been locally extinct for over 5 generations, how communities cope and what their attitudes are towards this large predator are discussed. Mechanisms that would permit long-term persistence of an increasing lion population in human dominated landscape in terms of lion demography, habitat needs, prey availability, conflict resolution and active management are presented. The facets of politics of lion conservation in India and the roles State and Federal Governments, Scientific Institutions, and the Judiciary have played are discussed.

DESIGNING MARINE PROTECTED AREAS IN A CHANGING WORLD: METAPOPULATION RESPONSE TO SPATIALLY-STRUCTURED FLUCTUATIONS IN LARVAL CONNECTIVITY

Ridouan Bani

McGill University

Frederic Guichard, McGill University

Metapopulation theories predict the dynamics of ecological systems that are connected through the limited movement of individuals over heterogeneous landscapes. One key property of such spatial dynamics is the fluctuation in the rate of movement between populations. In coastal habitats, spatial and temporal heterogeneity in movement and dispersal can result from changes in ocean transport and life histories. It can thus be driven by climate change and human activities, and should be integrated into coastal management tools such as marine protected areas. Based on observed and predicted evidence of fluctuations in marine connectivity, we present a theoretical framework that predicts how spatial structure found in temporal fluctuations of connectivity between populations can affect regional metapopulation growth. We build on recent work showing how the sign and strength of overall temporal covariance in connectivity between populations can affect metapopulation growth. In spatially-explicit metapopulations, we show that the effect of connectivity can be captured by the scale and density of regions of positively and negatively correlated fluctuations in connectivity. This spatial aggregation greatly simplifies the description of spatial dynamics in complex metapopulations, and allows optimizing the design of reserve networks in relation to current and predicted changes in ocean connectivity. Finally, we show how two life-history

traits of species, larval phase duration and timing of larval release, can be used to predict the response of species to the spatial structure of covariance in connectivity. We illustrate our predictions using quantitative models of larval transport along the West coast of Canada (British Columbia). In the context of marine protected areas, we discuss the optimization of size and spacing of protected areas, using either the spatial distribution of average connectivity or of its temporal covariance

MOVEMENTS OF AN ENDEMIC FRUIT PIGEON IN URBAN AREAS

Alice Baranyovits

University of Auckland

Jacqueline BEGGS, University of Auckland ; Mick CLOUT, University of Auckland ; Todd DENNIS, University of Auckland ; George PERRY, University of Auckland

Urban areas are often described as being highly modified and fragmented, characterised by a matrix of different land uses, some of which are capable of supporting native wildlife. The presence of native species within urban areas can provide ecosystem services as well as help to connect an increasingly urban human population with the surrounding native biota. In New Zealand, the kereru (*Hemiphaga novaeseelandiae*), a large (c.650g) endemic fruit pigeon is known to occur in urban environments. Within urban areas kereru are not restrained to just the remnant areas of native forest, but also utilise the resources found in many private gardens. However, little is known on the amount of time kereru spend within these different habitat types and how they move within the urban matrix. As kereru are key seed dispersers, known to consume the fruits of over 70 native plant species and several introduced ones, understanding their movements within urban areas is key to understanding the potential dispersal distances in these environments. We present kereru movement data collected using multiple tracking technologies (e.g. PTTs and GPS) from within the Auckland urban area. These data provide insight into how urban kereru move between and utilise different habitat types within the urban area.

GENOMICS INFORMING CONSERVATION STRATEGIES: WHICH POPULATIONS SHOULD BE RECONNECTED IN AN ENDANGERED RODENT?

Soraia Barbosa

CIBIO-InBIO, Porto University[INSTITUTE]Cornell University
Joana PAUPÉRIO, CIBIO-InBIO, Porto University ; Tom WHITE, Cornell University[INSTITUTE]Lancaster University ; Paulo Célio ALVES, CIBIO-InBIO, Porto University[INSTITUTE]University of Montana ; Jeremy SEARLE, Cornell University

To develop appropriate conservation practices in the context of current climate change and habitat reduction, it is important to determine which environmental factors most influence a

species distribution across the landscape. New sequencing technologies allow now the collection of genome wide data that can be used to detect functional connectivity between populations and, by associating it with the species ecological requirements, detect effective dispersal corridors. The Cabrera vole (*Microtus cabrerarum*) is a rodent of conservation concern, with fragmented populations within Iberia. Its specialisation to fast-disappearing Mediterranean herbaceous habitats, low dispersal ability and metapopulation like structure, makes this species highly susceptible to climate change and habitat loss. In this study we used Genotyping-by-Sequencing to analyse 86 samples representative of the species entire distribution, resulting in a set of over 5 400 SNPs. We were able to define 2 major evolutionarily significant units (ESUs): Western (W), distributed in Portugal and central Spain; and Eastern (E), distributed from northeast to southeast Spain. This ESU is further subdivided in three populations, matching the four described nuclei of the Cabrera vole distribution. There is, however a signal of population expansion from the southern regions of E to W, contrasting with previous results for the mitochondria. Despite this extensive admixture, analysis of least-cost paths and genomic similarity showed limited predicted and functional connectivity of populations between and within the ESUs, and detected the major limiting factors for the Cabrera vole to be associated with the maintenance of its herbaceous habitat year-round. Conservation efforts should thus focus on landscape management strategies that promote connectivity within each ESU, particularly in the inferred corridor areas, by preventing wetland drainage and ultimately the increasing isolation of the metapopulations.

THE RANGE EXPANSION OF THE KUH'L'S PIPISTRELLE BAT IN ISRAEL: WHAT CAN BE LEARNT FROM THE POPULATION'S GENETICS?

Shirli Bar-David

Ben-Gurion University of the Negev

Naama SHAHAR, Ben-Gurion University of the Negev ; Naama KOPELMAN, Weizmann Institute ; Amit DOLEV, Israel Nature and Park Authority ; Eran LEVIN, University of Arizona ; Eran AMICHAJ, Tel-Aviv University ; Carmi KORINE, Ben-Gurion University of the Negev

An understanding of the process of a population's range expansion can be applied to the conservation of recovering species and species that are shifting their range due to climate change and human activity. The insectivore bat Kuhl's pipistrelle, *Pipistrellus kuhlii*, is a common, Mediterranean species that is highly associated with anthropogenic habitats. During the last decades, the species has expanded its range in Israel from the Mediterranean zone south to the desert region. We aimed to explore whether genetic structuring occurred during range expansion, and if so, what can be learnt from the genetic structuring about the expansion process itself. 160

individuals were sampled in 18 foraging and roosting sites, here defined as “subpopulations”; throughout Israel and DNA samples were amplified by seven microsatellite loci. Significant genetic differences were found among subpopulations (AMOVA, $\phi_{ipt}=0.03$, $P=0.001$). STRUCTURE analyses indicated a composition of three main groups ($k=3$): the Mediterranean zone, the Negev Desert and Eilat (the most southern range of distribution). The Negev Desert subpopulations were genetically closer to each other than the other subpopulations (PCA). The Eilat subpopulation was characterized by the lowest genetic diversity: the lowest heterozygosity, the lowest number of alleles and no private alleles, indicating a recent founding event at the wave front of the population’s expansion. These findings support theoretical models and agree with some empirical studies that have shown that genetic structure can arise during range expansion, within a few generations and a limited range. Founding events at the range expansion’s wave front can lead to a decline in genetic diversity along the expansion front. Such a genetic structure, though it might diminish over time due to gene flow and additional range expansion, has the potential to facilitate adaptive evolution, thereby affecting the population’s long-term persistence.

82 QUANTIFYING THE RELATIVE IMPORTANCE OF FOREST QUALITY AND FOREST EXTENT FOR THE CONSERVATION OF TROPICAL BIOTA

Jos Barlow

Lancaster University

Most efforts to reduce human impacts on tropical forest biodiversity focus on maintaining forest extent, and recent reductions in the rate of deforestation in countries such as Brazil are considered a conservation success story. Yet the rate of forest degradation is rising in many parts of the tropics as remaining forests are affected by selective logging, wildfires and edge effects. Although these degradation events are known to reduce the conservation value of tropical forests, the relative importance of forest quality versus forest extent remains unclear. We evaluated this in two regions of the eastern Brazilian Amazon, using biodiversity data (dung beetles, birds, large and small stemmed plants) collected from over 250 forest transects in thirty-five 5000 ha catchments distributed along a gradient of forest loss (12-100% forest cover). We used Random Forests, a decision tree classification method, to link measures of deforestation and degradation with the occurrence of forest species. Across most taxa, measures of forest degradation were found to be as important as forest extent in determining species occurrence. Moreover, species responses to degradation were often correlated with life history traits associated with conservation importance, such as small range sizes. Finally, we quantify the extent to which forest degradation reduces biodiversity over and above

deforestation, defining conservation value as the summed reporting rate of forest species in catchments. On average, catchments which lost 25% of their forest cover lost 50% of their conservation value, indicating that degradation can be as important as deforestation in reducing forest biodiversity. Our results demonstrate that legal frameworks focussing only on forest extent are not sufficient to safeguard the unique biodiversity of tropical forests, and emphasize the importance of including forest condition as a key objective in forest conservation policies.

INVESTIGATION OF REPRODUCTIVE BIOLOGY OF ENDANGERED GREATER ADJUTANT LEPTOPTILOS DUBIUS IN ASSAM

Purnima Barman

Aaranyak

Dhiren SHARMA, Gauhati Univeristy

The breeding biology of endangered *Leptoptilos dubius* was investigated from August 2009 till December 2014 in Dadara-Pasariya-Singimari (26° 13'13.47"N or 26.2204083 N and 91° 38' 03.03 " E or 91.6341750 E) nesting colony, Kamrup District (25°46'- 26°49'N and 90°48'- 91°50'E) where more than 50% of the species' global population exist. We recorded 95 numbers of nests in 2009-10, 90 nests in 2010-11, 114 nests in 2011-12, 152 nests in 2012-13, and nests 128 in 2013-14 and 171 nests in 2014-2015. The breeding season of *Leptoptilos dubius* starts from late August to early April. Nesting colonies are very rarely seen within Indian Protected Area network in India. This colonial nesting bird forms nesting colonies in tall trees in thickly populated village in Assam. The bird mainly prefers tall trees *Anthrocephalus cadamba*, *Artocarpus heterophyllus*, *Pithecellobium monadelphum* and *Bombax ceiba* for nesting. We recorded up to 10 active nests in one single Dewa (*Artocarpus lakoosha*) tree In Assam. Breeding plumage of the birds appears on the onset of peak monsoon in July. From August they start moving to the breeding locations. Soon after they start making pair and select nesting trees. Nest building, Parental investment was studied. Both sexes participate in the nest building activity. Clutch size varies from one to four eggs although hatching success of four eggs is not reported earlier. In 2014 we recorded four clutch with four successful hatchling success in atleast four nests. The fledgling period varies from a minimum of 138 days to 145 days. We recorded high nest fall chick mortality of 46.5% in 2011-12, 50.9% 2012-2013, and 41.9% in 2013-2014. During our study period, some of the nest fall chicks were rescued and successfully released after hand raising at Assam State Zoo. Investigation was also carried out in guts contents of dead juveniles. Blades, nails, and some unusual foods were found in the stomach which is alarming for the population.

COMMUNITY DRIVEN MODEL VILLAGE OF ENDANGERED GREATER ADJUTANT STORK LEPTOPTILOS DUBIUS IN ASSAM

Purnima Barman

Aaranyak

Madhumita BORTHAKUR, Aaranyak[INSTITUTE]Aaranyak ; Dhiren SHARMA, Gauhati university

The Greater Adjutant is a globally endangered bird with less than 1000 global population. Habitat Loss and poaching are the major threats and the population trend is displaying decreasing trend. Assam is considered to be its last stronghold. In Assam, this colonial nesting bird makes nesting colonies in thickly populated villages. In recent years, many nesting colonies in Assam have disappeared. Nest-tree owners were cutting down the trees to avoid having rotten and smelly nest materials and the excreta of this carnivorous bird in their backyards and also to support income. The participation of the nest-tree owners is key. Since 2009, we initiated a community conservation programme in Assam. Objectives: a. Building support of tree owners and communities and develop an "ownership feeling factor" b. To protect the breeding and foraging habitat of Greater Adjutant. Methods: We promoted the environment education of a school where tree owners children get education. Youths of the villages including those youths disturbed the birds were engaged in bird rescue program and designated as "nest protector". To motivate women, we first organised crafts, cooking, weaving competition among women communities and also trained on various livelihood opportunities. Integration with local religious programme. The mythological story about the stork delivering a baby was narrated to elderly local women. We involved a famous filmstar to encourage the tree owners and sponsored scholarship programme for tree owners children. We motivated local Police Department as one of the stakeholder for the bird. As a result, the population of this bird has increased in this nesting colony. "ownership feeling" was developed. Kamrup police became the major stakeholder. Women became the responsible guardian. Local School sustains the campaigns by their own. This conservation story is recognized as a model of community conservation now.

TOWARDS A SYSTEM OF NATIONAL ENVIRONMENTAL ACCOUNTS: PRIORITIES FOR MONITORING

Megan Barnes

There is a long-standing need for reliable surveillance of national trends in ecosystem health and wildlife populations, to support decision-making and reporting in environmental and natural resource management at National scales. We are undertaking a prioritisation in Australia to select a draft national set of fauna indicator species using existing monitoring programs and capacity, as a component of a national environmental surveillance capability. We compiled a meta-database of existing monitoring initiatives and other key attributes for Australian fauna as a basis for developing and applying a prioritisation framework for selecting fauna indicator species. The prioritisation framework was developed to enable transparent evaluation of trade-offs between different species and monitoring methods based on attributes relating to required effort and investment, power to detect change and capacity to produce data that will permit reliable detectability across geographies and threats. The prioritisation tool selects a cost effective and complementary set of monitoring programs across geographies, threats and taxonomic groups using a greedy heuristic. Moreover, it can be modified to include specific institutional goals – for instance, citizen science based monitoring projects. The selected set in Australia is a first step towards a national environmental accounting system.

BATTITUDE: AN ASSESSMENT OF HUMAN ATTITUDE AND BEHAVIOUR TOWARDS THE CRITICALLY ENDANGERED PTEROPUS RODRIGUESIS (RODRIGUES FRUIT BAT).

Paul Barnes

ZSL and UCL

The study follows a period of 40 years of conservation action that has seen the bat population recover from only 70 individuals in 1974. Today, with human and bat populations higher than at any time in history, the likelihood of increasing conflict between people and bats has potential to threaten survival of this vulnerable species and undermine 40 years of conservation. The research was carried out using focus groups, structured questionnaires, semi-structured interviews and simplified questionnaires and games for young children, with over 350 respondents of all ages across the entire island. Attitudinal analysis was carried out on a 40-item Likert scale, which confirmed a number of attitude dimensions that could be analysed independently. The results showed that 90% of respondents held neutral to positive attitudes overall although there were significant numbers of respondents who now believe that bat numbers, roosting locations and

feeding patterns should be controlled. Perceived and actual knowledge were found to have significant relationships with all attitude dimensions tested. In relation, there was a large disconnect between respondents perceived and actual knowledge, suggesting that although people are very knowledgeable about bats they have low confidence in their ability. Taking part in conservation activities was related to a higher perceived knowledge and more positive attitudes but there are significant perceived and actual behavioural controls preventing respondents from taking part on bat counts. There was high social pressure to carry out mitigation (using deterrents to protect fruit) and persecution (killing bats to protect fruit) and nearly half of all respondents intent to use deterrents in future. The research gave unique insights into the effectiveness of sensitisation and education conservation work to date and results will be used as evidence for continued protection of bats and to alter the conservation strategy to improve efficiency.

INNOVATIVE CORPORATE-COMMUNITY PARTNERSHIP IN REHABILITATION AND CO-MANAGEMENT OF MANGROVE WETLAND IN CENTRAL PHILIPPINES

Abner Barnuevo

KPGroup Philippines, Inc.

Takashi ASAEDA, Department of Environmental Science, Saitama University; Yoshikazu KANESAKA, Kanepackage Co. Ltd.

The decimation of Philippine mangroves due to fishpond conversion stimulated several sectors to rehabilitate the damaged habitat. Several mangrove projects were initiated by the government and non-government agencies; however several efforts failed or had poor survival due to inappropriate site and species selection and lack of long term management. Presently, several industries initiated environmental activities as Corporate Social Responsibility (CSR) and planting mangroves is one of common options. This paper focused on mangrove conservation efforts in Olango Island, central Philippines which is the first Ramsar site in the country initiated through a corporate-community partnership. The private entity innovated and shifted the paradigm of widely accepted event-driven into integrated approach, mobilized locals in replanting degraded mangroves, established plant nursery and protection of the plantations. Lessons learned showed that community involvement is crucial in the success of industry-initiated effort. The locals serve as resource managers directly responsible for day to day decisions. Assessment of plantation showed remarkable survival rate of $87.78 \pm 5.6\%$ with mortality rate of $12.22 \pm 5.6\%$ and significant post-planting recruitment. In retrospect, the industry-led effort showed effectiveness of corporate-community partnership with streamlined long term management plan, appropriate technical design

and community participation. In addition to increasing the mangrove awareness, it promotes the locals' sense of resource stewardship to manage the natural resources where their daily subsistence depends.

68. EFFECTS OF MONOCULTURES AND MIXTURES ON ARTHROPOD COMMUNITIES

Nadia Barsoum

Forest Research

Catherine BRUCE, School of Biological Sciences, University of East Anglia; Doug W. YU, School of Biological Sciences, University of East Anglia; Lauren FULLER, Forest Research; Katy REED, Forest Research; Francis ASHWOOD, Forest Research

A mixed tree species composition is frequently proposed as a way to increase habitat heterogeneity and support greater biodiversity in commercial forests. International forest policy is increasingly advocating stands of mixed tree species, although supporting evidence of the biodiversity benefits is still needed. We investigated the effect of forest stand composition on arthropod community structure and composition. We conducted pitfall and malaise trapping in three common plantation forest stand types: oak monocultures, Scots pine monocultures, and intimate Scots pine and oak mixtures. The arthropod assemblages sampled by pitfall and malaise trapping showed different responses to the three forest stand types. The pitfall trapping results revealed that there were few differences in the species composition of ground-dwelling arthropods between the stand types and indicator species analysis found few species specifically affiliated with any of the stand types. The malaise trapping results showed a strong effect of stand type on the composition of arthropod communities, although species richness did not differ significantly between stand types. Our results do not support the perception that intimate mixtures of dominant tree species support greater overall levels of species richness or diversity. The composition of a forest stand was more important in shaping arthropod community composition, although the strength of this relationship was dependent on the taxonomic group being studied. Further research is required to determine optimum landscape-scale planting matrices of multiple canopy tree species in order to support forest biodiversity.

LARGE-SCALE DECLINE OF BATS AND BUSH-CRICKETS REVEALED THANKS TO AUTOMATIC ACOUSTIC MONITORING SCHEME.

Yves Bas

MNHN

Christian KERBIRIOU, MNHN; Alienor JELIAZKOV, MNHN; Isabelle LE VIOL, MNHN; Jean-François JULIEN, MNHN

A nation-wide acoustic monitoring program based on both car transects and point counts carried out by volunteers

was launched in France in 2006. Data gathered on 3560-km car transects and 1270 point counts, surveyed twice a year, revealed a negative trend for three common bat species whose decline was previously unsuspected: *Pipistrellus pipistrellus*, *Nyctalus leisleri* and *Eptesicus serotinus*. Useful data were also serendipitously collected on several species of bush-crickets (Orthoptera Tettigonioidae) thanks to their nocturnal activity producing ultrasonic songs. Using a new automatic identification process on the recordings, these data also revealed unexpected decline for two common species of bush-crickets: *Tettigonia viridissima* and *Ruspolia nitidula*. During this same period, new technologies allowed to achieve full-night sampling, and thus to increase sampling efficiency, especially for elusive species of both groups. This led us to propose in 2014 a third protocol taking advantage of these new detectors. Using both current data and simulations, we compared the three different types of acoustic data collection (car transect, short point counts, and full-night point recordings), and their statistical power to detect alarming species trends (-30 % over 10 years). Results showed that car transects were optimal for monitoring most bush-cricket species, and some of the most mobile and large bat species, while full-night recordings would provide a better monitoring for most bat species, especially those which have a high activity rate along the night. The protocols therefore showed a very good complementarity and keeping up them should help avoiding any representativeness bias.

STATUS AND FOOD HABITS OF THE ENDANGERED DHOLE CUON ALPINUS IN KHANGCHENDZONGA, SIKKIM, INDIA

Tawqir Bashir

Wildlife Institute of India

Tapajit BHATTACHARYA, Wildlife Institute of India ;

Kamal POU DYAL, Wildlife Institute of India ; Sambandam

SATHYAKUMAR, Wildlife Institute of India

We investigated the ecology of the endangered dhole or wild dog *Cuon alpinus* in Khangchendzonga Biosphere Reserve in Sikkim, India. Based on camera trapping and sign surveying along trails we assessed the relative abundance, distribution and activity pattern of dholes. Morphological characteristics evident in the camera-trap photographs indicated the dhole population in the area as the rare and genetically distinct subspecies *C. alpinus primaevus*. Dholes were detected over a wide elevation range (2,501–4,100 m) that encompassed the upper temperate, subalpine, and alpine scrub zones. Dholes were diurnal, with peak activity at 0800–1000 hours. Analysis of 41 scats indicated a diet comprising mainly mountain ungulates, rodents and pikas *Ochotona* sp. Based on historical reports (1888–1894) dholes were known to be formerly abundant in Sikkim but were hunted to meet the high demand for their alleged medicinal properties. With no information

on their status for over a century, our study suggests that the species is now rare in the area. Therefore, to aid the conservation of this rare population of dholes, extensive research and monitoring is required in the area and elsewhere in the Eastern Himalaya.

PLANT-LEAFHOPPER FOODWEBS IN LARGE VS. SMALL HABITAT FRAGMENTS AND OF COMPLEX VS. SIMPLE LANDSCAPES ARE SIMPLIFIED, BUT HARBOR MORE SPECIALIST SPECIES

Peter Batary

Georg-August-University

Verena RÖSCH, Georg-August-University ; Teja TSCHARNTKE,

Georg-August-University

Decline of grassland species diversity due to increased management intensity has been shown at local and landscape scales. However, studies on foodweb interactions are still very scarce. In 2010 we surveyed leafhoppers and plants on 14 small (0.1-0.6 ha) and 14 large (1.2-8.8 ha) semi-natural calcareous grasslands in Germany, differing in isolation from other calcareous grasslands and in composition of the surrounding landscape (i.e. a gradient from simple to complex landscapes). We quantified weighted trophic links between plants and their phytophagous leafhoppers for each grassland fragment. Analysing major characteristics of the foodwebs, we showed that both generality (no. of hostplant species per leafhoppers) and linkage density (mean of generality and vulnerability) increased with increasing connectivity in small fragments, but decreased in large fragments. This implies the prevalence of generalist (oligophagous and polyphagous) species in better connected small fragments, whereas better connected large fragments appeared to be dominated by specialist (monophagous) species. This pattern was also reflected in interaction diversity (Shannon diversity of interactions). Additionally, we found that in simple landscape the interaction diversity was enhanced by connectivity, but in complex landscapes the better connected fragments hosted more specialist species resulting in less complex interactions. In summary, our results show that in the remaining protected calcareous grassland fragments, hostplant-herbivore foodwebs are moderated by several interacting variables of landscape structure. If the conservation aim is to preserve the specialist species then we should focus on their simpler foodwebs in large and better connected fragments in complex landscapes.

EVIDENCE AND VALUE JUDGEMENTS IN CONSERVATION DECISIONS

Sana Bau

The University of Melbourne

The global biodiversity crisis demands effective, defensible environmental decision making. The drive towards an “effectiveness revolution” akin to that of medical practice has gained momentum in recent years. The impact of cognitive factors such as unconscious biases and heuristics on management and decision making is an important but rarely-acknowledged barrier to effective decisions. A common reliance on subjective judgement is problematic in conservation management as findings of judgement and decision making (JDM) research reveal that it is prone to systematic unconscious bias. This study explores the effect of one such bias in the interpretation of evidence informing a conservation decision scenario. Confirmation bias is a well-established phenomenon in which information that is consistent with a pre-existing conceptual understanding of an issue is privileged over contradictory information. Insights from JDM on decision making under uncertainty have direct relevance to conservation practice, due to the high uncertainty of complex natural systems intersected with social, economic and political dimensions. Using Australia’s Great Barrier Reef as a case study, the effect of confirmation bias on judgement tasks related to conservation management was investigated via an online experiment. A biasing effect of confirmatory interpretation was evident in the evaluation of factual and value-based arguments, for and against competing management alternatives, in addition to the degree of subjective belief in preferred management options. This research addresses the under-acknowledged issue of cognitive frailties in conservation decision making. In practice, confirmation bias may limit effective decision making by cognitively “filtering” the range of alternative management options in decisions reliant on subjective judgement. Understanding this phenomenon may help improve the effectiveness of management strategies in practice.

INFLUENCE OF SOCIAL SYSTEMS AND POPULATION DYNAMICS ON THE EVOLUTIONARY RESPONSES TO ENVIRONMENTAL PRESSURES - A CASE STUDY IN WESTERN LOWLAND GORILLAS

Alice Baudouin

The group of genes coding for the major histocompatibility complex (MHC) are among the most polymorphic ones because they are involved in pathogens’ defense. A high MHC variability improves the defense of individuals against a large range of pathogens and contributes to population sustainability. Population demographic crash is expected to strongly negatively affect the diversity of MHC. However, in social species, the type of social system is additional factor acting on the redistribution of MHC genes. Indeed, MHC is supposed to play a role in mate choice, although behavioral mechanisms (through olfactory communication or recognition of kinship) remain to be specified. We studied changes in MHC variability in a western lowland gorilla (*Gorilla gorilla gorilla*) population that suffered from a demographic crash due to Ebola epidemics. In this species, groups include only one dominant male that monopolizes the reproduction of its females. During natal or secondary dispersal, females join a solitary male or a new harem where they reproduce. We aimed at understanding the influence of gorilla social system on the effects of Ebola disturbance on MHC variability. We collected data on population structure and group composition through a long term monitoring of this population before and after Ebola and we used noninvasive DNA (i.e. feces) genetic analyses in order to investigate the intra and inter-group MHC variability before and after Ebola, and mate choice. We developed MHC haplotyping in gorillas using NGS and DGGE sequencing and a linked microsatellite. Preliminary results suggest that formation of new groups by solitary males after Ebola, possibly related to female mate choice, explained the changes in MHC variability. Applying this approach to other primate species with different social systems and different environmental pressures will allow to determine general patterns of the relative role of social and environmental pressure on MHC variability.

101-MANAGING SMALL NATURAL FEATURES: A SYNTHESIS OF EMERGENT SOCIO-ECONOMIC ISSUES

Dana Bauer

Clark University

Kathleen BELL, *University of Maine*; Erik NELSON, *Bowdoin College*; Vicenc ACUNA, *Catalan Institute for Water Research, ICRA*; Jessica BALUKAS, *University of Maine*

Several types of small natural features provide ecological benefits and ecosystem services disproportionate to their size. Desert springs, vernal pools, and rocky outcrops are a few examples. Key socio-economic issues associated with their conservation include: uncertainties over the location of individual features; temporal variations in their contributions to ecosystem services; a lack of understanding in their linkages to each other and to the surrounding landscape; spatial correspondence of the accrual of beneficial services and the costs of protection; the policy context; tensions between private property rights and public rights to environmental protection; and public perceptions of insignificance. However, their size and spatial distribution allow unique opportunities for experimenting with different conservation tools as they may require less total protected area, less coordination across diverse stakeholders, and less intensive forms of resource protection than their larger counterparts. In addition, interesting opportunities for diverse and nested management structures arise from different landscape-scale perspectives of these features. To improve understanding of these management challenges and to seize future management opportunities, we review current and historical approaches for conserving small natural features and synthesize emergent socio-economic issues and conservation success strategies. Comparing and contrasting experiences across distinct types of features reveals interesting patterns of the similarities and differences in conservation outcomes and the sensitivity of these outcomes to social, economic, and ecological factors. Further examination and testing of conservation approaches across different landscapes and features will advance our understanding of small natural features and yield important guidance for achieving greater strategic coordination and ecological coherence across disparate management efforts.

FOOD BASE OF THE SPOTTED HYENA (CROCUTA CROCUTA) IN ETHIOPIA MOSTLY ANTROPOGENIC

Hans Bauer

WildCRU

Gidey YIRGA, *Mekele University*; Claudio SILLERO, *WildCRU*

We investigated the food base of the spotted hyaena (*Crocota crocuta*) across Ethiopia. Scat was analysed from 17 randomly selected study sites, including two National Parks. We assessed livestock depredation in 10 sub-districts, interviewing 3080 randomly selected households. We found that most scat from all sites contain mostly antropogenic food remains. Garbage is the dominant food source, but households also reported losses of 2230 domestic animals, 3.9% of their stock over the past 5 years. All hair in all scat was of domestic origin, except for a

few hairs of natural prey in National Park. Survival of spotted hyenas in Ethiopia is thus dependent on livestock and waste management.

LARGE-SCALE FACTORS ASSOCIATED WITH BROWN BEAR DAMAGES IN EUROPE

Conflicts between humans and large carnivores are a challenge for conservation biologists and resource managers. Besides the large body of literature that tackles this issue, the mechanisms underlying these conflicts still remain unclear. We investigated which large-scale factors are associated with differences in the occurrence of brown bear (*Ursus arctos*) damages across European countries. We hypothesized that damage occurrence is related to (1) bear population size and density; (2) landscape features; (3) bear management; and (4) economic variables. We collected information on bear damages to livestock, apiculture and agriculture for 18 European bear population segments (hereafter populations), and used the number of compensated claims as an approximation for the number of damages. For each population, the most recent 6-year period was used to calculate the annual mean of claims divided by the estimated bear population. Overall, 45% of bear damages were to livestock, 34% to apiculture and 10% to agriculture. Damage patterns varied a lot among populations; e.g. in Southeastern Poland, 97% were damages to apiculture and in the Pyrenees 86% were damages to livestock. Our analysis reveals that, at a continental scale, the number of damages is associated with landscape features, such as the proportion of agricultural cover;

with management factors such as supplementary feeding practices and also with economic factors. Our results highlight the complexity of the mechanisms underlying this conflict and shows that a wide range of factors, from purely ecological to economic ones, affect the incidence of bear damages.

ECONOMIC ASPECTS OF BROWN BEAR DAMAGE ECOLOGY IN EUROPE

Human-wildlife conflicts occur whenever human activities and wildlife habitat overlap. In particular, damages to human properties are of special concern as may cause important economic losses and decrease social acceptance. Damage compensation systems aim to soften this conflict by covering the economic losses due to damages caused by wildlife. Taking the brown bear (*Ursus arctos*) as a study species, we found that the magnitude and typology of damages vary widely across Europe, as the schemes of the compensation systems do: some countries, like Ukraine have no compensation system at all, whereas other countries, like France, compensate all bear damages. We aimed at comparing the economic losses due to bear damages across European countries and exploring associations between economic indicators (e.g. the gross domestic product based on purchase power parity) and the amount of money compensated in each country. We expected that the countries that have a stronger economy (e.g. higher gross domestic product per capita) would spend more money to compensate bear damages. To answer this question we collected information on the money reimbursed

due to bear damage claims from 2007 to 2010 for 14 bear population segments across 10 different European countries. Compensations widely varied and ranged from 4 to 12,600 Euros per year and bear in Croatia and Norway, respectively. Overall, an annual mean of 2.3 million euro (± 0.03 ; standard deviation) was paid for the compensation of bear damages, which only represents less than 0.001% of the net national income at market price of the countries investigated. We discuss the influence of different indicators of the economic activity on the amount of compensations and its possible management implications.

EVIDENCE FOR INCREASING IMPACT OF INVASIVE SPECIES ON HUMAN HEALTH

Helen R Bayliss

Centre for Evidence Based Conservation, Bangor University *Stefan SCHINDLER*, Environment Agency Austria ; *Franz ESSL*, Environment Agency Austria ; *Wolfgang RABITSCH*, Environment Agency Austria ; *Andrew S PULLIN*, Centre for Evidence Based Conservation, Bangor University

Invasive alien species are frequently considered a serious conservation threat but some species also impact on human health through injury, allergy, or as vectors of disease. Despite this topic receiving increasing attention in the scientific literature, there have been few attempts to quantify recent changes in human health impacts. We present findings from a systematic mapping of the literature to identify evidence demonstrating a change in the occurrence, frequency or severity of impacts of invasive species for human health in Europe. Most studies relate to only a few species and often report specific cases. Difficulties in attributing human health impacts such as stings or allergies to a specific species likely complicate attempts to measure changes. Better cooperation between invasion ecologists, conservation managers and health professionals working in affected areas are likely to be necessary to reduce health and biodiversity impacts and improve the evidence base on this topic for the future.

WIRETAPPING THE WILDERNESS: USING AUTOMATED ACOUSTIC RECORDERS AS A COLLABORATIVE MONITORING FOR ASSESSING THE IMPACT OF ALBERTA'S OILSANDS

Erin Bayne

Alberta

Soundscapes provide a diverse mixture of wildlife, human, and other natural sounds that can be used for documenting status, trend, and impacts. Historically, many animal populations have been monitored by human observers visiting a location for a short period of time once a year and recording the species heard. These approaches have been uncoordinated

and poorly standardized, which has prevented large-scale assessment of the cumulative effects of different types of human development in space and time. Ineffective decision making has been the end result. Automated recording units (ARUs) provide a new approach to environmental monitoring that relies on a physical record of soundscapes that can be stored and used by various partners to make more informed decisions about the environmental impacts in a consistent and repeatable way. The Bioacoustics Unit at the University of Alberta – Alberta Biodiversity Monitoring Institute is a collaborative partnership working in Alberta’s oilsands region that has standardized approaches to the collection and processing of sound information using ARUs. Recent advances in computer-based species recognition, proper handling of species detection error, and ARU sampling design will be highlighted. The success of the approach in coordinating government, non-profit, and industry in an effort to assess and mitigate the effects of industrial noise and light on amphibians and owls in the oilsands region of northern Alberta will be described as case studies of how technology can improve environmental monitoring performance.

110 - UNDERSTANDING LOCALLY DEFINED HUMAN WELL-BEING TO MEASURE IMPACTS OF CONSERVATION PROJECTS ON THE NORTHERN PLAINS OF CAMBODIA

Emilie Beauchamp
Imperial College London

Successful natural resource management requires understanding human dimensions of system change including livelihoods and human wellbeing, which ultimately drive behaviour and participation in conservation. High resolution, contextual studies using social science methods are needed to take local realities, priorities and incentives into account in management decisions. Going beyond the principle of ‘doing no harm’, a wellbeing approach to conservation means giving communities an opportunity to voice what is important in their lives and to integrate such factors in impact assessments of conservation interventions. The concept of wellbeing recognises that poverty is multi-dimensional and bare economic proxies are an insufficient measure of a good life. I will present a flexible universal framework for monitoring and evaluating policy grounded in local definitions of wellbeing, which has been developed within a collaborative ESRC-DFID funded project. I applied this approach to the area of the Northern Plains in Cambodia where there are protected areas and Payment for Ecosystem Service (PES) projects implemented amidst rapid land use change and tenure insecurity. This talk will highlight challenges and guidelines for applying a wellbeing approach, and present early results from a year of field research. I will demonstrate the importance of

qualitative methods in providing internal validity, explaining relationships between phenomena, and in formulating locally meaningful quantitative indicators and appropriately disaggregating data. I will point to next steps and future directions in social monitoring and evaluation for improved management especially in rural communities in the global South.

SYMPOSIUM 177- NEWDISTRICT TRAINING TOOL: A DISTRIBUTED SIMULATION TO INTEGRATE BIODIVERSITY ISSUES IN PERIURBAN DEVELOPMENT PROJECTS

Nicolas Becu
CNRS
Nathalie FRASCARIA, AgroParisTech ; Julie LATUNE, AgroParisTech

In Europe where land use planning is an everyday headache due to the almost total absence of vacant spaces, peri-urbanisation projects often endanger biodiversity. The integration of biodiversity issues in the reflections of urban planners and construction companies on how and where to extend the urban areas is a real challenge. Biodiversity issue now receives attention from urban planners and builders starts to integrate in-house environment services. In order to bring these actors to best integrate the key concepts of environmental management such as ecosystem services or ecological land-use complementation, we developed a training tool based on participatory agent-Based simulation approach. NewDistrict tool aims at providing knowledge and sharing experience about biodiversity processes but as well at understanding how other’s activities impact urban development choices and consequently biodiversity. It is a distributed simulation: each participant interacts with the others using an individual computer. Participants interact as well verbally as they are all in the same room. There are six different roles represented, each one having his own interface providing specific information and action means. This asymmetry between roles and interfaces induce differentiated learning. A dozen of sessions have been carried with employees of construction companies and their learning experience has been assessed through inquiries carried at the end of the session. The results show that employees of construction companies learn a lot about how to communicate on urban development between stakeholders having different objectives: a context that recalls to them the difficulties to collaborate between services and branches they face within their own company. They also get to understand the relations between land use and biodiversity, the impacts of land use change and how the perceptions of the environment varies by trade group.

CRYPTIC DIVERSITY AND CONSERVATION PLANNING: THE CASE OF AMPHIBIANS AND REPTILES IN ALGERIA.

Menad Beddek

Centre d'Ecologie Fonctionnelle et Evolutive. UMR 5175 / Bureau d'Etudes Naturalia-Environnement

Olivier PEYRE, Bureau d'études Naturalia-Environnement ; Philippe GENIEZ, Ecole Pratique des Hautes Etudes (CEFE-CNRS, UMR 5175) ; José-Carlos BRITO, CIBIO, Centro de Investigação em Biodiversidade e Recursos Genéticos da Universidade do Porto / Instituto de Ciências Agrárias ; Pierre-André CROCHET, Centre d'Ecologie Fonctionnelle et Evolutive. UMR 5175

This study aims at improving our knowledge about the distribution of distinct genetic lineages within vertebrate species in the Maghreb region. Although the Maghreb is recognized as a biodiversity hotspot, its diversity is still underestimated. Indeed, several studies on bats, rodents, reptiles and amphibians have shown that a cryptic diversity is prevailing in most studied taxa. Furthermore, these studies show a common pattern of genetic lineages distribution: a deep divergence - often at specific rank - between eastern (Tunisia) and western (Morocco) populations of the same "species". However, a frequent lack of data from Algeria blurs our comprehension of diversity distribution in the Maghreb. Thus, several key questions remain unanswered: 1) is the location of the disjunction zone of the eastern and western lineages similar between taxa and if so, what is the processes behind the east-west disjunction in the Maghreb, 2) what is the impact of this cryptic diversity on conservation planning in the region? We propose a comparative phylogeography approach to address these questions. We selected a list of reptiles and amphibians of Algeria on which previous studies revealed an East-West disjunction (between Morocco and Tunisia) in the lineages, we collected samples of these species in Algeria along an east-west transect, then assigned these samples to either the eastern or the western clades based on mtDNA sequence data. Preliminary results show that 1) the two lineages are found in Algeria for every species, each time with distinct allopatric distribution and 2) for each species, both eastern and western lineages come into contact in the centre of Algeria. Finally, we 3) test whether conservation planning based on evolutionary lineages distribution is significantly different from conservation planning based on traditional species limits.

CONNECTING HABITATS, GENE FLOW, LARVAL DISPERSAL AND TURTLES: IMPLEMENTING CONNECTIVITY IN MARINE SPATIAL PLANNING

Maria Beger

The University of Queensland

Jennifer MCGOWAN, The University of Queensland ; Pei Ya BOON, Consultant ; Tessa MAZOR, CSIRO ; Eric TREML, University of Melbourne ; Cynthia RIGINOS, The University of Queensland ; Hugh POSSINGHAM, The University of Queensland

Connectivity in marine conservation is one of the last frontiers. Advancements in modelling of marine dispersal, identifying parentage of individuals, calculating recent migration from genetic data and telemetry to track migratory animals mean that spatial planning methods also need to be updated to integrate better ecological connectivity in conservation plans. I will review the different types of connectivity and demonstrate a portfolio of methods and solutions for them: a) mangrove-coral reef adjacency, b) larval dispersal in the Coral Triangle, c) recent gene flow in Indonesia, and d) connecting feeding and nesting habitats with migration routes for sea turtles in the Coral Triangle and the Mediterranean. I will demonstrate how incorporating larval connectivity creates very different sets of solutions from other potential conservation objectives. I further ask: what is the value of information of turtle tracks in marine conservation, and how should tracking target their research to help conservation planning questions.

DOES REPLANTING NATIVE TREES CREATE A FUNCTIONING COASTAL FOREST?

Jacqueline Beggs

University of Auckland

Stephen WALLACE, University of Auckland ; Robin GARDNER-GEE, Plant & Food Research

Revegetation is one of the most widely used interventions in terrestrial restoration, as the structure and extent of vegetative cover profoundly shapes both the physical and biotic features of a landscape. Such projects typically proceed on the premise that there is a causal link between re-establishing native forest cover and restoring native biodiversity, even though there have been relatively few assessments of the success of replanting native forest. This study assesses the response of biodiversity and ecosystem function to native re-forestation on Motuora Island, an 80-ha island about 40 km north of Auckland City, New Zealand. The island has been actively restored by a community-led group since 1991. We measured the beetle and plant communities, and litter decomposition rates on Motuora in 2004 and in 2014, comparing the successional trajectories of unmanaged natural restoration (c. 80 years old), native tree planting, and retired pasture. While planted sites followed the predicted successional pattern for some measures (e.g. beetle assemblages in planted forests have converged toward those found in unmanaged forest), other measures suggest that there is some way to go in order to establish a more natural forest (e.g. the low frequency of seedling and sapling establishment). This study illustrates the challenge of identifying a suitable

restoration target in the absence of a suitable reference site. Nevertheless, revegetation has established a native dominated community, which appears to be on a trajectory to forming a forest broadly typical of coastal northern forest in New Zealand.

CONSERVING NATURE'S STAGE: ABIOTIC SURROGATES EFFICIENTLY PRIORITIZE SITES FOR SPECIES REPRESENTATION

Paul Beier

Northern Arizona University

Fabio ALBUQUERQUE, Northern Arizona University

If a planner has species inventory data for all sites in a planning area, she can prioritize sites for their ability to represent species. But without wall-to-wall inventories, a planner has been unable to prioritize sites for species representation – until now. Here we show that Environmental Diversity (ED) can prioritize sites without ANY species inventories, and that Predicted Rarity-Weighted Richness (PRWR) can prioritize sites with inventories for < 20% of sites. ED (invented by Faith & Walker in 1996, but untested and forgotten) selects sites that best span multivariate space defined by freely-available abiotic data (e.g., elevation, insolation). Across 8 study areas, sites prioritized by ED (using no species data) represented species with 40% efficiency – i.e., ED was 40% as effective as having species inventories for 100% of sites in its ability to improve on random selection of sites. PRWR (invented by us, and described here for the first time) does require species inventories for a subset of sites in the planning area, and performance improves as the percent of sites inventoried increases. But with species inventories for a mere 20% of sites, PRWR can prioritize 100% of sites based on their abiotic conditions. PRWR's efficiency was a whopping 66% across 6 test datasets. ED and PRWR should be most useful in tropical regions with the highest biodiversity, greatest biodiversity loss, most severe lack of inventory data, and poorly-developed protected area networks.

27. THE '100 QUESTIONS FOR BIODIVERSITY CONSERVATION IN MEDITERRANEAN-TYPE REGIONS' INITIATIVE

Pedro Beja

InBIO - Research Network in Biodiversity and Evolutionary Biology

Francisco MOREIRA, InBIO - Research Network in Biodiversity and Evolutionary Biology

Researchers have a key role in providing solutions for conserving biodiversity in the face of multiple anthropogenic stressors and socio-economic challenges, but there is often a gap between the data generated by research and the information required by practitioners and policy makers. Here we make the opening presentation of an initiative contributing to bridge the gap between science and policy, focusing on

biodiversity conservation challenges in the five Mediterranean Type Regions (MTE) of the world: the Mediterranean Basin, the Cape Region of South Africa, Southwestern and South Australia, California, and central Chile. Despite their small geographic area, MTEs harbor a significant and exclusive proportion of the planet's biodiversity, which is threatened by a range of factors such as land use changes, overexploitation of natural resources, and global climate change. The initiative has joined a group of researchers from the 5 MTE regions of the world, who have worked together with a wide range of policy makers, conservation practitioners, natural resource managers, and environmental consultants, among others, to identify the 100 priority questions that, if answered, would contribute to preserve biodiversity values in the region. To set the context for this initiative, we provide in this presentation an overview of comparable exercises of research prioritization carried out in different parts of the world, outlining methodological approaches, potential limitations and shortcomings, and some key results. We then describe the methods adopted in the Mediterranean initiative, and how it has been implemented across regions and individual countries. Finally, we set the stage for the forthcoming presentations, providing a quick overview of the objectives and contents of the symposium.

THE ETHICS OF OFFSETTING BIODIVERSITY

Sarah Bekessy

RMIT University

Christopher IVES, RMIT University

Biodiversity offsetting has proliferated in recent years. Academic discussion has primarily concerned the ecological validity of offsetting with virtually no exploration of its ethical implications. Biodiversity offsetting was introduced as a novel approach to meeting technical legal obligations, yet the underlying values and duties that underpin environmental laws have not been referenced. Upon re-examining the ethical basis for conservation, we find that conservation policy exists to protect either the intrinsic or instrumental values of nature. Biodiversity offsetting raises ethical concerns on both these grounds. First, if individual living organisms have worth in themselves (intrinsic value), then a policy that makes it easier to destroy plants and animals is questionable ethically, regardless of conservation actions elsewhere. Similar concerns are raised if ecological communities are considered to have intrinsic value, since offsetting is based on two scientific fallacies: (i) ecological communities are identical, and (ii) ecosystems can be recreated. The intrinsic value of species is also jeopardised by offsetting since many policy applications heighten the uncertainty of species' long-term persistence. Second, biodiversity offsetting compromises the instrumental values of nature related to human benefits. If biodiversity is valued for the ecosystem services it provides then disconnecting people from biodiversity, as commonly done in urban contexts, may be

considered unethical and unjust. Finally, biodiversity offsetting emphasises anthropocentric philosophical view of nature (it can be owned, manipulated and traded), which is opposed by many people. We warn that biodiversity offsetting represents a fundamental shift in the ethical foundation of conservation and requires further scrutiny.

101 USING A HYBRID REGULATORY APPROACH TO CONSERVE SMALL NATURAL FEATURES: A MAINE CASE STUDY.

Kathleen Bell

University of Maine

Aram Calhoun, University of Maine ; Robert FREEMAN, Eastern Maine Community College

Small natural features introduce novel opportunities for designing and testing conservation tools. These features interact in complex ways and at multiple scales with social and ecological systems. The payoffs from advancing tools that embrace rather than overlook this diversity are not well understood. A recent policy process to conserve temporary ponds in Maine, USA, offers insights about the development and returns from such approaches. A stakeholder group including ecologists, economists, regulators, and the development community proposed a conservation approach that advances local-scale tools to complement an existing national regulatory framework. This mechanism recognizes variability in social and ecological systems, enables parallel pursuits of socio-ecological goals, and prioritizes flexibility and tradeoffs. Implemented at the local scale, the policy recognizes existing land-use planning tools that recognize growth and rural areas. Under the proposed mechanism, landowners in growth areas may meet current regulatory requirements using the new local tool. For a fee, landowners in growth areas can develop land that will result in the loss of temporary ponds. The mitigation dollars raised from these fees enhance conservation of pools in rural areas by supporting landscape-scale conservation. By employing an incentive-based mechanism that varies markedly from top-down regulatory requirements, the "hybrid" mechanism gained support from developers, regulators, ecologists and municipal planners. The mechanism fosters opportunities for improved conservation partnerships and outcomes. Policy simulation analyses completed in collaboration with the stakeholder group show opportunities for improved conservation outcomes from this emergent, innovative approach. Documentation and analysis of this policy process and mechanism provide an important first step towards greater strategic coordination and ecological coherence across efforts to conserve small natural features.

WHERE TO DEVELOP AGRICULTURE AND FORESTRY? PERSPECTIVE FROM STUDIES ON ANIMAL COMMUNITIES IN GRASSLANDS AND SUBTROPICAL FORESTS OF THE SOUTHERN NEOTROPICS

Isabel Bellocq

University of Buenos Aires

Gustavo ZURITA, Instituto de Biología Subtropical ; Julieta FILLOY, University of Buenos Aires

Each human activity that requires large extensions of land imposes a particular environmental filter to the species regional pool. Our general objective is to contribute to land use planning that considers biodiversity conservation in the context of native ecosystems, cultural values and local and regional socioeconomic scenarios. Here, we analyze how similarity in the composition of animal communities is influenced by agriculture and forestry depending on the native ecosystem in which the human activity is developed. In the study design we considered two widely used indicator taxa (birds and ants) from two contrasting conservation priority biomes in the southern Neotropics (southern Atlantic forest and Pampean grassland) and extended human-created habitats (eucalypt plantations and soybean cropfields). We used an integrated approach to study community differentiation considering three complementary facets of beta diversity (taxonomic, functional and phylogenetic), which are only recently being incorporated in conservation objectives. Non-metric multidimensional scaling showed that taxonomic, functional and phylogenetic differentiation in composition between bird and ant assemblages were associated to biome and land-use; study sites grouped into four groups on the bi-dimensional space (cropfields in forest and grassland, and tree plantations in forest and grassland), and that was consistent across beta diversity facets and taxa. Mantel and PERMANOVA tests showed that the three facets of beta diversity were positively correlated for both bird and ant assemblages. Tree plantations retained more bird native species when developed in forest than in grassland biomes, whereas cropfields held more native species in grasslands than in forests. In economies depending on human activities that require large areas, our results help to select the most appropriate biome to develop agriculture and forestry, contributing to sound land use planning and beta-diversity conservation.

ANTI-BIRDS NETTING IN FISH PONDS: ASSESSING THE ADVANTAGES FOR FISHERIES VERSUS DAMAGE FOR BIRDS

Gilad Ben Zvi

Ben Gurion University

Yossef LESHEM, Tel Aviv university ; Yoram YOM-TOV, Tel Aviv university

Fish-ponds provide a readily available food source for piscivorous birds. The geographic location of Israel on a major avian migration route increases predation pressure in Israeli fisheries to cause a conflict between fish farmers and piscivorous birds. During the last 30 years many fish ponds in Israel were netted against predation. However, birds are trapped and killed in the nets. A couple of studies dealt with this phenomenon but were limited in scope. The aims of our study were to estimate number of birds entangled in nets; to characterize the phenomenon in terms of bird species affected, season, area and other important factors; and to examine the possibilities to minimize harm to birds without causing economic harm to fisheries. 150 netted ponds in north and central Israel were observed throughout a year for dead and live birds. Pond, net and crop characteristics were documented. In addition, experiments compared predation in identical ponds that were netted, cabled (cables are a non-harmful protection measure cheaper than nets) or left unprotected. Our findings show that capture rate and numbers of trapped birds are lower than previously estimated, but that no less than 60 bird species are trapped. The major problem was found to be mortality of rare and vulnerable species. Foremost among these is the Black Stork (*Ciconia nigra*), dozens of which were entangled yearly. Capture rates were affected by crop species, fish mortality, net stretching level and net mesh size. The least harmful net was well-stretched one with small mesh size of up to 5*5 cm. Most importantly, cables were found to be equally effective to nets in predation prevention. Our management recommendations are thus to replace nets with cables, and to protect highly sensitive crops with nets of the sort mentioned above. We also encourage allocation of governmental budget for making fisheries more environment-friendly, thus turning conflictual status-quo into future cooperation.

TOWARDS MORE INCLUSIVE CONSERVATION: WHAT IS THE ROLE OF THE CONSERVATION SOCIAL SCIENCES?

Nathan Bennett

University of British Columbia

Robin ROTH, York University

While there have been numerous calls for increased engagement, the social sciences still remain somewhat marginalized as a conservation science, this is particularly true amongst small to medium sized conservation practitioners and organizations. The conservation social sciences are often underutilized, yet each sub-field can make unique and important contributions to understanding the relationship between humans and nature and to improving conservation practice and outcomes. This presentation will provide a

broad overview of the different fields of conservation social science, the topics and types of questions explored by each field, and the past and potential contributions of each field to conservation. It will draw from a report titled "The Conservation Social Sciences: What?, How?, and Why?" that emerged from a workshop hosted by the Social Science Working Group of the Society for Conservation Biology that was held at the North American Conservation Congress in 2014. Moreover, we urge that it is time to move beyond simply recognizing the potential of the conservation social sciences to fully engaging with all types of knowledge that will allow us to produce more effective and socially just conservation. It is time we mature beyond an 'add and stir' approach to one that engages the full range of social sciences to help build a renewed, integrated and more robust conservation science and practice.

124 BIODIVERSITY OFFSETS BY REGULATION: CAN WE DEFINE THE ELEMENTS OF GOOD POLICY?

Leon Bennun

The Biodiversity Consultancy

Kerry TEN KATE, Forest Trends ; John PILGRIM, The Biodiversity Consultancy

Although biodiversity offsets are the focus of much discussion, most actual offsets have so far been implemented under just a handful of Government regulatory schemes, notably in Australia and the USA. However, Government interest in biodiversity offsets is increasing. Over 30 countries or states now have policies or laws facilitating or requiring offsets or other compensatory measures, while many others are investigating policy options. Depending on how they are designed and implemented, regulatory offset schemes could help to slow biodiversity loss at national level – or could make it worse. Over the next few years, conservationists have a window of opportunity to input to and influence these emerging national offsets frameworks. While there is no 'one size fits all' solution, some important elements of good policy include (a) rigorous application of the mitigation hierarchy to avoid, minimize and restore project impacts before offsets are considered; (b) an aggregated approach that is integrated into wider land-use planning and takes into account cumulative impacts and national conservation objectives; (c) legal and financial instruments to secure long-term implementation; and (d) effective arrangements for performance monitoring and enforcement. Secure and transparent governance mechanisms are a key overarching requirement. In addition, individual and institutional capacity are needed nationally to support offset design and implementation, including the management of biodiversity data, assessment of biodiversity losses and gains, and brokering of outcomes acceptable to all stakeholders. In many countries, inadequate capacity could undermine the effectiveness of regulatory offsets, and investment in capacity strengthening should be a key component of offset schemes.

ECOLOGY AND CONSERVATION GENETICS OF THE ENDANGERED BARBARY MACAQUE IN ALGERIA

Lamine Mohamed Benrabah

University of Lincoln

Bonaventura MAJOLA, University of Lincoln ; Malgorzata PILOT, University of Lincoln

Primate population assessments provide valuable data for both comparative and conservation studies. The Barbary macaque (*Macaca sylvanus*) is the only surviving primate in Africa north of the Sahara desert, the only native species of primate to occur in Europe, and the only member of the genus *Macaca* found outside Asia (ICUN, 2008). The species once ranged through parts of Europe and across North Africa (Delson, 1980; Camperio Ciani, 1986). Its current geographic range is limited to fragmented patches of forest and scrub gorges in Algeria and Morocco (Fa, 1984; Camperio Ciani, 1986; Menard and Vallet, 1993; Scheffrahn et al., 1993). As an endangered species there is an urgent need for successful management strategies. In developing such strategies, it is essential to have reliable baseline population count estimates and assessments of changes in size through time (Plumptre and Reynolds 1994). In Algeria, the population was estimated at 5,500 approximately 30 years ago (Taub, 1977) since then numbers are unknown (Hodges and Cortes, 2006). The Moroccan populations were more recently estimated to be 6,000-10,000 individuals (Ross, 2004), whereas in 1975 it was estimated to be 17,000 (Taub, 1975). Similar pressures present in Morocco have been recorded in Algeria of habitat loss, human disturbances and inadequate conservation policy & enforcement (Fa et al, 1986; Deag, 1900; Taub, 1986). Through our longitudinal study in Algeria, we present the current population size estimate, distribution and genetic variability of the endangered Barbary macaque for future conservation consideration.

STATUS, HABITAT USE AND BEHAVIOUR OF WINTERING GREATER FLAMINGOS PHOENICOPTERUS ROSEUS IN SEMI-ARID AND SAHARAN WETLANDS OF ALGERIA

Ettayib Bensaci

Department of Natural and Life Sciences, University of M'sila
Menouar SAHEB, Department of Natural and Life Sciences, University of Oum El-Bouaghi ; Yacine NOUIDJEM, Department of Natural and Life Sciences, University of M'sila ; Abdelaziz BOUZEGUAG, Institute of Natural and Life Sciences, University of Mila ; Asma ZOUBIRI, Department of Natural and Life Sciences, University of Oum El-Bouaghi ; Moussa HOUHAMDI, Biology, Water and Environment Laboratory, University of 08 May 1945, Guelma

The Greater flamingo is considered the flagship species of wetlands across semi-arid and Saharan regions of Africa,

especially Chotts and Sebkhass, which also concentrate significant numbers of bird species. Flamingos have different status (wintering and breeder) which vary between sites in different parts of Algeria. We conducted surveys and recorded banded flamingos across distinct regions within two climatic belts: semi-arid (Hauts Plateaux) and arid (Sahara), showing the importance of these sites in the migratory flyways particularly the relation between West Mediterranean and West Africa populations. The distribution of Greater flamingos varied between sites and seasons, where the concentrations mainly were in the wide, lees deep and salt lakes. Many of the sites (17) in the surveyed area were regularly supporting at least 1% of regional population during winter. The analysis of Greater flamingos behaviour in different climatic regions in relation showed that the feeding is the dominant diurnal activity with rates exceeding 60 % of the time. While feeding varies between seasons, and showed a negative relationship with the degree of disturbance. Keywords: Greater Flamingo, *Phoenicopterus roseus*, semi-arid, Sahara, Algerian.

EFFECTS OF FOREST EDGE ON PEST CONTROL SERVICE PROVIDED BY BIRDS IN FRAGMENTED TEMPERATE FORESTS

Krisztina Bereczki

MTA ÖK Lendület Ecosystem Services Research Group, Institute of Ecology and Botany, MTA Centre for Ecological Research

Katalin HAJDU, Faculty of Veterinary Science, Szent István University ; András BÁLDI, MTA ÖK Lendület Ecosystem Services Research Group, Institute of Ecology and Botany, MTA Centre for Ecological Research

The natural control of herbivorous insects by insectivorous birds is considered to be one of the most important regulating services in forest ecosystems. The fragmentation of forest habitats and associated edge effects, however, modifies the abundance and community structure both of birds and insect herbivores, and thereby may have an impact on the predator-prey interactions. In the present study we aimed to examine how the insectivorous bird abundance as well as bird predation rate on caterpillars was affected by edges and how far the edge effect penetrated into the forest patch in a fragmented temperate forest of southwest Hungary. To measure edge effect, four middle aged forest stands dominated by turkey and sessile oaks were selected situated next to meadows. In the selected forest stands, four transects were laid out parallel to the forest edge at the distances of 0 m, 10 m, 25 m and 50 m. Predation rate was measured using artificial caterpillars made by green plasticine fastened to the branches of selected trees situated along the assigned transects. To estimate insectivorous bird abundance, a line transect method was used. Forest structural variables included stand structure and shrub density were also examined along the assigned transects. We found

an unusual non-linear pattern to predation rate as well as bird abundance, having peaks both at the edge and forest interior. A significant positive correlation between bird abundance and predation rate was shown, supporting the important role of birds in pest control. Interestingly, insectivorous bird abundance had negative relationships to forest structural variables, e.g. to the basal area and tree species richness, where positive interactions were expected. We may conclude that this is due to the context-dependency of edge effects that can not be fully explained by our study. Therefore, further studies are needed to explore the general pattern of edge effect on insect pest control.

SYM ID 88: THE EFFECTS OF LEARNING ON THE MOVEMENT PATTERNS OF REINTRODUCED PERSIAN FALLOW DEER AND ARABIAN ORYX

Oded Berger-Tal

Institute for Conservation Research, San Diego Zoo
David SALTZ, Ben-Gurion University

Knowledge improves performance, and experienced animals succeed better than animals without the relevant experience in almost all aspects of their life history. We therefore expect animals that lack the appropriate knowledge to make the gaining of that knowledge a high priority. We investigated the post-release behavioral modifications (PRBMs) movement of two ungulate species reintroduced in Israel: the Persian fallow deer (*Dama mesopotamica*) and the Arabian oryx (*Oryx leucoryx*). Both species were equipped with GPS collars prior to their release and their movement recorded from their first steps into the novel landscape all through their familiarization with the environment process. Despite a reduced sample size, our results clearly show that the movement behavior of both Persian fallow deer and Arabian oryx immediately following their release into the wild is very different from the movement behavior of the same individuals several months later, supporting the hypothesis that explorative movement in an unknown landscape differs from knowledge-based movement in a familiar environment. We will go through the principles given in the symposium's opening lecture and demonstrate how they apply for the reintroduction programs of the Persian fallow deer and the Arabian Oryx in Israel.

SYMPOSIUM #20 SMART: A NEW TOOL FOR MONITORING AND INCREASING THE EFFECTIVENESS OF CONSERVATION LAW ENFORCEMENT

Richard Bergl

North Carolina Zoo

Alexa MONTEFIORE, SMART Partnership ; Emma STOKES, Wildlife Conservation Society ; Jonathan PALMER, Wildlife Conservation Society

One of the greatest threats to biodiversity is the illegal exploitation of wildlife. Even within legally protected areas, conservation agencies encounter significant challenges effectively enforcing wildlife laws. The Spatial Monitoring and Reporting Tool (SMART) is a software application and associated management approach developed by a broad partnership of conservation organizations to improve overall law enforcement effectiveness in general, and anti-poaching efforts in particular. SMART enables the collection, storage, communication, and evaluation of a wide variety of conservation-relevant data including patrol effort (e.g., area patrolled, patrol distance), patrol results (e.g., number of snares removed, arrests made), and threat levels (e.g., number of gunshots heard, number of hunting camps encountered). When effectively employed to create and sustain information flow between ranger teams, analysts, and conservation managers, SMART can help to substantially improve protection of wildlife and their habitats and enhance accountability of protected area staff. SMART can be used to manage protection programs at any conservation area that relies on patrol teams enforce wildlife laws and regulations. SMART has demonstrated its effectiveness in improving conservation law enforcement, improving morale of enforcement teams, and reducing threats to wildlife and other natural resources at numerous sites around the globe. SMART is free, open source and supports the use of mobile devices. Additionally, the SMART Partnership is committed to providing ongoing support, training and developing additional functionality for the software. Recently released additions to the software include a biological survey module and a networked version is in development. At present SMART is being implemented in more than 120 conservation areas in 27 countries worldwide and is fast becoming a global standard for conservation law enforcement monitoring and management.

MEASURING AND MONITORING COMPLIANCE IN NO-TAKE MARINE RESERVES

Brock James Bergseth

Australian Research Council Centre of Excellence for Coral Reef Studies

Garry RUSS, Australian Research Council Centre of Excellence for Coral Reef Studies ; Joshua CINNER, Australian Research Council Centre of Excellence for Coral Reef Studies

No-take marine reserves are increasingly popular tools for conservation and fisheries management. While much attention has been paid to evaluating the effects of design aspects (size, location, etc.) in achieving reserve objectives, less emphasis has been placed on the role of stakeholder

compliance. Therefore, the first aim of this study was to evaluate the state of compliance literature and examine the methods used to measure compliance in reserves. The state of compliance literature is limited, although publications with compliance information have increased sixfold in the last decade. However, most studies containing compliance information (63%) fail to provide quantitative estimates. Furthermore, most (95%) quantitative estimates of compliance were reported using a single method, which is problematic because each method has biases and limited applicability. Methods used to indicate compliance include (i) direct observation; (ii) indirect observation; (iii) law enforcement records; (iv) direct questioning; (v) expert opinion; and (vi) modelling. Our second aim was to empirically demonstrate the critical role of compliance in reserve outcomes by comparing a mixed-effects model on compliance data synthesized from 63 marine reserves to that of a null model. The model of best fit demonstrated a negative relationship between non-compliance and target species biomass response ratios. Thus, without incorporating any aspects of reserve design, compliance data predicted reserve response ratios of fish biomass. Accordingly, researchers should explore ways to better understand and measure non-compliance. Therefore, future research should triangulate multiple sources of quantitative compliance data collected using standardized techniques and conduct baseline surveys before reserve implementation.

24. THE PROBLEM OF SPATIAL FIT IN SOCIAL-ECOLOGICAL SYSTEMS: DETECTING MISMATCHES BETWEEN ECOLOGICAL CONNECTIVITY AND LAND MANAGEMENT IN AN URBAN REGION

Arvid Bergsten

Stockholm University

Diego GALAFASSI, Stockholm University; Örjan BODIN, Stockholm University

The problem of institutional fit in social-ecological systems has been empirically documented and conceptually discussed for decades, yet there is a shortage of approaches to systematically examine the level of fit. We address this gap focusing on spatial fit in a peri-urban region where natural wetland habitat is ecologically fragmented at a scale beyond the control of single managers; requiring them to coordinate their activities to address institutional fit at the appropriate scale. We present a research approach that maps patterns of collaborations between actors who manage different parts of a landscape, and then relates these patterns to structures of ecological connectivity. We apply our approach to evaluate the fit between a collaborative wetland-management network comprising all 26 municipalities in the Stockholm County in Sweden, with an ecologically defined network of dispersed but ecologically interconnected wetlands. Many wetlands in this

landscape are either intersected by the boundary between two or more municipalities, or located close to such boundaries, which implies a degree of ecological interconnectedness and a need for inter-municipal coordination related to wetland management across boundaries. We first estimate the level of ecological connectivity between wetlands in neighboring municipalities, and then use this estimate to elaborate the level of social-ecological fit vis-à-vis inter-municipal collaboration. We find that the level of fit is generally weak. Also, we identify critical misalignments of ecological connectivity respectively inter-municipal collaboration, as well as collaborations that represent an adequate alignment. These findings inform on where to most effectively allocate limited resources of collaborative capacity to enhance the level of social-ecological fit. Our approach and results are graphically illustrated using maps, which facilitates the potential application of this method in land-use planning practice.

RECOVERING THE LAST WILD BLUE-THROATED MACAWS

Igor Berkunsky

Universidad Nacional del Centro de la Provincia de Buenos Aires

Federico P. KACOLIRIS, Universidad Nacional de La Plata ; Gonzalo DANIELE, Universidad Nacional de La Plata ; Rosana M. ARAMBURÚ, Universidad Nacional de La Plata

The Blue-throated Macaw (*Ara glaucogularis*) is a rare, critically endangered and endemic macaw of savannahs in northern Bolivia. The species was discovered in the wild in 1992, and during the last decade intensive conservation work was carried out in order to identify and solve the critical parameters delaying the population's recovery. Field conservation actions were aimed at increasing nest site availability, protecting active nests against predators, increasing nestling's survival and establishing protected areas. We evaluated the performance, limitations and costs of these field conservation actions; and we analyzed the information documented by this long-term study related to occupancy, density, and breeding success of Blue throated Macaws in northern Bolivia. The application of these actions resulted in higher nest success and higher nestling survival. Despite this reproductive improvement, the breeding population is not yet recovering. The number of macaws at each breeding site has been stable or decreased; and at a few sites, local extinction has taken place. As the Blue throated Macaw is currently a conservation dependent species, we consider the value of increasing the wild population through the release of confiscated and captive-bred individuals.

SUMATRAN ELEPHANT FEEDING PREFERENCES TOWARD 10 AGRICULTURAL AND PLANTATION COMMODITIES IN ACEH-INDONESIA

Kaniwa Berliani

North of Sumatra University

Hadi S ALIKODRA, Faculty of Forestry IPB ; Burhanuddin MASY'UD, Faculty of Forestry IPB ; Mirza D KUSRINI, Faculty of Forestry IPB ; Wahdi AZMI, Center for Wildlife Veteriner Medicine of Syiah Kuala University

Research on feeding preferences of Sumatran elephants (*Elephas maximus sumatranus* Temminck) toward 10 agricultural and plantation commodities in Aceh's Elephant

Conservation Center has been conducted in December 2014. The method used is a test method to feed 10 of commodities crops cultivated by people in conflict areas using two captive elephants. Feeding is done by the method of restricted feeding. The data were then analyzed using the equation Neu's index. The results of the research showing various preferences of the crops ranked from the highest as follow; paddy plant (*Oryza sativa*), banana (*Musa sp*), rubber (*Havea brassiliensis*), palm (*Elais guenenensis*) and nut (*Areca atechu*). While the types of cacao (*Theobroma cocoa*), chilli (*Capsicum frutescens*), Tamarind (*Aleurites moluccana*), coffee (*Coffea Arabica*) and Patchouli (*Pogostemon cablin*) showed a low preference. Low elephant preferences for the type of crops cultivated by the villager is some commodity crops that could potentially be developed in the area adjacent to the elephant habitat to mitigate human elephant conflict. Key words : elephant, conflict, plantation commodities, preferences

30 YEARS OF LAND USE DYNAMICS IN THE COASTAL MEDITERRANEAN WETLANDS

Marianne Bernard

Tour du Valat

Coralie Beltrame, Tour du Valat ; Isabelle LEVIOL, Muséum National d'Histoire Naturelle ; Thomas GALEWSKI, Tour du Valat

Mediterranean wetlands are ecosystems especially important for biodiversity and human well-being. They lost about 50% of their area in the 20th century. The Mediterranean coast is also under heavy pressure from urbanization, tourism and development of industrial and transport infrastructures. There is thus a convergence of ecological, human and economic issues in the Mediterranean coastal wetlands. Changes in land use / land cover between 1975 and 2005 were characterized in 214 of them. We observed an artificialisation of wetland habitats. Indeed, within them, the area of natural wetland habitats decreased by 10% in 30 years, a loss of 1248 km². At the same time, artificial wetland habitats increased by 54%, that is to say, a gain of 661 km². The main direct pressure on natural wetland habitat was agriculture with 71% of these habitats converted into agricultural areas. Urbanization had less direct impact but had eaten into peri-urban agricultural areas, and these lost agricultural areas are displaced to surrounding natural habitats. Furthermore in this water-scarce region, the increasing abstraction of water and intensified water management practices have a major impact on natural wetland habitats as the transformation of wetland hydrological regimes, the conversion of natural wetlands into artificial wetlands, and decreased flows in watercourses.

POPULATION ESTIMATES OF AN ENDANGERED GAME BIRD IN THE OVERHUNTED BRAZILIAN ATLANTIC FOREST HOTSPOT

Christine Steiner S. Bernardo

UNEMAT[INSTITUTE]UESB

Joedison Santos ROCHA, UESB ; Fernando Cesar GONÇALVES, UESB ; Aiala SOUZA, UESB

Threatened species are frequently difficult to record, leading to few data available for helping to select the best conservation strategies. When deforestation of the northern Atlantic forest and poaching intensified in the late 1960's, red-billed curassows (*Crax blumenbachii*, Cracidae, Galliformes) began their slow journey towards the center of the extinction vortex. This endangered game bird is nowadays one of the largest frugivores in the northern Atlantic Forest, where other game species with similar ecological niche are already extinct, such as the white-lipped peccaries and tapirs. We surveyed populations of the species from 5 a.m. to 18 p.m. by line-transect in two of the largest forest fragments of northeastern Brazil, Una Biological Reserve (18,000 ha) and Conduru State Park (9,000 ha), totalling 496 km of walked trails. Red-billed curassows are most abundant in the north region of Conduru (0.42 records/10 km), where the species were mostly recorded from 9 to 11 a.m. This abundance is similar to findings in the southernmost region with the largest population ever recorded (Vale Natural Reserve - 23,000 ha). However, the species is absent from most of the forest fragments of the species extension range, where hunting pressure is high. Red-billed curassow abundance is small in Una (0.20 records/10km), similar to the smallest population ever recorded for the species (Descobrimento National Park, 21,000 ha). This important demographic data on wild populations of red-billed curassows helps on the update of the conservation status of this endangered game bird, which is targeted by reintroduction programmes and conservation actions led by national and international conservation boards. Furthermore, it is the first step for monitoring wild populations of the red-billed curassow in the long-term.

BEYOND DELINEATION: EXPLORING THE BIOLOGICAL SIGNIFICANCE OF GLOBAL ZOOGEOGRAPHICAL UNITS

Rubén Bernardo-Madrid

Biological Station of Donana

Manuela GONZÁLEZ-SUÁREZ, Biological Station of Donana ; Joaquín CALATAYUD, University of Alcalá[INSTITUTE]Natural Museum of Natural Sciences ; Eloy REVILLA, Biological Station of Donana

The identification of biogeographic entities is essential to understand large-scale ecological and evolutionary processes and resulting biodiversity patterns. The recent increased in

availability of geographic information and the development of new statistical tools have resulted in diverse studies aimed to define biogeographical regions. However, these studies have largely focused on delineating the spatial regions without identifying the species that determine them, even though understanding the biological components could provide valuable information. Here we address this shortcoming using a derivation of flow-based method to analyze global distribution data for terrestrial non-volant mammals (n=3948). Our analysis identifies 36 distinct zoogeographic units determined by species assemblages with a median of 52 mammals (range 2-779). These assemblages are formed by species with distinct life-histories and levels of vulnerability to extinction. For instance, assemblages in Southeast Asia include many species with large adult body masses whereas in North and Central America small-sized mammals prevail. The most sensitive units (those formed by highly threatened assemblages) are found in Madagascar whereas the entire Holarctic is characterized by mostly unthreatened species. The present study goes beyond zoogeographical entities delineation to explore the biological significance of these entities, identifying sensitive regions based on their assemblage composition and proposing new hypotheses for observed biogeographic patterns.

1. THE RELATIONSHIP BETWEEN POPULATION SIZE, EFFECTIVE NUMBER OF BREEDERS AND THE ENVIRONMENT IN BROOK TROUT

Thais Bernos

Concordia University

Dylan FRASER, Concordia University

The understanding of interannual fluctuations in the effective population size (N_e) and the relationship between N_e and census population size (N) is important to predict genetic and demographic changes for populations of conservation concern. Difficulties in measuring N_e have spurred interest in a more practical surrogate: the effective number of breeders per cohort (N_b). We empirically evaluated the relationship between the environment, N_b , and N , for five consecutive cohorts in brook trout populations located in Cape Race, Newfoundland, Canada. These populations are isolated, pristine, and differ greatly in population size, life history and environmental characteristics. We found a strong, positive correlation between N_b and N . There was no evidence that year, populations, or stream conditions affected this relationship. These results provide valuable insights onto the relationship between the evolutionary and the demographic parameter across populations. Collectively, our results suggest that it might be possible to infer N_b from N , or vice-versa. The better understanding of the relationship between N_b and N is crucial for wildlife management and conservation as it would provide valuable insights into local and contemporary environmental, genetic or demographic threats in natural populations.

DETECTING SEX-BIASED DISPERSAL THROUGH NETWORK TOPOLOGIES

Philip Bertrand

Trent University

Jeff BOWMAN, Trent University ; Rodney DYER, Virginia Commonwealth University ; Paul WILSON, Trent University ; Micheline MANSEAU, University of Manitoba

Sex-biased dispersal is characterized by the propensity of individuals of one sex to disperse while individuals of the other sex tend to stay or return to its natal site for reproduction. With the recent advances of molecular tools, this evolutionary process is commonly observed in vagile species but show an important variation in magnitude and directions. Methods available for both population- and individual-level have been successful at detecting such process but investigation at the system-level is yet to be explored. Considering such level let investigators exploring patterns lying in higher dimension where genetic structure among all populations is capture concurrently. Population Graph is a multivariate network-based framework that investigate the significant structural covariation patterns of intraspecific systems. Population Graph connectivity structure is built upon the statistical significance of the interactions. Although not yet explore, decomposition of the interactions by variation of the alpha-value (i.e. significance level) reserves the capacity to explore the strength of the interactions within system. Based on these patterns, we propose a novel approach to investigate sex-biased dispersal process from Sex-Specific Graphs (i.e. Unisex networks). Based on the rational that dispersing sex would demonstrate a higher level of functional connectivity, we hypothesize that dispersing sex-network would show a more resilient behavior to alpha-decomposition. Global topological metric, such as the averaged shortest-path distance between nodes, were used to assess the hypotheses. Significance of the test is evaluated by randomization approach. Type-I and Type-II errors are currently under evaluation using individual-based Monte Carlo simulations. We believe that this new perspective could enhance the investigation of sex-biased dispersal, leading to a better understanding of dispersal process and its effects on wildlife population viability.

ECOLOGICAL CORRIDORS AS STRATEGY FOR FOREST ECOSYSTEMS CONSERVATION OF THE CAPARO FOREST RESERVE, BARINAS STATE, VENEZUELA

Alejandra Betancourt

Instituto de Ciencias Ambientales y Ecológicas(ICAIE), Universidad de Los Andes

Eulogio CHACÓN-MORENO, Instituto de Ciencias Ambientales y Ecológicas(ICAIE), Universidad de Los Andes

Deforestation is causing a landscape transformation leading the degradation and fragmentation of ecosystems, with the consequent loss of biodiversity. The semi-deciduous forests in Venezuela are critically endangered and threat due to its intervention, including plant and animal species that inhabit these forests. In the country, Forest Reserves north of the Orinoco have had bad management and have largely been completely deforested; however in some of them as the Caparo Forest Reserve (CFR), there are still large patches of forest that can be used for restoration and conservation. A conservation proposal for forest ecosystems is presented in this work, mainly focused on the semi-deciduous forests of the CFR, establishing preliminary ecological corridors to rescue biodiversity flows, assuming that the negative consequences that may have impair connectivity in patches, are despicable for being a forest that was connected 60 years ago. For the development of these corridors, was used as spatial basis, the distribution of all natural ecosystems and human intervention systems (Ecosystems Map). By satellite imagery analyzing and processing and GIS use, six ecological systems or ecosystems and four human intervention systems were defined. The spatial arrangement of forest fragments was determined and analyzed, and the corridors as conservation strategies were defined. Based on the use of ecological criteria, 66 links between patches of the original forest was proposed. The next step in the conservation process of the CFR is the development a concerted conservation planning with the community, in order to present a project that includes this strategy to the government environmental authorities. With this strategy we are one step further towards the restoration of the forest in the reserve, with more biodiversity, with a healthy composition and structure maintained over time, in harmony with its inhabitants for the people of today and tomorrow

SYMPOSIUM 126: CRITICAL REFLECTIONS ON THE EFFECTIVENESS OF BIOMASS STANDARDS TO ENFORCE SUSTAINABILITY

Tina Beuchelt

Center for Development Research (ZEF)

Anna MOHR, Center for Development Research (ZEF) ; Detlef VIRCHOW, Center for Development Research (ZEF) ; Rafaël SCHNEIDER, Welthungerhilfe

With the emerging bioeconomies in Europe, more biomass is imported. Sustainability concerns led to the development of EU regulations esp. regarding bioenergy. Hence, private certification standards for biomass proliferate but with major differences regarding environmental and social criteria. The potential of these standards for human development are e.g. income opportunities for farmers and workers or

the compliance with human rights and labour standards. To protect the environment, regulations exist to safeguard biodiversity and natural resources. Positive but also negative changes for the environment and livelihoods are observed on and around certified farms in developing countries. While the standards can monitor good agricultural practices, they are limited in controlling complex issues such as food security, transparency/informed consent, biodiversity or land conflicts. The question arises whether standards can satisfy sustainability expectations regarding complex problems and basic human rights and what (governance) arrangements could enhance their effectiveness. In addition, there are implementation problems of the certification system. It must be critically scrutinized what can be verified in the field due to missing documentation, financial reasons, fraud or capacity constraints. The financial dependency between auditors, standard setters and employing enterprises raises questions of the system's legitimacy. Research institutes and CSOs can play an important role as evaluators regarding the performance and implementation of the standards. Given the positive impact of standards on some criteria, political and societal expectations in private labels are high. Regarding complex problems and settings like in biomass exporting counties with governance, poverty and hunger problems, the overall performance of certification systems is unsatisfactorily. More research is required to solve these complex challenges and increase the performance towards sustainability.

ONE PLAN TO HELP THEM ALL: SPATIAL HABITAT RESTORATION PLANNING FOR MULTIPLE SPECIES IN METAPOPOPULATIONS

Hawthorne Beyer

University of Queensland

Renato CROUZEILLES, Federal University of Rio de Janeiro ; Morena MILLS, University of Queensland ; Karen MUSTIN, University of Queensland ; Hugh POSSINGHAM, University of Queensland

Species persistence often depends not only on habitat protection, but also on habitat restoration. The effectiveness of species conservation through habitat restoration can be enhanced by explicitly considering the combined effects of the total amount of habitat and its spatial configuration. Metapopulation theory indicates that habitat configuration can have a profound influence on extinction risk but also that species respond to habitat configuration in different ways depending on patch size requirements and dispersal ability. Here, we address the problem of how to prioritise restoration spatially in order to maximise benefits to a broad range of species. There are two dimensions to this problem. How do we quantify the value of habitat configuration to a species? And how do we prioritise restoration for a set of species? Although these issues can often be solved exactly using mathematical

optimisation for very small problems, we are interested in realistically complex problems such as the restoration of the Brazilian Atlantic Forest (>250,000 patches). We developed an approach that uses the probability of connectivity (PC) metric to quantify patch and configuration value at the species level, and distributions of patch size and dispersal variables to prioritise restoration for all species of interest using heuristic optimisation methods (simulate annealing). Differences in the relative value of species can be accommodated with weights. The benefit of this approach is that, unlike simple measures of connectivity, PC is closely related to metapopulation dynamics, and simultaneously considering many species can greatly increase the cost-effectiveness of the solution. We apply the method to landscape restoration problems in Australia and Brazil.

133-FAITH, FORESTS, AND FOOD: TOWARDS A CONCEPTUAL FRAMEWORK FOR FAITH-BASED FOREST CONSERVATION IN AFRICAN AGRICULTURAL LANDSCAPES

Shonil Bhagwat

The Open University

Culturally-protected forests are an integral component of agricultural landscapes in many low-income countries of Africa. Indigenous and community-conserved areas include Kaya forests of coastal Kenya, customary forests in Uganda, sacred forest groves in Benin, and dragon forests of The Gambia—all of which are embedded within agricultural landscapes and have significance for the people who live within or in close proximity to them. Faith-based forest conservation plays an important role in maintaining biodiversity in highly human-dominated landscapes and by providing smallholder farmers with food, fuel, fodder and shelter on non-farmed land. However, the links between faith-based organizations, their forest protection traditions, and the ecosystem services they provide to predominantly agricultural landscapes remain unrecognized, unexplored, and under-theorized. Understanding and communicating the contemporary relevance of these culturally-protected forests are keys to their future protection. How can multifarious connections between faith, forests and food (a primary force of life) help reinvent reasons for safeguarding culturally-protected forests?

IRRIGATION TANKS, BIRD SANCTUARIES OR WETLANDS- THE MANAGEMENT DILEMMA

Avantika Bhaskar

Care Earth Trust

Jayshree VENCATESAN, Care Earth Trust

In a tropical country like India, rainfall distribution varies both spatially and temporally. In Tamil Nadu, a state located

in southern part of the country, low and seasonal rainfall and unfavourable geology for groundwater storage led to development of a traditional means of water harvesting through a system of tanks as early as 9th century AD. There are nearly 40,000 tanks in the state. Over time these local water bodies apart from providing water for irrigation turned into havens for both resident and migratory birds and other forms of biodiversity. Consequently, some of these tanks were declared as Protected Areas. Hence, over time their management shifted hands from village communities to Public Works to Forest Department affecting their ecological character. Our study of the socio-ecological character of 10 bird sanctuaries located on irrigation tanks revealed an array of management and conservation issues ailing these wetlands. For instance the wetlands in Ramanathapuram experienced low water levels owing to conflicts amongst villages and caste groups in the tank cascade, encroachment, and maintenance irregularities by different departments in the upstream region. In some cases, the close association of wetlands and agriculture was found to be conducive both for birds and farmers, as in the use of agricultural fields as feeding ground by birds and use of guano rich silt from tanks as fertilizer. However, on the other hand, drainage of agricultural runoff into the tanks resulted in eutrophication favouring invasive fish species like Tilapia and Giant African Catfish to thrive. Further, while on some occasions birds visiting the farms were hunted, on others, the farmers complained of crop raiding. The study led to conclude that while wetlands in India still do not have an exclusive administrative status, their management at all levels entails community participation in addition to regulatory policies and scientific planning.

THE PAST, PRESENT AND FUTURE OF THE WORLD DATABASE ON PROTECTED AREAS

Nina Bhola

United Nations Environment Programme World Conservation Monitoring Centre
Diego JUFFE-BIGNOLI, United Nations Environment Programme World Conservation Monitoring Centre ; Brian MACSHARRY, United Nations Environment Programme World Conservation Monitoring Centre ; Marine DEGUIGNET, United Nations Environment Programme World Conservation Monitoring Centre ; Naomi KINGSTON, United Nations Environment Programme World Conservation Monitoring Centre

Conservation planning requires reliable information on the location and extent of protected areas that is often difficult to obtain. Building upon the mandate behind the UN List of Protected Areas in 1981, IUCN and UNEP established the World Database on Protected Areas (WDPA). The WDPA is managed by UNEP-WCMC in collaboration with governments and NGOs in 240 countries and territories and is the most

comprehensive global database of marine and terrestrial protected areas. The WDPA has been and continues to be used extensively in conservation science and policy to inform conservation planning and monitor progress in global biodiversity indicators. However, the WDPA is not without its limitations. For example, some protected areas do not have boundary data or are not accurately mapped and many sites are not assigned IUCN management categories. The decision to include or exclude such sites during data analysis likely affects the results of conservation studies. There is also little understanding about how the WDPA is compiled and hence the implications of the decisions taken during data preparation for data analysis. Prior to 2015, the WDPA did not include information on particular types of conservation areas that did not meet the IUCN definition of protected areas but which might still contribute substantially to biodiversity conservation in some countries, such as private or communal reserves. To address these limitations, some existing fields within the WDPA have now been updated and new fields added. Improved validation processes and quality metrics have also been put in place. We review the evolution and application of the WDPA, highlighting key statistics derived from recent analyses, and caveats associated with analytical decisions made in preparing the database. We then explain in detail the improvements made to the database in 2015 and how they will help move the conservation agenda forward.

FOREST RESTORATION THROUGH AFFORESTATION AND CONSERVATION PROCESS BY SOCIAL PARTICIPATION IN INDIA

Shashi Bhushan

Jawaharlal Nehru University

Forest has always contributed an influential role to maintain natural resources in India but last two decades were very important in terms of Afforestation scenario, when it faces the flutter due to several daunting challenges like development process and social activities. Accordingly, it attracts government and policy maker attention towards protecting the existing forest area and restores the degraded land by introducing the afforestation and management process by social participation. Present study attempts to identify the structure of forest management and afforestation scheme with social participation involving local people in and evaluate the role of Joint Forest Management (JFM) in context of forest conservation in India. This paper is at micro level study covers all districts of India and the estimation of forest growth has been analyzed by FSI (Forest Survey of India) bi-annually using the Digital Image Processing (DIP) to estimate the forest area on a map at 1:50,000(2001-09) scale. The results of the study revealed that, there has been a significant increase in the total forest cover in India in last two decades,

where forest management with social participation helped to reduce the illicit felling of trees, reduces area under illegal encroachments and forest fire prevention. Results also indicate that Afforestation programme helped in forest conservation and regeneration by community involvement for non timber forest production which has impacted on the livelihood of the districts. Community involvement assures the participation of different caste, class, religion and gender according to available population proportion in particular region through 'Van Panchayat (village administration of forest)' system. Scheme of Afforestation programme succeed by focusing on agro forestry, linear forest plantation and regeneration of native plants in degraded area under National Afforestation Programme (NAP).

EVALUATING THE SYNERGISTIC EFFECT OF MULTIPLE ANTHROPOGENIC STRESSORS ON THE POPULATION DYNAMICS OF PLANTS, USING A HAWAII ENDEMIC SHRUB, DELISSEA WAIANAENSIS, AS A CASE STUDY

Lalasia Bialic-Murphy
University of Hawaii at Manoa

Anthropogenic stressors can have long-lasting effects on a species' vital rates and thus is thought to be the primary driver of population decline and extinction. To understand the influence of species interactions and environmental changes on population persistence, it is necessary to explicitly link the impact of stressors on plant vital rates to population dynamics. For endangered species that occur in extremely altered environments, it is also important to assess which combination of management actions will likely result in the desired end goal – autogenic (i.e., self-sustaining) populations. In this five-year study, we examined the synergistic effects of fruit depredation by non-native rodents and pollen limitation on the population dynamics of a critically endangered Hawaii endemic shrub, *Delissea waianaensis*. We used a stochastic stage structured model and transient analysis to explore how plant interactions with multiple biotic stressors influenced the long and short-term population dynamics. This study provides insight into the likely outcomes of employing various rare plant conservation strategies.

THE TEMPORALITY OF POSITIVE AND NEGATIVE IMPACTS ON LOCAL PEOPLE

Cecile Bidaud
Bangor University

In developing countries, conservation projects are addressing to precarious people who are asked to change their land use. Those projects have different kind of actions, with in one hand

positive incitation and in another hand restrictions more or less repressed. If both types of actions can be developed in parallel, their impacts have not the same temporality. If restrictions can take place immediately, land use change actions will be longer to have an impact on local people. This temporal gap and its effect on local people will be here questioned through a case study of biodiversity offset project of a mining company working in Madagascar. Biodiversity offsets are projects developed by big infrastructures degrading the environment in which they engaged beyond their environmental obligation to protect nature. BOs have been designed very much as a response to mitigating biodiversity impacts of development, but have potential impacts on local livelihood. As most of conservation projects, they combine restrictions and agricultural development project. In this communication, I will balance the positive and negative impacts as bare by the local population living around a biodiversity offset project showing their different temporality. This will lead to broader considerations on ethics and environmental justice.

USING STRUCTURED DECISION MAKING TO SELECT CULTURALLY, ECONOMICALLY AND ECOLOGICALLY APPROPRIATE SALMON HABITAT RESTORATION STRATEGIES IN THE QUINALT INDIAN NATION

Kelly Biedenweg
University of Washington, Tacoma

Incorporating socio-cultural needs and their potential impacts from restoration into environmental decision-making is complicated by the fact that many of these issues are difficult to measure. This paper presents the collection of socio-cultural data to inform a Structured Decision Making process for selecting culturally, economically, and ecologically appropriate salmon habitat restoration strategies in the Quinalt Indian Nation, U.S.A. Socio-cultural data were collected during two seasons of interviews with 36 tribal members and a subsequent survey launched to a representative sample of the nation. Interviews identified the important socio-cultural aspects associated with salmon and riparian areas while the survey measured the status of those aspects using constructed (i.e., Likert-style) and economic measures. This data was then used in a structured decision making process with QIN resource staff to compare three alternative scenarios across social, economic and ecological goals. The author will present the indicators identified in the interviews, the measures developed to quantify those indicators, and lessons learned from incorporating cultural values in a decision making process.

SYMPOSIUM ID 94: FOSTERING THE EMERGENCE OF CONSERVATION IN A BUDGET-CONSTRAINED WORLD: COMMUNITY-BASED ACTION TO COUNTER THE ILLEGAL WILDLIFE TRADE

Duan Biggs

University of Queensland

SYMPOSIUM ID: 94 Biodiversity is under increasing threat, whilst available budgets to mitigate against these threats continue to be constrained. There is an urgent need to become more cost-effective. One strategy is to create an enabling environment that facilitates individual agents to self-organise and behave in a way that leads to conservation outcomes. In contrast to externally-driven initiatives which are formulated and implemented by government departments or conservation NGOs, conservation outcomes can therefore also be achieved by the autonomous and self-organised action taken by individual agents. This enhances the cost-effectiveness and the sustainability of conservation outcomes. But how can this 'emergence of conservation' be achieved? Emergence, and robustness, two related concepts from the common pool resources and the complexity literature provide guidance. Emergence refers to the coming about new activities and initiatives that can deliver conservation benefits, and robustness refers to the durability of these new behaviours and actions over time. We demonstrate the application of the concepts through presenting a theory of change to strengthen community-level action against the illegal wildlife trade to achieve more cost-effective and lasting conservation outcomes than externally driven-initiatives.

ECOLOGICAL NETWORK DYNAMICS IN A FLOODPLAIN ECOSYSTEM UNDERGOING EXTREME WET-DRY FLUCTUATIONS

Gilad Bino

University of New South Wales

Skye WASSENS, Charles Sturt University ; Jennifer SPENCER, Office of Environment and Heritage ; Rachael THOMAS, Office of Environment and Heritage ; Richard KINGSFORD, University of New South Wales

Ecological networks, the interactions between species and nutrients, represent the flow of energy and biomass through the ecosystem. This continuum and its supporting linkages are critical for stability and persistence of ecosystems, often only represented by single "snapshots" in time. We carried out repeated surveys over five years (2008-2014) of a range freshwater-dependant biota (frogs, tadpoles, fish, and waterbirds) in wetland complexes that form part of the Lowbidgee floodplain, a large terminal delta system in inland south-eastern Australia. Surveys encompassed the last three

years of the Millennium Drought, one of the most extreme drought events in Australia's history and subsequent large scale flooding and normalisation of the system. We quantified direct and indirect interactions within the floodplain ecosystem between underlying ecological drivers (inundation extent, water quality) and our biota, using structural-equation models. Key biological responses significantly linked to inundation, reflecting predicted top-down and bottom-up interactions. By separating analysis into two periods: drought (2008-2009) and post flood recovery (2010-2014), we found considerable variation in trophic interaction strengths, mediated by strong regulating factors such as water availability and temperature. Our work, part of an ongoing long term monitoring project, provides a unique empirical opportunity to test relationships between water availability and biotic responses. As pressure on the world's freshwater resources increases, understanding of these often complex interactions between hydrological, biological, and geochemical processes undergoing extreme hydrological fluctuations is critical for identifying the impacts of water extraction and managing their long-term persistence with management tools such as environmental flows under increasing climatic uncertainty.

DESTABILISATION OF COASTAL DUNES FOR CONSERVATION OF BIODIVERSITY IN ISRAEL

Tania Bird

Ben Gurion University of the Negev

Pua BAR (KUTIEL), Ben Gurion University of the Negev ; Amos BOUSKILA, Ben Gurion University of the Negev ; Elli GRONER, Dead Sea & Arava Science Center

The proximity of Nizzanim Nature Reserve to both desert & Mediterranean ecosystems has resulted in unique species assemblages in this Israeli coastal dune reserve. Due to land use changes over the last 50 years, there has been rapid dune stabilization leading to loss of mobile dunes, the preferred habitat for many endemic and specialist species, causing concern for the conservation of these species. Unlike most coastal dune restoration projects that seek to stabilize dunes to prevent coastal erosion, restoration in Nizzanim involves perennial vegetation removal to create a heterogeneous environment of different dune types for biodiversity conservation. Species diversity and community structure have been monitored on mobile, semi-stabilized and stabilized dunes (with removal and control replicates) for more than 10 years in five taxonomic groups; annual & perennial plants, arthropods, reptiles & rodents. Such long-term data across so many taxa is rare in conservation biology and to our knowledge, unique in coastal dune research. We examine species composition and diversity trends on natural dunes and treated dunes and compare differences in responses among taxonomic groups. Complex standardization techniques and multivariate analyses are required to deal with this extensive

multi-taxa database. Preliminary ordination analysis suggest that different taxa respond differently to dune treatments, with implications for conservation management decisions. Specific recommendations will be provided in the next phase of this research for coastal dune management under different conservation priorities that can be adjusted according to changes in societal conservation values.

EFFECTS OF LANDSCAPE COMPLEXITY ON MULTI-TAXON INDICATOR BUNDLES FOR ECOSYSTEM SERVICES

Klaus Birkhofer

Lund University

Henrik G. SMITH, Lund University

Species across taxa can be directly or indirectly related to the provision of ecosystem services (ES) and a multi-taxon indicator approach may therefore act as a reliable assessment tool to allow predictions about the level of ES provision in agricultural landscapes. We use information on more than 680 invertebrate, vertebrate and plant species to create bundles of species that act as indicators for the provision of several ES in agricultural landscapes in Southern Sweden. We find that a relatively high proportion of invertebrate and plant species are reliable indicators for the provision of ES, but that individual relationships differ markedly between taxonomic groups. Grouping species with similar relationships to ES across taxa allows quantifying the effect of landscape complexity on indicator bundles. Positive indicators (positive relationships between abundances and an ES) for biological control benefitted from landscape complexity, whereas negative indicators were less abundant in complex landscapes. Positive indicators for the conservation value of an area were more abundant in complex landscapes. Negative indicators for yield were more abundant in complex landscapes, with the opposite relationship observed for positive indicators. Indicators for hunting quality, pollination potential and soil organic carbon content did not show such contrasting patterns. Identifying response patterns of indicator bundles to landscape complexity across taxa is an important step in understanding how landscape complexity affects the provision of multiple ecosystem services via alterations of biotic communities. The provision of multiple ecosystem services can be promoted by taking up conservation measures that simultaneously promote sets of positive indicator species. We therefore argue that the identification of indicator bundles can be useful to develop conservation strategies that target the provision of multiple ecosystem services in agricultural landscapes.

IUCN RED LIST IN EASTERN EUROPE: DO WE HAVE ENOUGH INFORMATION FOR CATEGORIZING VERTEBRATE SPECIES?

Zsolt Biró

Institute for Wildlife Conservation, Szent István University
László PATKÓ, Institute for Wildlife Conservation, Szent István University ; Mihály MÁRTON, Institute for Wildlife Conservation, Szent István University ; László SZEMETHY, Institute for Wildlife Conservation, Szent István University ; Miklós HELTAI, Institute for Wildlife Conservation, Szent István University ; Miha KROFEL, University of Ljubljana ; Dusko ČIROVIĆ, University of Belgrade ; Peter URBAN, Matthias Belius University ; Krzysztof KLIMASZEWSKI, Warsaw University of Life Sciences; Gergely Schally, Gödöllő, Szent István University, Institute for Wildlife Conservation

International nature conservation often uses IUCN categorization and criteria for evaluating threatened species. A given species degree of vulnerability might change in different spatial levels, thus categorizing species on a national level can be beneficial for nature conservation. Experts from five Eastern Europe countries (Hungary, Slovenia, Slovakia, Poland and Serbia) were asked about IUCN related questions. Every countries use national conservation levels, such as "protected", "strictly protected" or "huntable", but only Slovenia's government has officially adopted the IUCN evaluation. Free and easily accessible online databases are rare in these countries. In Serbia there are no such information sources on vertebrate species, in Slovenia all of these databases have a price to pay. Online databases exist in almost all countries but these are based on voluntarily data collection. Volunteer helps are favourable in nature conservation, but in case of monitoring it raises the questions of representativeness, reliability and regularity. We think basic data collecting should be based on scientific monitoring methods, and for IUCN categorization it should be carried out on a historical scale. We could only find one reliable and representative information source (National Game Management Database of Hungary), which can be used on a long term basis. Based on NGMD, we have evaluated game species of Hungary and found that grey partridge (*Perdix perdix*) and brown hare (*Lepus europaeus*) should be in threatened categories (CR, VU respectively), due to their population decrease in the last 10 years. With the lack of sufficient and reliable data we might end up protecting species that are flourishing and neglect species that are in need of help.

HOW FARMERS INFLUENCE BIODIVERSITY ON THEIR FARMS

Simon Birrer

Swiss Ornithological Institute

Judith ZELLWEGER-FISCHER, Swiss Ornithological Institute ; Lukas PFIFFNER, Research Institute of Organic Agriculture ; Markus JENNY, Swiss Ornithological Institute ; Sibylle STÖCKLI, Research Institute of Organic Agriculture

Across Europe, agri-environment schemes (AES) have been established to reverse the decline of farmland biodiversity. However the impacts of AES on biodiversity are mixed, and no general increase in farmland biodiversity has been observed. One reason for partial success of AES at plot scale but mostly failures at regional or national level might lie in the fact that farmers base their management decisions on economic aspects rather than on what is most effective for biodiversity. The principle unit of decision making is the farm, and decisions about participating in AESs are also taken at the farm level. Thus we investigated how farmers can best enhance biodiversity on their land with a whole-farm approach. We therefore compared diversity of breeding birds and abundance of several farmland bird species on 133 Swiss lowland farms with factors that are directly influenced by farmers and considering a range of environmental variables. We found a highly positive effect of quantity and ecological quality of habitats under AES management on diversity of breeding bird species and on abundance of several bird species. There was also a significant correlation between these variables and habitats in the surroundings of the farm, average field size and proportion of grassland, whereas farm type (organic vs. integrated farming), density of livestock and some arable and grassland management option seem to be of minor importance. We also correlated diversity of plants, grasshoppers and butterflies with the same explanatory variables and found similar relationships. We conclude that farmer's decisions are a major driver for diversity and abundance of biodiversity. The most effective way for farmers to support biodiversity on their farms is to maintain or create habitats (semi-natural habitats or AES options) with high ecological quality.

HOOLOCK GIBBON CONSERVATION: PROMOTING COMMUNITY OUTREACH AND EDUCATION IN KARBI ANGLONG UNDER KAZIRANGA-KARBI ANGLONG LANDSCAPE, ASSAM, INDIA

Jihosuo Biswas

Primate Research Centre

Richard TARO, Primate Research Centre ; Sudipta NAG, Primate Research Centre ; Nabajit DAS, Primate Research Centre ; Joyнал ABEDIN, Dibru Saikhowa Conservation Society

Hoolock gibbons, the only two representatives of lesser apes in India, is threatened by habitat loss and hunting throughout its range in seven northeastern states, resulting $\geq 90\%$ decline in population during last few decades. The state of Assam, NE India alone holds $>70\%$ Indian population and Karbi Anglong

district of Kaziranga-Karbi Anglong Landscape contribute about $\geq 65\%$ population in the state. But despite having huge scope, severe anthropogenic pressure due to poor social condition of the fringe communities in the district and lack of knowledge and appreciation towards conservation and lack of capacity of the management authority remains the main challenges. Community Education and Outreach programs, which are often based in areas that face such challenges, have been a vanguard in creating means to integrate people with their natural environment and thus conquer supporters for the protection of natural habitats. Educating students, school-teachers, foresters and community members in support of conservation and sustainable development and improving the management capacity provide a basis for long-term changes in attitude and practice. Extensive conservation education, outreach and orientation programs have been conducted during 2011- 2014 for various target groups. Integrated teaching modules containing information on the species, its ecological role in forests and biodiversity were carried out using different indoor and outdoor teaching-learning activities like drama, role play and debates besides audio-visual presentations and field visits. During the campaign ($n=15$), we covered 5 PAs and educating 4500 community members, training 60 foresters and sensitizing management authorities and decision makers. To assess what was offered and effectiveness of such program evaluation was carried out which suggested that protection became enhanced through awareness and capacity building and such programmes can be effective and should be established far more widely.

24 - WHO IS RESPONSIBLE FOR BIODIVERSITY OUTCOMES? A FRAMEWORK FOR EVALUATING THE PERFORMANCE OF CONSERVATION NETWORKS

Patrick Bixler

University of Oregon

Large landscape conservation seeks to mitigate contemporary ecological problems through conservation interventions at multiple and overlapping scales. Implementation requires leveraging networks and as conservation practitioners increasingly work to integrate local-scale conservation action with broad-scale goals and objectives, an informed understanding of the governing dimensions of these systems is needed. However, empirical research that measures the performance of network governance in this context is limited. This paper uses a well-established large landscape conservation network, the Roundtable on the Crown of the Continent, to explore application of a performance evaluation framework. We propose a framework that provides an organized way to set goals, track progress towards those goals, and collect data for feedback to an adaptive management network. We discuss the challenges of "counting" network outcomes in large landscape conservation and present a

framework that guides the evaluation of ecological outcomes, the network itself, and the value-added benefits to network participants.

HUMAN MODIFICATION: CONCEPTS, METHODS, AND A CALL FOR STANDARD TERMINOLOGY

Shannon Blackadder

University of Calgary

Greg J. MCDERMID, University of Calgary ; Erin SEXTON, University of Montana, Institute on Ecosystems ; Caryn MISKE, Flathead Basin Commission ; Bill DOLAN, Alberta Environment & Sustainable Resource Development

It is becoming increasingly important to document the extent and intensity of human modifications on the surface of the Earth, both as a first step in understanding the effects of these modifications, and also as a necessary input for developing conservation strategies for resource-management. This broad motivation has led to a growing demand for spatially explicit metrics that describe human modification, and marks an interface where science and managers meet. For example, the Crown Managers Partnership – an international collaboration of managers from the U.S. and Canada – is using human modification analysis in the Crown of the Continent Ecosystem to identify priority areas for conservation in this 42,000-square-kilometer transboundary landscape. As with any growing field of research, the study of human modification faces a number of methodological and ontological challenges. For example, many of the fundamental terms used in these studies are poorly or inconsistently defined - including human modification, human footprint, impact, and intensity - leading to substantial confusion about what the corresponding metrics are actually measuring. Additionally, the limitations and assumptions made in academic studies using these metrics are not always explicit, leading to inappropriate interpretation and applications. In this study, we review the current literature on human modification in order to identify problems with methods, definitions, assumptions, and stated limitations. After doing so, we outline a proposal for standard terminology, and identify key areas research required in this important and burgeoning field. Our goal is to ensure that the results of these studies provide useful and meaningful information that can be used to inform resource management guidelines and environmental legislation, as well as effective stepping stones for ongoing conservation research.

AN ASSESSMENT OF TARGETING IN A COMPENSATION SCHEME FOR HILSA (TENUALOSA ILISHA) CONSERVATION IN BANGLADESH

Annabelle Bladon

Imperial College London

Essam Yassin MOHAMMED, International Institution for Environment and Development ; E J MILNER-GULLAND, Imperial College London

Conservation payments are increasingly advocated as a way to meet both social and ecological objectives, particularly in developing countries, but payments often fail to reach the right individuals. A payment scheme for hilsa (*Tenualosa ilisha*) conservation in Bangladesh provides compensation to coastal and riverine fishers affected by temporal fishery closures. The primary goal of the scheme is hilsa conservation through the protection of juvenile hilsa, locally called jatka, but it also has an implicit goal of vulnerability reduction, targeting households which are fully dependent on fishing. However, concerns have been raised over the distribution of compensation in terms of targeting effectiveness, equity and fairness. This research used data collected from 800 recipient and non-recipient households within the area affected by the fishery closures to examine the current drivers and distribution of compensation allocation. Generalised linear mixed effects models demonstrated that the probability of receiving compensation is largely influenced by geography; households in some villages and districts are much more likely to receive compensation than others as a result of the political influence and the importance of hilsa fishing in the area. The models also showed a weak positive effect of household size and, to a lesser extent, dependency ratio, on the probability of receiving compensation. Contrary to what would be expected from the goals of the scheme, no evidence was found for an effect of fishing dependence (measured using an index developed through principle component methods), household income, or jatka fishing. These results provide evidence of poor targeting effectiveness. By setting clearer selection criteria and specifically targeting jatka fishers and high dependence on fishing within ecologically important areas, the scheme's perceived legitimacy, effectiveness and efficiency could be improved.

DEVELOPMENT AND APPLICATION OF THE DANISH HIGH NATURE VALUE (HNV) FARMING INDICATOR

Jesper Bladt

Aarhus University

Ane Kirstine BRUNBJERG, Aarhus University ; Martin BRINK, The Danish AgriFish Agency, Ministry of Food, Agriculture and Fisheries of Denmark ; Rasmus EJRNÆS, Aarhus University ; Peter MIKKELSEN, Aarhus University ; Jesper E. MOESLUND, Aarhus University ; Bettina NYGAARD, Aarhus University ; Flemming SKOV, Aarhus University

It has been recognized that farmland areas play an important role in the conservation of European biodiversity. Based on the UN Biodiversity Convention all EU membership countries are obliged to develop a High Nature Value (HNV) farming

indicator. In 2015 the Danish HNV indicator will be used to allocate part of the agricultural subsidies under the Rural Development Program to areas that are expected to be particularly important for biodiversity conservation. Here, we present the HNV indicator and its application in the Danish agricultural subsidy system. The HNV indicator has been developed in accordance with the guidelines of the European Commission and is based on landscape parameters, current land use, occurrence of seminatural habitats, analysis of vegetation plots and known distribution of threatened species. It ranks all agricultural and seminatural areas on a 0-13 point scale from low to high nature value. Farmers can apply for subsidies to areas reaching at least 5 points. Higher scoring areas are given preference when allocating the subsidies. The indicator will be updated annually to include the growing knowledge of species occurrences and land use changes.

RESTORING A VIABLE POPULATION OF LYNX IN THE FRENCH VOSGES MOUNTAINS: INSIGHTS FROM A SPATIALLY EXPLICIT INDIVIDUAL-BASED MODEL

Laetitia Blanc

Centre d'Ecologie Fonctionnelle et Evolutive
Stephanie KRAMER-SCHADT, Leibniz Institute for Zoo and Wildlife Research ; Cyril BERNARD, Centre d'Ecologie Fonctionnelle et Evolutive ; Fridolin ZIMMERMANN, KORA ; Eric MARBOUTIN, Office National de la Chasse et de la Faune Sauvage ; Olivier GIMENEZ, Centre d'Ecologie Fonctionnelle et Evolutive

Habitat destruction and fragmentation are important threats to large carnivores as they are wide-ranging species and live in human-dominated landscapes. The road network is getting denser and acts as a barrier for these species as well as it increases the risk of collisions with vehicles; the creation of corridors is often advocated in these situations as a way to restore connectivity. Because of increasing conflicts with humans, large carnivores are also particularly vulnerable to poaching resulting in small and isolated populations; reintroductions are often used as a reinforcement strategy in such situations. Here we compared these two conservation strategies, reintroduction and corridor, in order to determine the optimal solution to halt the decline of the Eurasian lynx population in the Vosges Mountains (France). We developed Spatially Explicit Population Viability Analyses (SEPVA) to evaluate the efficiency of alternative conservation strategies. The SEPVA is particularly relevant in the context of species viability in fragmented landscapes as it combines a population dynamics model and a habitat model through explicit dispersal. We explored the efficiency of i) different reintroduction scenarios in the German Palatinate that is in continuity with the Vosges and ii) a scenario involving a corridor between the stable lynx population in the Jura Mountains, shared between France and Switzerland, and the

declining population of the Vosges Mountains. We found that performing reintroductions performed better than building corridors, and reduced significantly the extinction risk. Further work will focus on refining the corridor strategies and the integration of inbreeding effect. Overall, our approach has the potential to provide an efficient and relevant tool for setting up a management plan for the species.

117-INVESTIGATING MARKET ENTHUSIASM AMONGST CONSERVATION PROFESSIONALS

Libby Blanchard

University of Cambridge

Chris Sandbrook, UNEP World Conservation Monitoring Centre ; Janet FISHER, University of Edinburgh ; Bhaskar VIRA, University of Cambridge

Market-based instruments have recently become more common within biodiversity conservation, reversing an earlier, more adversarial, relationship between conservation, markets, and economic development. Whilst a number of conservation organisations have aligned themselves with this 'neoliberal' shift, relatively few studies interrogate the extent to which this move reflects the values of conservation professionals. An earlier study (Sandbrook et al 2013b) used Q methodology to understand the views of conservationists participating in the 2011 Society for Conservation Biology annual conference. This paper extends the work of the original study by applying the same Q-survey to a group of Cambridge, UK-based conservation professionals. Both studies reveal positive and negative perspectives on the use of markets in conservation; however, whilst the negative perspectives differed in various ways, the positive perspectives in both samples were virtually identical. Such similarity across two studies is unusual, as Q methodology is designed to illuminate subjective opinions that are typically not consistent across groups, or periods of time. This finding confirms a growing body of research that suggests that pro-market attitudes have permeated the thinking of decision makers and staff of conservation organisations around the world, and lends some support to the suggestion that a transnational conservation elite represents an epistemic community that is driving the uptake of such pro-market approaches.

TREES AND PEOPLE TOGETHER AGAINST DESERT: THE POSITIVE EFFECT OF SAHARAN AGROPASTORALISM ON ACACIA WOODLANDS

Julien Blanco

IRD

Drylands encompass 41% of the global land area and 38% of the human population. Ten to 20% of the drylands are considered to be threatened with severe desertification,

which constitutes a major challenge for the conservation of ecosystems and biodiversity and for human well-being. Meanwhile, the causes and processes of desertification still remain subject to debate, mainly because of the lack of understanding of dryland Human-Environment systems. In particular, the respective roles of anthropogenic and natural factors on desertification processes remain unclear. We addressed this issue in a multidisciplinary perspective in Saharan Morocco, in an area used as a rangeland for semi-nomadic herders and for grain cultivation during wet years in zones liable to flooding. We considered woodlands as indicators of ecosystem degradation and assessed (1) the dynamics and vitality of acacia woodlands and (2) the effects of human activities on their structure. Our results showed that acacia woodlands were constituted of sparse trees (4.8/ha) and had high regeneration (47.8%) and recruitment rates, associated with low mortality (3.3%). Tree regeneration and density was especially high in cultivated areas and human activities had more influence on stand structures than topography or edaphic conditions. Despite intensive traces of pruning (60.3% of the trees) and debarking (33.9%), no correlation with tree mortality was found. Our results contrast with the common discourse of a human-induced desertification, on which are based most of forestry policies in drylands. On the contrary, the overall positive effect of human activities on Acacia woodlands suggests that traditional Saharan agropastoralism may be compatible with dryland conservation. Such conclusions may serve local conservation policies, which ones fail to simultaneously address socio-economical and ecological issues. In particular, a better involvement of local populations in conservation projects may be considered.

DEVELOPING ECOSYSTEM VIABILITY ANALYSIS TO INFORM THE IUCN RED LIST OF ECOSYSTEMS

Lucie Bland

The University of Melbourne

Emily NICHOLSON, Deakin University ; Tracey REGAN, Arthur Rylah Institute ; David KEITH, The University of New South Wales ; Nick MURRAY, The University of New South Wales ; Jon Paul RODRÍGUEZ, IVIC

The IUCN Red List of Ecosystems (RLE) is a new global protocol to assess the risk of collapse of terrestrial, freshwater and marine ecosystems. The RLE will monitor progress towards international biodiversity targets, and promote conservation and natural resource management from global to local scales. The RLE assessment protocol comprises five criteria based on distributional and functional symptoms of ecosystem decline. However, predicting the risk of ecosystem collapse remains difficult due to the lack of appropriate theory and tools, in particular for quantifying functional declines. To estimate the probability of ecosystem collapse in the next decades, we

develop Ecosystem Viability Analysis (EVA) as an analogue to PVA for species. EVA will synthesize existing knowledge on the key processes and functions of ecosystems to underpin criterion E of the RLE ("quantitative estimate of risk of collapse"). Models for EVA should be: 1) relevant to key ecosystem processes, 2) applicable among a range of ecosystem and threat types, 3) stochastic rather than deterministic, 4) easily understood and applied by RLE assessors. Other desirable attributes include the ability to integrate multiple types of data (e.g. spatial, temporal, and expert-derived), transparently communicate uncertainty, and availability through open-source software. Candidate modelling methods include state-and-transition models, mass-balance models (e.g. Ecopath), bifurcation plots, network theory, individual-based models (e.g. Dynamic Global Vegetation Models), and general ecosystem models (e.g. Madingley). EVA will provide an overarching framework for RLE criteria, as PVA does in the species Red List. Its application will improve our global understanding of ecosystem dynamics, degradation and recovery. We also demonstrate how EVA can be incorporated into wider conservation approaches, such as climate change adaptation and disaster risk reduction.

KNOWN UNKNOWN: GLOBAL PATTERNS OF CONSERVATION DATA DEFICIENCY

Lucie Bland

The University of Melbourne

C. D. L. ORME, Imperial College London ; Jon BIELBY, The Institute of Zoology, ZSL ; Ben COLLEN, University College London

Knowing which, where, and why conservation data are lacking is crucial to assessing the reliability of conservation schemes and identifying priority areas for research. Focusing on IUCN Data Deficient (DD) species, we present the first species-level analysis of global conservation data deficiency. We focus on six taxonomic groups: mammals, amphibians, reptiles, freshwater crabs, crayfish and odonates. We assess the spatial congruence of centres of data deficiency among groups, with a grid cell size of just under 1.5°. We investigate the relative roles of species biology and human sampling effort in driving patterns of data deficiency, both at the geographical assemblage (grid cell) level and at the species level. We use two contrasting proxies of global sampling intensity: human population density and remoteness. We find that centres of data deficiency are not congruent among groups, and that the highest levels of data deficiency are closely associated with species-poor areas in all groups. Species-level analyses reveal that DD species share few biological characteristics, representing a range of data deficiencies rather than a homogenous group. We conclude that initiatives to prioritize areas for conservation research should be taxon-specific. Our analysis suggests that global patterns of conservation data deficiency are primarily driven by

spatial patterns of natural history research. Our study highlights the importance of taxonomic and fundamental ecological information in conservation assessments, and calls for renewed investment in taxonomy and field inventories globally. Taking into account biases in biodiversity knowledge is paramount to designing robust conservation and data collection schemes, particularly for the world's poorly known and speciose taxa.

DEVELOPING A GEOCOLLABORATORY FOR INDIGENOUS TOURISM RESEARCH AND BIODIVERSITY CONSERVATION (217)

Sylvie Blangy

CEFE, CNRS, UMR 5175

Holly DONOHOE, University of Florida

Collaboratories have been defined as virtual places where collaborative research can be undertaken. As part of the Aboriginal Tourism Network (ABORINET) www.aboriginal-ecotourism.org, a geocollaboratory was developed to support Indigenous tourism research and cultural and biology diversity. Indigenous communities are culturally distinct and remotely located and this presents geographic and sociocultural constraints when conducting research on issues affecting these communities. ABORINET's development focused on the specific goal of enabling collaboration between researchers and Indigenous peoples on issues related to Indigenous tourism planning, land management, biodiversity conservation and the general issue of enabling the sharing of differing knowledge and management approaches among research and Indigenous communities. The purpose was to develop a multi-scale and multi-method data collection and analysis protocol for better understanding Indigenous tourism in a way that supports multi-site and longitudinal comparisons, for connecting Indigenous communities across the world, and for sharing the results in ways that are meaningful to stakeholders within and beyond Indigenous communities. This presentation outlines the development of the geocollaboratory and describes the lessons learned with specific attention afforded the geographical nature of the collaboratory. Recommendations for mitigating challenges are proposed and future research opportunities are identified.

USING BIO-ASSESSMENT OF DNA IN THE ENVIRONMENT TO INFER SPECIES DISTRIBUTION

Scott Blankenship

Cramer Fish Sciences

Gregg SCHUMER, Cramer Fish Sciences

Commonly, geneticists infer population boundaries when elevated "between-group" variance is observed in genetic diversity data. These barriers to gene flow could be natural or anthropogenic in origin. While it may be important to identify these barriers, given they provide a means for local adaptation,

documenting barriers that are strong enough to influenced genetic diversity may be beyond what is necessary for basic conservation/management objectives, as well as being costly and technically challenging. Application of molecular biology methods to ecological issues is increasing, with technical advancements on species detection directly relevant to barrier issues. In essence, these methods detect (or sense) DNA in an environment (i.e., water, soil, organic matter) through the collection and interrogation of biological particles. This presentation includes a brief description of methods and protocols surrounding species detection (barcoding coupled with quantitative polymerase chain reaction). Following, examples studies are shown where these methods were applied, with emphasis placed on how species distributions can be inferred using detection of DNA. The first example pertains to detecting the presence of Oregon Spotted Frog (*Rana pretiosa*), a medium-sized cryptic (visually evasive) aquatic frog endemic to the U.S. Pacific Northwest that is a candidate species Federal protection (U.S. Endangered Species Act). The second example pertains to interactions between bull trout (*Salvelinus confluentus*), a native fish, with non-native (invasive) brook trout (*S. fontinalis*). The last example pertains to documenting the distribution of native a Smelt (*Hypomesus* spp.) using detection of DNA in stomachs of a larger invasive piscivorous species (*Morone* spp.). In other words, the target species was detected post-ingestion, where the predatory species (diet) was used as sampling mechanism.

THE SEMI-AQUATIC ANTELOPE KAFUE LECHWE SHOWS A REMARKABLE, BUT EFFECTIVE, FOOD ADAPTATION UPON CHANGED FLOODING CONDITIONS AND SHRUB ENCROACHMENT

Wilma Blaser

ETH Zurich

Griffin SHANUNGU, Zambia Wildlife Authority ; Peter EDWARDS, ETH Zurich ; Harry OLDE VENTERINK, Vrije Universiteit Brussel

Declining populations of many African herbivores have been linked to habitat modification and destruction. However, the magnitude of these impacts will vary depending on how they affect the resources that are most critical for population persistence. We studied annual habitat use alongside changes in the nutritional status of the vulnerable semi-aquatic antelope, the Kafue lechwe (*Kobus leche kafuensis*), in relation to two major drivers of habitat modification - flood management through dam construction, and shrub encroachment. The annual migration pattern of lechwe in Kafue Flats floodplain ecosystem is driven by flood height in the floodplain and availability of food resources in the wet season habitat, which is not flooded and accessible throughout the year. Faecal nitrogen levels indicate that lechwe suffer from nutritional stress at the beginning of the dry season when they are forced to remain in their wet season habitat

(termitaria grasslands) until floods recede. During this period of food scarcity, lechwe - although considered a strict grazer - alter their diet to consume seedpods of the encroaching shrub *Dichrostachys cinerea*, which appear to have positive effects on their nutritional status. Our results demonstrate that the migrating lechwe antelope are dependent on both wet and dry season feeding habitats, but a critical factor affecting population dynamics is the timing of the flood, which is now strongly dependent on dam management. Dam management affects both grass production as the waters rise and animals' access to the floodplain as the waters fall, while shrub encroachment has allowed lechwe to offset some of the negative effects of this altered hydrological regime. By combining information about habitat availability, movement patterns, and nutritional status, our results demonstrate a complex interaction between two major drivers of habitat modification on the population dynamics of a threatened herbivore.

126. DOES SUSTAINABILITY CERTIFICATION OF NATURAL RESOURCE PRODUCTION AND SUPPLY CHAINS DELIVER POSITIVE IMPACTS ON BIODIVERSITY? APPLYING AN ECOSYSTEMIC APPROACH IN THE EVALUATION OF CERTIFICATION SCHEMES

Jeanette Blumroeder

Centre for econics and ecosystem management - University for sustainable development Eberswalde

Anja KRAUSE, Centre for econics and ecosystem management - University for sustainable development Eberswalde ; Peter HOBSON, Centre for econics and ecosystem management - Writtle College ; Pierre IBISCH, Centre for econics and ecosystem management - University for sustainable development Eberswalde

The environmental certification scheme for the sustainable management of natural resources such as timber, soy and palm oil, is a market-based tool designed to reduce negative impacts on ecological and social systems. A set of standard principles, criteria and indicators for sustainability are adopted by growers and manufacturers operating under certification. Whilst the certified resource use and production systems cannot avoid any negative impact, they claim to be significantly more sustainable than homologous production systems without certification and various conservation NGOs actively support corresponding certificates. In many cases the adoption of certification-related measures promise benefits for the target systems, but systematic effectiveness evaluations are still scarce. A systemic approach derived from an ecosystem-based method for adaptive risk and vulnerability management (MARISCO method related to the Open Standards for the Practice of Conservation) is proposed as a holistic approach to

evaluating the industry. First, a conceptual model is generated to depict the breadth and depth of human impact on natural systems. Derived cause-effect 'webs' leading from factors related to social systems (e.g., politics, socioeconomics, land use) include the range of threats and stresses to biological and social systems caused by resource use management. Certification criteria and indicators representing mitigation strategies are mapped into the model to allow for an analysis of the perceived theory of change and the plausibility of effectiveness of certification. Finally, indicators considered to be most appropriate to measure effectiveness in the field are then identified. The method is illustrated by examples from boreal Russia (Forest Stewardship Council – FSC) and tropical Malaysia (Round Table for Sustainable Palm Oil – RSPO; International Sustainability & Carbon Certification – ISCC).

CONSERVATION IN THE MAKING: CONFLICT AND CONTESTATION AROUND TERRITORIALITY FOR WILDLIFE CONSERVATION CORRIDORS IN SOUTHERN TANZANIA

Jevgeniy Bluwstein

Copenhagen University

Jens Friis LUND, Copenhagen University

Tanzania's policy on Wildlife Management Areas (WMA) entails the creation of new territories for conservation of natural resources and wildlife on village lands. Underlying the policy is an idea of functional separation of landscapes for settlements, agriculture, photographic and hunting tourism, livestock grazing, and wildlife. Implicit in this separation is the creation of new territories through the negotiation, demarcation, and representation of boundaries in an institutional context that is characterized by competition over authority to spatialize, authority that is often claimed by project partners by means of producing maps. We show how territoriality for wildlife conservation operates within the context of historically evolving project-based attempts to demarcate and map community land. We unpack the dynamics of territoriality by examining how 1) neglect to adequately appraise challenges of boundary-making in combination with 2) politics of conservation and development interventions 3) foreclose a genuine participation and inclusion of local residents in decision-making over conservation territory and rules of access. This inevitably creates or exacerbates conflict and contestation of project-based processes of territorialization, further undermining the success of conservation interventions.

110: WHAT ARE LOCAL VOICES AND WHY DO WE WANT TO HEAR THEM?

Jevgeniy Bluwstein

Copenhagen University

Jens Friis LUND, Copenhagen University

This talk will outline different ways of including local people in community-based conservation practice. From manipulation and tokenism, consultation, informed consent to participatory action research we try to include people who are part of conservation interventions. Every form of inclusion involves a particular way of giving voice to people and a particular way we imagine 'community' for community-based conservation. Typically we include local people because we have to (e.g. following ethical standards or donor requirements in conservation & development practice), because we think that this will benefit the intervention (believing in win-win outcomes), or because we see value in including people (just) because they are humans. With this we want to ask what are the implications of the different ways of giving voice to local people for project success, in other words what are the conservation outcomes, what are the development outcomes, and how sustainable will the intervention be?

PANGOLIN BUSHMEAT TRADE IN GHANA: A THREAT TO THEIR SURVIVAL

Maxwell Kwame Boakye

Tshwane University of Technology

Darren William PIETERSEN, African Pangolin Working Group ; Antoinette KOTZÉ, African Pangolin Working Group ; Desiré Lee DALTON, National Zoological Gardens of South Africa ; Raymond JANSEN, African Pangolin Working Group

Bushmeat remain a key source of animal protein and income during lean agricultural periods in Ghana and mammals are regarded as the prime source of bushmeat. A mammal that is frequently hunted as a source of bushmeat in Ghana are the endangered pangolins (*Pholidota: Manidae*). Currently, pangolins can be regarded as the most traded group of mammals on Earth, however, very little is known with regards to the level of trade of pangolins in Ghana. The aim of this study was to determine the level of trade among additional stakeholders outside of major bushmeat market surveys in the bushmeat commodity chain for pangolins in Ghana. Data were gathered through semi-structured interviews and direct observation from 153 stakeholders comprising 84 chopbar operators, 48 farmer hunters and 21 wholesalers between September 2013 and January 2014. A total of 341 pangolins were recorded to have been traded in this study period and, of this number, 98 pangolins were personally observed. 82% of pangolins traded were white-bellied pangolins (*Phataginus tricuspis*) and 18% were black-bellied pangolins (*Phataginus tetradactyla*), but no trade was observed for the giant ground pangolin (*Smutsia gigantea*). The number of pangolins traded was negatively correlated to the distance between stakeholder's settlements and protected forest regions where the animals are mostly sourced. Snares were the most

commonly used hunting technique. The current levels of pangolin harvest in Ghana can be considered as unsustainable due to the very high offtake levels and the low reproductive rates of these mammals. In addition, the Wildlife Conservation Act of 1971 (LI 685) classifies pangolins under Schedule 1, prohibiting any person from hunting or being in possession of pangolins, an indication that legislation pertaining to pangolin conservation is not being implemented in Ghana.

185-OPTIMAL MULTISPECIES ERADICATION SCHEDULES FOR A COMMON INVADED ISLAND ECOSYSTEM MOTIF

Michael Bode

University of Melbourne

Symposium: Complex systems modelling to support biodiversity conservation Oceanic islands are global hotspots of both biodiversity and extinction. Invasive species are a primary threat, and many islands have been invaded by more than one. Multispecies eradications are therefore essential to island conservation, but eradicating invasives in the wrong order can be disastrous for endemic species. We use dynamic control theory and qualitative modelling to construct optimal multispecies eradication schedules – temporally explicit allocations of resources between species – when eradication budgets are limited. We identify an eradication schedule that is consistently optimal for any realisation of a common ecosystem motif, where two prey species (one endemic, one invasive) are consumed by an invasive predator. Our results show that it is always best to target the predator first, and thereafter gradually shift efforts towards the invasive prey. Invaded islands could be described by a limited taxonomy of ecosystem motifs. Our approach could therefore offer decision-support for many data-poor eradication projects.

76-THE RETURN OF LARGE CARNIVORES TO EUROPE

Luigi Boitani

University of Rome La Sapienza

John LINNELL, Norwegian Institute for Nature Research ; Petra KACZENSKY, Research Institute of Wildlife Ecology ; Guillaume CHAPRON, Grimsö Wildlife Research Station ; Arie TROUWBORST, Tilburg Law School ; Urs BREITENMOSER, FIWI and KORA, Bern University

Europe hosts five species of large carnivores (bear, wolf, Eurasian lynx, Iberian lynx and wolverine). With the exception of the Iberian lynx that survives only in southern Spain, the other species have all shown a generalized expansion of range and increase in numbers. What appears to be a remarkable conservation success is the outcome of a mix of active conservation measures and policies, changes in human values and attitudes, and independent social and economic

transformations of European societies and landscapes. During the post-WW2 decades, these transformations have extensively affected patterns of land use across the continent and facilitated the conversion of former marginal agricultural land into abandoned pastures and secondary forests. Wild prey populations recolonized these areas both naturally and through active reintroduction mainly by hunters, and provided the favourable conditions for the natural recolonization of large carnivores. Furthermore, the successive introduction of national and pan-European legislation has reduced the direct human persecution of large carnivores. While the concurrent impact of all these processes is indisputable in causing the return of the carnivores, it is extremely difficult to disentangle the role of individual processes and assess their effectiveness. In this presentation, we will present and discuss the potential role of conservation actions and historical processes that are reasonably linked to the return of the carnivores, including national and European legal frameworks, changes in human attitudes, financial support to conservation action, improved techniques to prevent and mitigate human-carnivore conflict, availability of suitable habitats, new protected areas, and increases in prey populations. We will then discuss the practical, legal, economic and social challenges associated with moving from a "saving from extinction" phase to one where we seek to turn this success story into one of lasting coexistence.

MODELLING POLLINATOR COMMUNITIES IN HETEROGENEOUS LANDSCAPES

Arvid Bolin

Lund University

Eric LONSDORF, Franklin & Marshall College ; Henrik SMITH, Lund University ; Ola OLSSON, Lund University

There has been a general decline in pollinator abundance and species richness over the last century, which is at least partly due to changes in the agricultural intensity, habitat loss, and changes in landscape structure. This could have profound implications for pollination ecosystem services, and their resilience. We present an expansion of a recent central place foraging framework into a spatially explicit competitive model based on pollinator behavioral strategies. The strategies are based on how species makes tradeoffs between foraging efficiency and travel efficiency. Using this modelling framework we predict which landscapes would be more beneficial for species with different traits and whether or not coexistence between species could occur. We can show how pollination services could be affected by landscape structure, for example the proportion and distribution of semi-natural habitat. Further, we show how interspecific competition could either lead to coexistence or competitive exclusion depending on landscape structure. We also demonstrate how an agri-environmental scheme could benefit both biodiversity and pollination service in mass flowering crops.

142 HOW MUCH AND WHERE: THE MOST CHALLENGING QUESTION FOR ENHANCING BIOLOGICAL DIVERSITY IN FRAGMENTED LANDSCAPES

Janine Bolliger

WSL Swiss Federal Research Institute

Felix KIENAST, WSL Swiss Federal Research Institute

Conservation management aims at mitigating the negative effects of landscape fragmentation by enhancing connectivity between the remaining populations. Such measures include e.g. locally established stepping stones or agri-environmental schemes (AES) which have a legal component. Since many of these conservation measures are expensive for the tax payer, a broad scientific assessment is needed to check under what spatio-temporal circumstances the measures fulfill their goals. Thus empirical studies for implementation into action plans are urgently needed. In our paper we give an example of such an assessment. Starting point is a large-scale European assessment of landscape fragmentation using effective mesh size. This appealing and widely applied land-use indicator is able to identify hotspots of high structural landscape fragmentation at any given spatial scale. If the indicator had any link to population processes, it would be an ideal tool to steer connectivity measures. To challenge this link we assessed functional connectivity in various regional structural fragmentation hotspots and evaluated measures that may mitigate connectivity. Results from various case studies in highly fragmented landscapes suggest that the link between structural fragmentation or measures for improvement (e.g., AES) and functional connectivity is often weak. Also, that demographic parameters such as population size or the spatial arrangement of the populations may contribute significantly to driving functional connectivity... Are we at the onset of a revival of the SLOSS debate?

A COLOURFUL HISTORY OF A POLYMORPHIC FINCH: A MOLECULAR ANALYSIS OF DEMOGRAPHIC HISTORY AND POPULATION STRUCTURE IN A THREATENED AUSTRALIAN FINCH (ERYTHRURA GOULDIAE)

Peri Bolton

Macquarie University

Lee Ann ROLLINS, Deakin University ; Andrea WEST, Deakin University ; James BRAZILL-BOAST, Macquarie University ; Jeremy AUSTIN, University of Adelaide ; Sarah LEGGE, Australian Wildlife Conservancy ; Kimberley MAUTE, University of Wollongong ; Simon GRIFFITH, Macquarie University

The Gouldian finch (*Erythrura gouldiae*) is an iconic finch from northern Australia, with a history of population decline. Little is known about their past and present population size

and how these birds move across their now restricted range. Moreover, the Gouldian finch has two common co-occurring colour morphs, which correspond to different behavioural and physiological strategies. Theoretically, distinct strategies associated with colour polymorphism can have effects on population dynamics and on the partitioning of genetic variation in the population. But this has not been explicitly examined in a conservation context. Studies in captive birds have shown strong positive assortative mate preference and a genetic incompatibility between morphs that reduces offspring survivorship. This incompatibility between morphs has restricted gene flow and there is genetic structuring between colours. Based on the captive studies, we predict that there should be significant genetic structure between colour morphs in the wild. However, our results from 10 microsatellite markers and mtDNA, from five contemporary populations indicate that there is extensive gene flow across their range and between morphs, suggesting successful interbreeding in the wild. Our analysis of these contemporary samples against museum samples from 1890-1920 also provides important insight into the depletion of genetic variation through the precipitous decline of this species over the last century. We discuss our results in the context of previously unforeseen consequences of colour polymorphism for conservation.

A 20 YEARS MONITORING OF THE BROWN BEAR POPULATION IN THE PYRENEES, FROM 1994 TO 2013: RESULTS AND PERSPECTIVES

Nicolas Bombillon

Office National de la Chasse et de la Faune Sauvage - CNERA PAD

Jean-Jacques CAMARRA, Office National de la Chasse et de la Faune Sauvage - CNERA PAD ; Jérôme SENTILLES, Office National de la Chasse et de la Faune Sauvage - CNERA PAD ; Ivan AFONSO JORDANA, Medi Ambient - Conselh Generau d'Aran ; Santiago PALAZÓN, Biòleg del Servei de Biodiversitat i Protecció dels Animals - Direcció General del Medi Natural i Biodiversitat ; Ramón JATO, Departamento de Servicios Medioambientales - Sociedad Aragonesa de Gestion Agroambiental S.L.U. Gobierno de Aragon ; Pablo MUÑOZ, Jefe de la Sección de Hábitats - Gobierno de Navarra ; Jordi SOLÀ DE LA TORRE, Cap d'àrea d'hàbitats i fauna - Dept. De Patrimoni Natural - Govern d'Andorra ; Pierre-Yves QUENETTE, Office National de la Chasse et de la Faune Sauvage - CNERA PAD

During the 20th century, the Pyrenean brown bear population dramatically decreased down to only 5-6 individuals in 1995. To avoid the extinction, two reinforcement plans were carried out in 1996-1997 and 2006 with the translocation of 8 bears from Slovenia. This study presents the effects of those reinforcement plans on the distribution area and the population dynamics. In this framework, the monitoring of the population in all

Pyrenees (France, Spain and Andorra) during the 20 past years (1994 to 2013) is used. The study was divided into 5 distinct periods tied to the two reinforcements. The monitoring of the population relies essentially on no invasive techniques (detection of bear signs, DNA typing and camera traps). In 1994, the bear is only present in a small area located in the western Pyrenees. In 1996-1997, the first reinforcements of 3 individuals occurred in central Pyrenees, 50 km apart of the main bear range, in an area where the last specimen disappeared 10 years ago. The species expanded largely on the French and Spanish slopes and reached a threshold of 5-6 bears. With the second reinforcement of 5 individuals in 2006, the population increased up to a minimum of 23 bears in 2013. Consequently, the central Pyrenees distribution area grew quickly until some individuals disappeared or came back to the core area and so the area was made smaller in the last past years. Simultaneously, whereas the western population size strongly decreased with only 2 male bears in 2013, the related bear area increased to the same size of the central area. Despite reintroduction plans, the brown bear is still an endangered species in the Pyrenees and new releases would be necessary. We discuss also the necessity to have both a reliable monitoring population to develop viability analysis and sociological studies for the conservation of this population.

ID177 FROM SCIENTIFIC MODELS TO COMPANION MODELLING: ENGAGING A DIALOGUE WITH LOCAL ACTORS IN AN AMAZONIAN FLOODPLAIN ABOUT BIODIVERSITY MANAGEMENT AT A TERRITORIAL LEVEL

Pierre Bommel

CIRAD

Marie-Paule BONNET, IRD ; Emilie COUDEL, CIRAD ; Eva HAENTJENS, CIRAD ; Cleber Nunes KRAUS, Universidade de Brasilia - UnB ; Anne-Elisabeth LAQUES, IRD ; Gustavo MELO, CIRAD ; Stéphanie NASUTI, Universidade de Brasilia - UnB ; Ina De Souza NOGUEIRA, Universidade de Brasilia - UnB

The Amazonian floodplain is among the most productive and diversified ecosystems in the world. The moving littoral enables a rapid nutrient recycling, explaining the large productivity and biodiversity of the system. Attracted by such favourable conditions for agricultural activities and fishing, populations have settled in the floodplains and developed complementary activities to cope with important variations in their environment, between the flood season and the dry season. However, in the past decades, the rhythm of these floodplains has changed, obliging the actors to deal with great uncertainty. Based on several years of hydrological and biogeochemical studies to understand the reasons of these environmental changes, the "life scientists" of our team invited the "social scientists" with the following question: Can the results about

the dynamics of these floodplains help local populations better anticipate the future fluctuations of the river and adapt their activities to be less vulnerable to such change? To address this, we first chose to turn the perspective around: what were the preoccupations and strategies of local populations and what did they expect from scientists? The challenge was to enable the perceptions and knowledge of local populations to dialogue with scientific knowledge. Based on a Companion Modelling approach, we engaged a participatory process to collectively discuss the current situation and possible future scenarios. Using a role-playing game as an interface for this dialogue, we have progressively built a model to integrate both the knowledge of the local actors regarding their practices and possible environmental impacts and the knowledge of the scientists on environmental dynamics. This has obliged researchers to learn to work together and simplify their knowledge, and requires finding common points of interest with local populations, translating "biodiversity" into concrete issues that have a meaning for local actors.

RHINOS ARE NOT VICUNAS: THE COMMERCIAL USE DELUSION

Cristian Bonacic
Fauna Australis, UC

Rhinos are under heavy threat from poaching. Their horns are being used for medicinal purposes although no scientific evidence exists to suggest rhino horn has such medicinal efficacy. Yet meeting this demand from Asia potentially elsewhere, via a regulated trade in white rhino horn, is being currently proposed. Trade has been suggested as a last resort for saving rhinos from extinction in the wild. Those who promote commercialization of rhino horn, tout the vicuna, a South American Camelid, as an example of conservation through sustainable use. Vicuna wool shearing for international markets is said to be a good model for rhino horn harvesting. We discuss the ecological, ethical, economic and practical dimensions and pitfalls of the sustainable use model learned during 15 years of vicuna shearing for markets in The Andes of South America. We also explain why vicuna poaching is escalating and difficulties for control. We also address the viability of commercial use of keystone species like Rhinos and Vicunas for conservation in a globalized world with never-ending demands.

WHY PUMA AVOIDANCE OF LIVESTOCK IS NOT ENOUGH TO MINIMIZE CONFLICTS BETWEEN AYMARA SUBSISTENCE FARMING AND PREDATORS IN THE HIGHLANDS OF NORTHERN CHILE

Cristian Bonacic
Fauna Australis, UC

Jorge LEICHTLE, Pontifical Catholic University of Chile ; Omar OHRENS, University of Wisconsin-Madison ; Adrian TREVES, University of Wisconsin-Madison

Puma concoloris well known as a livestock predator along its entire distribution range in the Americas. Pumas living in the Andes of South America cause problems to Aymara farmers. Retaliation by hunting and poisoning is common, but puma population density, prey preference and human perceptions about them are barely known. We studied livestock concentration areas and estimated domestic and wild prey availability during two years in an area of 12,997 km² between 3,500 and 5,000 masl. Also, we described herding practices and perceived threat by local farmers. Puma density was estimated by capture-recapture camera trapping and is one of the lowest known for the species (0.6/100 km²). Diet preferences were Lama pacos (total biomass), but wildlife prey (*Vicugna vicugna*) was higher in terms of frequency in feces compared to prey availability (Ivlev index). A total of 61 Aymara farmers listed the puma as their main wildlife threat followed by foxes (*Lycalopex culpaeus*). However, 41% declared that predation events are in decline, 24% that events were rising. In contradiction to what was perceived by the authorities, we conclude that a minority of individuals perceived increasing conflict with pumas, which has implications for future decision making on puma-human coexistence in the Altiplano region. Also, puma preyed mainly on wild prey despite low abundance and camera trapping detected puma presence in areas where livestock was not attacked. We conclude that managers should focus on further human dimensions work to identify causes of recent complaints, and at the same time understand the variables that are leading the puma to prey upon livestock.

POPULATION STRUCTURE OF CARIBBEAN TURTLE "HICOTEA" (TRACHEMYS CALLIROSTRIS) UNDER EXTRACTION PRESSURES

Maria Bonilla
Universidad Nacional de Colombia
Fredy VARGAS, Universidad Nacional de Colombia ; Luisa Fernanda PALACIOS, Universidad Nacional de Colombia ; Marjorie PINZON, Universidad Nacional de Colombia ; Adrian VASQUEZ, Universidad Nacional de Colombia

Colombian populations of "hicotea" turtle (*Trachemys callirostris*) have been used at the Caribbean region since Pre-Columbian times. Nowadays it is used by local people for consumption during Holy Week and is pressed by extraction, illegal traffic and degradation of natural habitats. The objective of this work was to analyze the structure of a "hicotea" population in four swamp areas near Cartagena, Colombia, in March and May 2014 during the extraction season. In each swamp area we tagged, measured and sexed all turtles captured by local fishermen. We analyzed 197 individuals, 75%

were adults in sizes between 10 and 26 cm. The sexual ratio was 1.62 females for each male. Comparing with sampling made in other places at the Caribbean Region we found that the size of turtles of our study site was smaller probably related with differential conditions of water productivity or the effect of extraction that is moving the structure of the population toward smaller sizes. This study was the first step looking to involve local people for a long term communitarian monitoring of "hicotea" population dynamics.

DEALING WITH OBSERVER BIAS WHEN MAPPING SPECIES DISTRIBUTIONS USING CITIZEN SCIENCE DATA: AN EXAMPLE ON BROWN BEARS IN GREECE

Anne-Sophie Bonnet-Lebrun

University of Cambridge

Alexandros KARAMANLIDIS, ARCTUROS - Civil Society for the Study and Protection and Management of Wildlife and the Natural Environment ; Miguel DE GABRIEL HERNANDO, ARCTUROS - Civil Society for the Study and Protection and Management of Wildlife and the Natural Environment ; Olivier GIMENEZ, Centre d'Ecologie Fonctionnelle et Evolutive - UMR 5175

Citizen science data are increasingly used to map species distribution. These are useful as they are cheaper, they come in greater quantity and cover much larger areas than data that scientists alone can collect. However, such data are presence-only data (no information on absences, hence no possibility to estimate detection rates) and suffer from observer bias (individuals are more likely to be detected where more people are going). Warton et al. (2013) developed a method to deal with these issues, using Poisson point processes and correcting for observer bias (by making the difference between variables that are likely to affect the species presence – environmental variables – and variables that are likely to affect detection – observer bias variables). Here we apply this method and use citizen science data collected on brown bears in Greece as a showcase. It is particularly relevant to map this species' distribution as there is evidence of human-bear conflicts in Greece. Besides, citizen science data are especially relevant for these large carnivores which are very difficult to detect (they are cryptic and solitary, and occur in low densities in very large areas). This study emphasizes the usefulness of citizen science data, and the need for a deeper modelling of what influences not only how the species uses space but also how the people collect data.

HALTING BIODIVERSITY LOSS IN AGRO-ECOSYSTEMS OF CENTRAL GREECE: CREATING A TECHNICAL GUIDE FOR TARGETED RESTRUCTURING OF SELECTED ELEMENTS IN THE AGRICULTURAL LANDSCAPE IN ORDER TO PRODUCE AGRI-ENVIRONMENTAL SCHEMES

Vasileios Bontzorlos

Agriculture Economics & Policy Research Institute

Biodiversity loss in intensified agro-ecosystems has been one of European Union's rural policy main aims. According to recent holistic approaches, the EU target "halt biodiversity loss" by 2010 was not finally met, at least in human induced agricultural landscapes. Although agri-environmental schemes are far more enhanced in the new CAP, still, according to recent scientific reviews the danger of not reaching the target "halt biodiversity loss by 2020" is eminent once again. One main factor driving this possible new failure is a gap between European legislation, EU member's national regulations and the application of concrete in-situ measures in agro-ecosystems management. A try was initiated in Greece in order to bridge that gap as a post-doctoral research project in the Agriculture Economics & Policy Research Institute. The project is based in 4 main pillars. Firstly, in situ field work will assess avian and small mammal diversity indices in selected sites in the largest agro-ecosystem of Greece, the Thessaly plains, with standard international methodology. The diversity indices will be explored upon environmental gradients which define the major land uses in the agro-ecosystem (irrigation schemes, arable and non-arable crops, annual and multi-annual crops, set-aside fields and natural grasslands, different crop types such as cereals & industrial crops). Secondly, meta-analysis of all existing literature in the region concerning diversity indices will also be realized. Thirdly, modeling the results in large spatial scale. Finally, a technical guide will be produced written in "simple language", which will aim to the main stakeholders of the area, the farmers who exploit the land. The technical guide will be a product of the Hellenic Agricultural Organization Demetra which is part of the Ministry of Rural Development, and will try to bring the land stakeholders in a direct application of proper agro-environmental schemes

'MANNEM THAPNEE': THE CROCODILE WORSHIP RITUAL OF AN AGRARIAN COMMUNITY OF INDIAN STATE OF GOA, AND ITS CONSERVATION CONTEXT

Manoj Borkar

BIODIVERSITY RESEARCH CELL, CARMEL COLLEGE FOR WOMEN

Crocodiles have been an indivisible part of Goa's ecology, history, culture and religion. Incorporation of this reptile in the local folklore, cultural artefact and folk-religion confirms and reiterates its sociological relevance in the state's cultural ethos. The crocodile in Goa evokes both; a rational fear and a spiritual submission. On one hand its introduction and 'deployment' in the territorial waters; by the then Muslim Rulers as deterrents to invasions from the sea is an amusing piece of Goa's history, whereas on the other hand its veneration by the agrarian Gawdas of this maritime state even till date is curious folk-religious response replete with conservation value. Of the 3 Indian species of crocodiles, it is only *Crocodylus palustris*, (Lesson, 1831) a Schedule I candidate as per the Indian Wildlife Protection Act, 1972, whose largest natural population is found associated with the mangrove forests of the Cumbarjua canal, an important backwater system. This reptilian population has swung from almost a point of no return, to the present day teeming numbers, with a spill-over beyond the metapopulation habitat. Despite the general anthropogenic pressures of local habitat loss, pollution, and hunting for meat and hide, the reptile has shown signs of recuperation in Goa. Complementing the efforts by the state wildlife authorities in conserving this reptile, is the agrarian community of Hindu Gawdas settled on the banks of the Cumbarjua canal who have been zealously guarding and protecting these 'lizards of the Sea'; as they have been referred to in some Portuguese chronicles. These indigenous people who reside in the proximity of crocodilian habitat, have bestowed upon the crocodile, a sacrosanct status, and their reverence of the reptile manifests into an interesting folk-religious practice locally known as 'Manngem Thapnee', whose anthropological context and conservation spin-off has been discussed in this paper.

POWER LINES AND BIRD COLLISION: ESTIMATING BIASES ASSOCIATED WITH CARCASS DETECTION AND PERSISTENCE

Leyli Borner

Sorbonne Universités-MNHN-UPMC-CNRS
Olivier DURIEZ, Université Montpellier 2 - Centre d'Ecologie Fonctionnelle et Evolutive - CNRS; Vivien CARRERE, Sorbonne Universités-MNHN-UPMC-CNRS; Frédéric JIGUET, Sorbonne Universités-MNHN-UPMC-CNRS

Bird mortality by collision along power lines is an international conservation issue. Quantification of this mortality is complicated by the heterogeneity of the survey methods used and the biases associated with carcass persistence and observer search efficiency. To estimate these biases we conducted three persistence experiments, lasting 30-days each, by placing 239 carcasses of red-legged partridges (*Alectoris rufa*) and common pheasants (*Phasianus colchicus*) under

power lines in 14 sites, and two search efficiency experiments, testing the detection of 108 carcasses by 19 observers. We used mark and recapture survival analysis and generalized linear mixed models to estimate daily carcass persistence probability and detection probability. We also investigated the factors affecting scavenger and search efficiency biases. The daily average carcass persistence probability was highly variable between sites up to an 8-fold variation (0.11 to 0.92). Carcass age was also significant, with a fast decrease of carcass persistence probability for the first 10-days of the survey, followed by a stabilizing after the 10th day. Carcass detection by observers was significantly affected by carcass size. Observers detected a common pheasant with a 0.48 mean probability while smaller partridge chicks were detected with a 0.0027 mean probability. These results suggest that carcass persistence varies strongly at a small landscape scale, although this is often not taken into account when correcting estimates of birds mortality surveys. In the site with highest persistence rate, the probability that a bird of the size of a common pheasant is not scavenged for 7 days and then detected by an observer conducting a mortality survey was 0.267. This reached a low of 0.0015 in the site with the lowest persistence rate. Unbiased estimation of bird collision mortality along power lines might thus require a substantial field effort.

JAGUAR AND ASSOCIATED BIODIVERSITY CONSERVATION ACROSS INCREASING OIL-PALM LANDSCAPES IN COLOMBIA

Valeria Boron

University of Kent

Esteban PAYAN, *Panthera*; Joseph TZANOPOULOS, University of Kent

Habitat loss is considered the main threat to biodiversity worldwide, and especially for large carnivores like jaguars (*Panthera onca*), due to their slow reproduction rate and large-area requirements. Information on Neotropical species in unprotected areas is scarce and baseline data for conservation and management are crucially needed, especially in ever increasing oil-palm (*Elaeis guineensis*) landscapes. We used camera trapping (50 stations, 2 km apart, 120 survey-days) across an agricultural area with oil-palm plantations in the Magdalena river valley of Colombia in order to compile a species inventory, calculate species capture rates across different habitat types, and estimate jaguar density through classic and spatially explicit capture-recapture models. In addition, we conducted 42 semi-structured interviews with relevant stakeholders and reviewed Colombia's agricultural policy to understand how to foster jaguars' conservation through adequate policies and management. We recorded 61 species, of which 21 mammals, and 12 jaguar individuals (143 independent capture events) with density resulting in 3.06-5.45 jaguars/100 km² depending on the analysis used. At the edge

of oil-palm areas with natural habitats capture rates increased for several species with respect to the oil-palm habitat showing that species can co-exists with agriculture and even oil-palm plantations if natural habitats persist in the landscape. It's therefore worthwhile to manage these landscape for species connectivity and survival. Potential solutions to achieve this emerged to be incentives for multi-crop farms and agroforestry, mandatory investments by large producers in small farmers alliances/projects, enforcement of land use plans, and tax breaks conditional to establishing conservation areas and respecting environmental laws. Other key sustainability objectives for the area would also benefit: conservation of natural resources, rural and social development, and institutional capacity.

ORGANIC MATTER DECOMPOSITION IN SOIL AFFECTED RATHER BY ABIOTIC ENVIRONMENT THAN TOPOGRAPHY AND LANDSCAPE HETEROGENEITY

Gergely Boros

Centre for Ecological Research

Krisztina BERECSKI, Centre for Ecological Research ; Rita FÖLDESI, Centre for Ecological Research ; Réka ÁDÁM, Centre for Ecological Research ; András BÁLDI, Centre for Ecological Research

Organic matter decomposition in soil is a fundamental regulating ecosystem service. However, it is the sum of three different processes (leaching, comminution, and mineralisation) decomposition typically measured as mass and nutrient loss from dead organic material. These materials are influenced by biotic and abiotic factors but their effect can be considerably different. We studied the effects of topographical complexity, landscape heterogeneity and wood cover as landscape traits as well as soil properties and herbaceous plant cover as local abiotic and biotic variables on decomposition rate in traditional grasslands in Southern Transylvania, Romania, Central Europe. We had 14 geographical distinct study sites around 11 villages, characterized by three environmental variables; a) high or low topographical complexity with diverse relief, b) landscape heterogeneity and c) wood cover – latter two measured on a trivalent rank scale. Decomposition of fine litter was pursued during 5 months by the minicontainer method with 2 mm mesh size to allow access micro- and mesofauna. Soil temperature and moisture were continuously measured on field by buried data loggers, other physical, chemical properties and inorganic nutrients were measured in laboratory from soil samples. There were no differences in decomposition rates concerning topography, heterogeneity and wood cover. Decay curves showed that decomposition rates were affected by soil moisture and temperature on the first place. Thus, we can conclude that

organic matter decomposition in soil is influenced by abiotic soil properties rather than landscape features and other biotic factors.

A GIS-BASED DECISION MAKING APPROACH FOR PRIORITIZING SEABIRD MANAGEMENT FOLLOWING PREDATOR ERADICATION

Stephanie B. Borrelle

Auckland university of Technology

Rachel BUXTON, Department of Zoology, University of Otago ; Holly P. JONES, Department of Biology and Institute for the Study of the Environment, Sustainability, and Energy, Northern Illinois University ; David R. TOWNS, Auckland university of Technology

Given that 29% of seabird species are threatened with extinction, protecting seabird colonies on offshore islands is a global conservation priority. Colonies of seabirds are vulnerable to non-native predator invasions, which reduce or eliminate seabird populations. Consequently, predator removals have been the focus of conservation efforts to protect seabirds and island biodiversity. However, affected populations are often left to passively recover following predator eradications, and while seabirds are highly mobile, their life history traits can limit passive re-colonization to newly predator-free habitat. In such cases, seabird colonies can potentially be re-instated with active restoration via chick translocations or social attraction methods, which can be risky and expensive. We used biogeographic and species behavioral data in the Hauraki Gulf, New Zealand, a global hotspot of seabird diversity and predator eradications, to illustrate the use of geographic information systems based multi-criteria decision analysis to prioritize islands for active restoration of seabirds. Using habitat criteria, seabird colony data and recolonization evidence, we identified islands that have had little or no observed passive recovery of seabirds post-eradication, and classified these as sites where active seabird management could be prioritized. This included Hauturu (Little Barrier Island), a restoration site with multiple complex conservation challenges, including ambiguity of ecological targets, and the recent discovery of the critically endangered New Zealand Storm petrel (*Fregetta maoriana*). On seabird islands with complex restoration challenges, decision tools that help island conservation practitioners to decide whether active seabird management should be paired with eradication can optimize restoration outcomes and ecosystem recovery.

POPULATION GENOMICS OF THE INVASIVE LIONFISH, PTEROIS VOLITANS: IMPACTS OF DRIFT AND SELECTION ON GENETIC DIVERSITY DURING RAPID RANGE EXPANSIONS

Eleanor Kathleen Bors

Woods Hole Oceanographic Institution

James A MORRIS JR., National Oceanic and Atmospheric Association ; Thomas F SCHULTZ, Duke University Marine Lab ; Timothy Mitchell SHANK, Woods Hole Oceanographic Institution

The invasion and ecological damage of the Indo-Pacific lionfish *Pterois volitans* in waters off the US Atlantic Coast, Gulf of Mexico, and Caribbean Sea are unprecedented for a marine fish invasion. Lionfish have invaded the Atlantic in a matter of decades, representing a model system for understanding rapid genetic change on the leading edge of marine invasions. Our research uses population genomics to address two fundamental questions central to invasive genetics and other range expansions (e.g., climate-driven spatial shifts): 1) what is the relative contribution of pre-invasion vs. post-invasion adaptation to invasion success and the evolution of invasive species; and 2) what are the roles of genetic drift and selection in the shaping of post-invasion genetic diversity and post-invasion adaptation? We describe patterns of genetic diversity and population structure throughout the lionfish's invaded range using genome-wide genetic markers (i.e., loci) generated through double digest restriction enzyme associated DNA sequencing (ddRAD-seq). RAD-seq methods generate tens- to hundreds-of-thousands of loci distributed throughout the genome (including neutral, regulatory, and protein-coding regions). We use these data to identify outlier loci in the genome that may be associated with selection or extreme genetic drift known as 'allele surfing'—the process by which rare alleles or new mutations can "surf" the front of the invading population wave to high frequencies near the edge of a species' newly-colonized range. Allele surfing is predicted to have marked impacts on genetic diversity and future adaptive potential. Alignment of loci of interest to existing fish genomic resources will highlight which genomic regions are subject to invasion-specific genetic drift and natural selection. This work lends insight into patterns of genetic diversity in order to better approach the management of biodiversity in the face of rapid range expansions and species invasions.

GENETIC AND FIELD SAMPLING TECHNIQUES FOR TIGER MONITORING IN LOW POPULATION DENSITY PROTECTED AREAS OF NORTH EAST INDIA

Udayan Borthakur

Aaranyak

Pranjal Kumar DAS, Aaranyak ; Rumi Dev BARMAN, Aaranyak

Application of molecular genetic tools in wildlife monitoring has gained a tremendous momentum in India in past one decade, especially with mandatory application of these techniques in monitoring of tiger in protected areas with low population density. In the present study, we employ faecal DNA analysis and field sampling techniques to ascertain

species, individual and sex identity of tigers in several protected areas in North East India, viz., Orang National Park, Manas National Park, Dampa Tiger Reserve, Pakke Tiger Reserve and Namdapha Tiger Reserve. The process of genetic monitoring starts with the development of mitochondrial DNA sequencing markers for species identity, optimisation of a panel of microsatellite loci for individual identity and development of sex-chromosome linked markers for sex identification of tiger individuals. In low population density areas, sampling techniques for population estimation requires consideration of the field efforts, accessibility and repeatability, as most of these areas lie in physically challenging hilly terrains. We have adopted a single session sampling design and maximum likelihood estimator for genetic population estimation, instead of the traditional multi-session sampling in capture-recapture framework. This single session sampling based monitoring was applied using beats as sampling units, which are the smallest management blocks in a protected area. Using management blocks as sampling units allowed us to carry out joint tiger genetic monitoring with several protected area authorities. Our work has revealed the presence of tigers in areas such as Dampa and Namdapha, in addition to robust population estimates for Orang, Manas and Pakke. We plan to conduct long term genetic monitoring of tigers in these protected areas, in order to understand population dynamics and corridor functionality through demographic and genetic exchange in tigers of North East India.

A METHODOLOGICAL COMPARISON FOR REAL POPULATION SIZE AND ESTIMATES FROM A CONSERVATION PERSPECTIVE THROUGH THE USE OF THE SUWEON TREEFROG (HYLA SUWEONENSIS) AS A MODEL SPECIES.

Amaël Borzée

Seoul National University

Yikweon JANG, Ewha W. University

The estimation of amphibian population size has been a notoriously difficult task since the earliest ecological studies on the subject. No sound comparison of all general methodologies is readily available and amphibian conservation is strongly impacted as a result. The need for an ideal model species for a comparison of the methods used for population size estimation lead to the selection of the endangered Suweon Treefrog (*Hyla suweonensis*). This species is ideal for model testing because it can be easily surveyed by counting calling males, and since it has a limited geographic range and small population size it is possible to sample the entire extent of the population in a single field season. The population size was estimated for this species from a field survey over a single season. This information was used to test the efficacy of two types of models, one based on surface occupancy and

the other on ecological preferences. The software PRESENCE and genetic tools agreed on four out of five instances on the size of the population for the species. This methodological comparison demonstrates that four of the methods used for population size estimation are effective and provide similar results. Our results indicate that the tools described here can accurately estimate population size and can therefore be used for making informed decisions for identification of populations of importance and for preserving endangered species.

49-THE EFFECTS OF LANDSCAPE FRAGMENTATION ON THE HABITAT USE OF WOODLARKS LULLULA ARBOREA AND THEIR INVERTEBRATE PREY

Laura Bosco

University of Bern

Alain JACOT, University of Bern ; Raphael ARLETTAZ, University of Bern

Vineyards in Switzerland are among the most intensively managed crop systems where up to 90% of the parcels do not have any ground vegetation cover. However, there has been a considerable reduction in the application of herbicides over the past decades, leading to more vegetation of higher diversity on the ground. These different management types lead to a fragmented and almost binary system of few parcels with ground vegetation and lots of parcels with bare ground. The woodlark (*Lullula arborea*) is an endangered ground-nesting bird species that occurs in vineyards and during the breeding season mainly feeds on arthropods. Here, we investigated whether fragmentation negatively affects arthropod abundance and diversity using a combination of pitfall traps and sweep nets sampled along a gradient from low to high fragmentation effects (connectivity and habitat amount). In a second part we studied the habitat use of woodlarks using radio-telemetry with respect to arthropod abundance and fragmentation effects. Our findings indicate that fragmentation directly impedes the movement of arthropod prey, as in areas with higher connectivity and habitat amount the abundance and richness of arthropods increased. As a consequence the woodlark adjusts its habitat use in relation to the availability and abundance of its prey by using less fragmented areas more intensively. Using these findings, our project aims to give clear recommendations to winegrowers about the amount, distribution and connectivity of parcels with ground vegetation within the vineyards, which should ultimately favour biodiversity in general and woodlarks in particular.

USING CASE STUDIES FOR ENHANCING CAPACITY IN CONSERVING FOREST GENETIC RESOURCES

David Boshier

Department of Plant Sciences, University of Oxford

Michele BOZZANO, Bioversity International ; Judy LOO, Bioversity International ; Per Rudebjer, Bioversity International

Forest trees are long-lived species with high genetic diversity that is central for their survival, regeneration and adaptation to climate change. However, forest managers and conservationists are often not well informed about genetic aspects of population viability. Lack of understanding of forest genetic resources (FGR) therefore constrains conservation of tree species, increases genetic risks in subsequent generations and hinders adaptation to climate change. Tertiary education curricula cover FGR issues poorly or not at all. A vicious cycle is looming in which teaching and understanding of FGR and its importance to conserving forest tree species – in protected areas and in production landscapes – becomes increasingly marginalised. We describe a case study-based approach to teaching and learning about FGR use and conservation, based on real research results and subsequent recommendations. For example, the three case studies in the first module of the Training Guide focus on development of conservation strategies for tree species with different reproductive biology and ecological niches. Module two contains two case studies on conservation of trees outside of forests. Designed to promote 'FGR-friendly' decision-making, the Training Guide covers practical issues in forest and tree conservation and management of both global and local relevance. Each case study provides genetic, ecological and socioeconomic information as a basis for students' analysis. Teacher's notes, PowerPoint presentations and videos give background information to each case. The guide is intended for both tertiary education and on-the-job training. It is or will soon be available in English, Spanish, French, Russian and Chinese. The material has proved popular with trainees and is flexible and easy to use in a range of formal and informal learning situations.

HIGH PLANT AND ARTHROPOD DIVERSITY IN GRASSLAND AND SAVANNA FIELD MARGIN HABITATS OF SOUTH AFRICA

Monique Botha

North West University

Stefan SIEBERT, North West University ; Johnnie VAN DEN BERG, North West University ; Bheki MALIBA, Eskom, Research, Test and Development

Intensive, large-scale cultivation has led to a postulated decrease in biodiversity worldwide, which have been ascribed to fragmentation and degradation of natural habitat bordering crop fields. Maize is the most widely planted grain crop in the Grassland and Savanna Biomes of South Africa, but it is unknown what effect crop production has on species diversity and composition. This study intends to address this knowledge gap by comparing diversity patterns and species assemblages

between maize fields and margins of six localities in South Africa across two biomes for plants and associated arthropods. A total of 15019 individuals and 824 native and exotic species were recorded for plants and 39 497 individuals and 1 629 morpho-species for arthropods. Although biodiversity loss was apparent in maize fields, field margins between 30 and 100 m from maize fields and natural areas had similar plant and arthropod diversity. Field margins and natural areas also shared very similar plant and arthropod species assemblages. Plant species assemblages were best predicted by agricultural disturbance while arthropod communities were mainly determined by biome. Our results suggest that the crop field margins (30-100 m from field edge) were not species poor ecosystems, but were surprisingly rich in plant and arthropod diversity. Field margins may therefore be of conservation value in the agricultural landscape with a diversity of species supporting important ecosystem services.

IMPACTS ON FOREST-BIRD DIVERSITY DOWN TO SINGLE INDIVIDUAL'S THROUGH RECREATIONAL ACTIVITIES - AN EXPERIMENT

Yves Bötsch

Swiss Ornithological Institute

Zulima TABLADO, Swiss Ornithological Institute ; Susi JENNI-EIERMANN, Swiss Ornithological Institute ; Bettina ALMASI, Swiss Ornithological Institute ; Lukas JENNI, Swiss Ornithological Institute

The human world population increases continuously, and more and more humans also conduct some outdoor recreational activities. Because it is difficult to distinguish between the effect of disturbance caused by the presence of humans and the anthropogenic changes in habitat, we decided to do a study in which we experimentally applied a disturbance similar to recreational activities, but without modifying the habitat. Our main objective was to evaluate whether human disturbance affects breeding site selection of birds. For this, we set up a split-plot design, in which plots with highly homogeneous habitat were divided in half and one half was then disturbed and the other one served as control. The disturbance consisted of a small group of people walking through the woods, twice a day, with human conversations coming from a loudspeaker. This disturbance was performed during early breeding season (from March until mid-April) to try to influence breeding site selection. In each split plot the same number of nest boxes was distributed for small cavity nesting birds (mainly tits). In order to evaluate the effects of the disturbance, several parameters were measured later in the season. We monitored the breeding territories of all species through monthly counts. Moreover, we examined nest box occupancy, breeding biology, physiology, and behaviour of tit species. Despite the low level of disturbance, we observed a lower number of species and a lower number of overall

breeding pairs in the disturbed split plots compared to the control. Although the results are still preliminary, there seemed to be also differences in physiological parameters between control and disturbed split plots. Overall, it appears that the level of human disturbance that we applied was enough to negatively affect breeding site selection of forest birds.

EVIDENCE FOR THE IMPACT OF NATURE CONSERVATION ON HUMAN WELL-BEING

Madeleine Bottrill

Conservation International

Samantha CHENG, University of California, Los Angeles ; Janet EDMOND, Conservation International ; Margaret HOLLAND, University of Maryland, Baltimore County ; Samuel DUPRE, University of Maryland, Baltimore County ; Sierra SHAMER, University of Maryland, Baltimore County ; Ruth GARSIDE, University of Exeter

Global policy initiatives and international conservation organizations have sought to emphasize and strengthen the link between the conservation of natural ecosystems and human development. While many indices have been developed to measure various human well-being domains of conservation intervention, the strength of evidence to support the effects, both positive and negative, of conservation on human well-being, is still unclear. Rigorous and comprehensive evidence is necessary to enable efficient, defensible and targeted decisions and investment in advancing goals for improved human well-being in conservation. We present a systematic map, a thematic synthesis that visually illustrates the extent and diversity of published and unpublished sources of evidence, of studies linking conservation interventions to human well-being. We identified over 1000+ relevant studies based upon a search of online databases, specialist websites, and key informants. Data were extracted on characteristics of the study, types of conservation interventions, and human well-being outcomes. The map enables us to articulate pathways by which different interventions affect different aspects of human well-being, from income and basic materials to rights and equality. Furthermore, the results will inform priorities by pinpointing knowledge gaps to guide future monitoring and evaluation efforts. In this presentation, we explore the implications of the existing evidence base and its key findings for different audiences, in particular, conservation and development non-governmental organizations, donor agencies, and researchers.

BIODIVERSITÉ ENTOMOLOGIQUE INVENTORIEE PAR L'UTILISATION LA TECHNIQUE DES POTS BARBER AUX ABORDS DU MARAIS DE RÉGHAÏA(ALGER)

Belkacem Aimene Boulaouad

Ecole nationale supérieure agronomique

Oussama ALLAM, Ecole nationale supérieure agronomique ; Abdeljalil BOUAZIZ, Ecole nationale supérieure agronomique ; Samia DAOUDI-HACINI, Ecole nationale supérieure agronomique ; Saleheddine DOUMANDJI, Ecole nationale supérieure agronomique

La présente étude est déroulée aux abords du marais de Réghaïa (3° 19' à 3° 20' E. ; 36° 46' à 36° 47' N). L'inventaire des arthropodes a été réalisé par la méthode des pots Barber. Nous avons installé 10 pots-pièges pendant la période du mois de septembre jusqu'au mars de l'année 2013-2014, avec 1 série par mois. 916 individus sont recensés. Ils appartiennent à 6 classes, 21 ordres et 77 espèces. Les Insecta est la plus fréquente (A.R.% = 50,76 %), suivi par les Arachnida (A.R.% = 41,16 %). L'ordre des hyménoptères est le mieux représenté en espèce (A.R.% = 83,23 %), il est suivi par les diptères avec (A.R.% = 5,38).

IDENTIFYING CLASSES OF DEGRADED FORESTS IN AN AMAZONIAN LANDSCAPE FROM REMOTE-SENSING

Clément Bourgoïn

CIRAD

Nicolas BAGHDADI, IRSTEA ; Lilian BLANC, CIRAD ; Joice FERREIRA, EMBRAPA ; Valéry GOND, CIRAD ; Lucas MAZZEI, EMBRAPA ; Yohann OZWALD, Université Rennes

In the Brazilian Amazon, deforestation and forest degradation have resulted in a complex mosaic of forest types. Nearly 20% of the Brazilian Amazonian forests have been cleared. In this area, abandonment of fields led to regrowth of secondary forests of varying ages. A fraction of the remaining forested land has also suffered from anthropic degradation (mainly over-logging and fire). Human-modified Amazonian landscapes are therefore an assemblage of these various forests associated with pastures and agricultural lands. These landscapes are now at the centre of political concerns. Coercive measures taken by the Brazilian government to curb deforestation, associated with private initiatives (soy and beef moratoria) drastically reduced deforestation rates. The colonization of the Amazonian territory through agricultural expansion over forest areas is now severely restricted. Consequently, conciliation between agricultural production and environmental conservation should be pursued in all human-impacted forests. However these secondary and degraded forests have not received the necessary attention. While identification and characterization of degraded forests became a critical task, there is an overall limitation in the remote sensing analyses developed so far. To define management plans for these areas and to understand their role in the maintenance of ecological services, the first challenge is to identify and characterize the forests that result from different disturbance trajectories. We carried out a study aiming at classifying the large spectrum of degraded

forests into forest classes based on degradation levels using satellite data. The study area took place in the municipality of Paragominas (eastern Amazonia). A large range of captors (optical, radar and lidar) have been tested combining with ground-truth validation. This classification has important applications in ecological studies as well as in supporting decisions for land-use planning.

USING REAL-TIME FOREST LOSS ALERTS AND GLOBAL DEFORESTATION MAPS TO ASSESS THE EFFECTIVENESS OF AFRICA'S TROPICAL PROTECTED AREAS.

Jenna Bowker

University of Cape Town

Graeme CUMMING, University of Cape Town ; Alta DE VOS, University of Cape Town

Tropical forests are the most biologically diverse and vulnerable ecosystem, undergoing rapid changes over the last two decades and resulting in the loss of irreplaceable biodiversity. Parks have been established in an attempt to slow biodiversity loss, but the effectiveness of this tool has been questioned, particularly in areas such as tropical Africa suffering from widespread conditions of poverty, rapid population growth and political instability where little or no formal management exists on the ground. As few countries within Africa have stable monitoring systems to generate time-series data of forest cover change, remotely-sensed satellite imagery offers a practical way to examine trends in forest cover change within and outside parks. Recent advances in remote sensing technology have allowed conservationists to investigate forest cover trends at increasingly large scales at high resolutions across whole biomes, offering an efficient, practical and affordable way to explore park effectiveness. I used the remotely sensed global forest change data of Hansen et al. (2013) and near-real-time tree cover loss alert system (FORMA) released by the World Resource Institute in early 2014 to analyze forest loss within parks and immediate surroundings in Africa at 50m and 500m resolution respectively. A total of 224 parks within the tropical and subtropical moist broadleaf forest biome were chosen. Results indicated that the majority of African tropical parks in this study are effective in deterring forest loss inside park boundaries. Smaller parks were less effective at preventing forest loss than larger parks and parks of differing IUCN categories showed no difference in effectiveness. West African parks exhibited the largest amount of forest loss, while Central Africa exhibited the least. This study highlights the potential of remote satellite imagery for estimating the relative impact of park establishment for Africa and identifying effective and failing parks.

FINE-SCALE GENETIC STRUCTURE IN AN AFRICAN ANTELOPE SPECIES DISTRIBUTED ACROSS A LANDSCAPE OF FRAGMENTED FORESTS.

Andrew Edward Bowkett

University of Exeter

Trevor JONES, Southern Tanzania Elephant Project ; Amy Bridget PLOWMAN, Whitley Wildlife Conservation Trust ; Jamie Robert STEVENS, University of Exeter

Fine-scale genetic structure has important implications for population management and conservation but has not previously been studied in a duiker species. We investigated spatial genetic structure in Harvey's duiker *Cephalophus harveyi*, a small-bodied antelope dependent on vegetation cover, in the high biodiversity fragmented forests of the Udzungwa Mountains, Tanzania. We genotyped 141 geo-referenced fecal samples collected over 35 months from across the central Udzungwa range at eight microsatellite loci. We found a highly significant pattern of isolation by distance across the study area (Mantel test: $r_{xy} = 0.189$; $P < 0.001$) and positive global spatial autocorrelation at distances below 10 km ($r = 0.033$; $P < 0.001$). However, within sampling areas of continuous forest there was little evidence for genetic structure, indicating possible local panmixia. There was no evidence for temporal structure across the sampling period. Bayesian individual-based methods indicated a genetic structure of either two (location prior model in STRUCTURE) or four (correlated alleles model in Geneland) clusters with a well-supported division between the central forest blocks and two outlying forests. Although designated as Forest Reserves, these latter forests are outside of the Udzungwa Mountains National Park and Kilombero Nature Reserve and subject to illegal hunting of forest antelopes and other species. Our results indicate that different landscape features, in addition to isolation by distance, influence genetic structure in Harvey's duiker with the area's large rivers appearing to separate genetic clusters. This study suggests that Harvey's duiker is able to disperse through non-forested habitats and therefore will likely benefit from attempts to establish wildlife corridors between protected areas in the Udzungwa Mountains.

CANOPY CAMERA TRAPPING WITHIN AN OCCUPANCY FRAMEWORK TO MONITOR ARBOREAL WILDLIFE IN THE PERUVIAN AMAZON

Mark Bowler

Institute for Conservation Research, San Diego Zoo Global
Matt ANDERSON, Institute for Conservation Research, San Diego Zoo Global ; Bryan ENDRESS, Oregon State University ; Michael GILMORE, New Century College, George Mason

University ; Mathias TOBLER, Institute for Conservation Research, San Diego Zoo Global

Camera trapping as a means to assess animal communities has grown in popularity in recent decades, but forest canopies have rarely been surveyed using camera traps and never within an occupancy modelling framework. We installed 42 camera traps on a randomly positioned grid for six months in the rainforest canopy at a moderately hunted site, in the Maijuna-Kichwa Regional Conservation Area in the northeastern Peruvian Amazon, with the objective of estimating occupancy for arboreal mammals. We obtained reliable occupancy estimates for nine species including five primates, kinkajou, olingos, Brazilian tree porcupine and the two-toed sloth. Half of these species are nocturnal and therefore hard to survey by alternative means. Occupancy of the frequently hunted woolly monkey was positively correlated with distance from the village, whilst the occupancy of two smaller-bodied primates and the tree porcupine were negatively correlated with distance from the village. Whilst detection probabilities were low, our traps were positioned in a number of configurations and not targeted at particular species. Thus, detection is likely to increase as experience improves and trap positioning is being standardized. That detection was correlated with trap height for four species further illustrates the influence of trap positioning on detection probability.

ID34: CITIZEN SCIENCE MEETS SATELLITE REMOTE SENSING: OPPORTUNITIES FOR LAND COVER MAPPING

Doreen Boyd

University of Nottingham

Giles FOODY, University of Nottingham

Citizen science has a long history but has grown rapidly in recent years, notably due to technological developments. This growth indicates considerable potential to develop and indeed revolutionize aspects of remote sensing, with a real potential to address major barriers to progress. This is evident in many application areas of remote sensing but perhaps most apparent in relation to the acquisition of ground data that are used in support of remote sensing studies. Within the context of biological diversity it is the production of land cover maps that is particularly important and ground data are central to the production process providing producers and users with confidence. The key focus of this paper will be on how citizen sensors can provide useful data to support land cover mapping endeavours which are underpinned by remote sensing. A number of case studies will be covered to demonstrate how unknown volunteers as well as internet projects can provide the ground reference data needed to validate land cover maps. Moreover, it will be shown that without any formal ground data at all it is possible to gain information on map accuracy

and the quality of the individual volunteers in relation to their contributed data. The latter is important as citizen derived data is typically highly imperfect and critically is of unknown and variable trust levels. These examples are important in terms of helping to realize the potential of remote sensing as a source of land cover information robust enough to support conservation initiatives within scientific, management and policy communities.

EFFECTS OF SIMULATED RECURRENT INCLEMENT WINTER WEATHER ON THE STRESS RESPONSE AND FEEDING BEHAVIOUR OF WHITE-THROATED SPARROWS (*ZONOTRICHIA ALBICOLLIS*)

Andrea Boyer

University of Western Ontario

Climate change has been linked to increasing frequency and severity of violent, unpredictable winter storms and other extreme weather events at nearly all latitudes. As such, it is important to study and understand the effects that changing weather patterns have on avian species. There has been prior research regarding how birds cope with winter weather and their ability to predict oncoming inclement weather, but limited research surrounding how birds respond, both physiologically and behaviourally, to recurrent inclement winter storms over a long-term period. I investigated these effects of recurrent inclement winter weather cues on the stress response system and feeding behaviour of a native Canadian songbird species, the white-throated sparrow (*Zonotrichia albicollis*). I used a hypobaric climatic wind tunnel to simulate storms approaching, residing, and subsiding by altering barometric pressure and temperature accordingly, and measured behavioural responses, body composition, and baseline corticosterone levels in birds exposed, or not exposed, to weekly simulated storms. After environmental manipulations, experimental birds had a significantly higher fat mass, in addition to increased lean mass. Baseline corticosterone levels decreased over time in both groups, and feeding duration increased over time among both groups as well. This novel research provides further evidence that birds can detect changing weather patterns and respond appropriately. Understanding how species will respond to predicted environmental changes will give an insight into future conservation and management strategies surrounding climate change.

INCORPORATING INTRA-ISLAND MOVEMENT IN A SPATIALLY EXPLICIT CAPTURE-RECAPTURE REEF SHARK POPULATION DENSITY ESTIMATE AT AN UNFISHED CORAL REEF

Darcy Bradley

University of California, Santa Barbara

Eric J. CONKLIN, The Nature Conservancy, Hawai'i ; Yannis P. PASTAMATIQU, University of St. Andrews ; Douglas J. MCCAULEY, University of California, Santa Barbara ; Kydd POLLOCK, The Nature Conservancy, Hawai'i ; Amanda M. POLLOCK, U.S. Fish and Wildlife Service ; Bruce E. KENDALL, University of California, Santa Barbara ; Steve D. GAINES, University of California, Santa Barbara ; Christopher G. LOWE, California State University, Long Beach ; Jennifer E. CASELLE, University of California, Santa Barbara

Reef shark populations have been devastated by ever increasing fishing pressure and baseline population density estimates are lacking. Traditional diver based visual surveys suffer from a lack of comparability and reproducibility and different survey methods have been shown to result in a contradictory picture of shark abundance. The grey reef shark (*Carcharhinus amblyrhynchos*), which is listed as Near Threatened on the IUCN Red List of Threatened Species, is highly mobile and therefore particularly difficult to monitor. At the same time, its mobility is precisely what has stymied its protection in much of the world – without understanding the spatial behavior of reef sharks, it is impossible to design spatial management strategies to protect them. Shark abundance through both space and time can be better estimated by directly accounting for reef shark movement in population estimates without the biases inherent in diver-based visual surveys. A spatio-temporal understanding of animal movement and abundance also allows managers to identify critical habitats, movement between habitats, and track changes to population size and structure. To directly address and incorporate animal movement in estimates of reef population size and density, we used a spatially explicit capture-recapture model from an eight year capture-recapture program augmented with telemetry data to produce the first baseline population density estimate of grey reef sharks and to further describe their spatial and temporal distribution at Palmyra atoll, a remote U.S. National Wildlife Refuge in the central Pacific Ocean. We found that diver based visual surveys had significantly over estimated shark density at an island wide scale. While our analysis revealed density 'hot spots', sharks also underwent regular excursions around the atoll, indicating that large scale spatial protection is necessary to recover reef shark populations globally.

HUMAN POPULATION REDUCTION IS NOT A QUICK FIX FOR ENVIRONMENTAL PROBLEMS

Corey Bradshaw

University of Adelaide

Barry BROOK, University of Tasmania

The inexorable demographic momentum of the global human population is rapidly eroding Earth's life-support

system. There are consequently more frequent calls to address environmental problems by advocating further reductions in human fertility. To examine how quickly this could lead to a smaller human population, we used scenario-based matrix modeling to project the global population to the year 2100. Assuming a continuation of current trends in mortality reduction, even a rapid transition to a worldwide one-child policy leads to a population similar to today's by 2100. Even a catastrophic mass mortality event of 2 billion deaths over a hypothetical 5-y window in the mid-21st century would still yield around 8.5 billion people by 2100. In the absence of catastrophe or large fertility reductions (to fewer than two children per female worldwide), the greatest threats to ecosystems—as measured by regional projections within the 35 global Biodiversity Hotspots—indicate that Africa and South Asia will experience the greatest human pressures on future ecosystems. Humanity's large demographic momentum means that there are no easy policy levers to change the size of the human population substantially over coming decades, short of extreme and rapid reductions in female fertility; it will take centuries, and the long-term target remains unclear. However, some reduction could be achieved by midcentury and lead to hundreds of millions fewer people to feed. More immediate results for sustainability would emerge from policies and technologies that reverse rising consumption of natural resources.

123 FOREST ECOSYSTEM SERVICES: FROM THE PAST INTO THE FUTURE

Richard Bradshaw

University of Liverpool

Modern forests provide a broad range of ecosystem services ranging from the provisioning of wood and fibre, to the regulation of flooding and soil erosion and the cultural benefits of recreation and wilderness experience. Their contribution to human security, health, welfare and social relations has changed through time and analysis of these changes helps with anticipation and planning of future dynamic relationships between forests and human needs. The transition from hunting and gathering to agriculture altered the provisioning and regulating role of forests and subsequent changes in agricultural practice further readjusted the service role of forests in Europe and North America. Forests have always contributed significant cultural services, formerly through a spiritual role and latterly through their contribution to recreation and the conservation of 'natural' values. Case studies illustrate the temporal dynamics of forest ecosystem services: 1) carbon sequestration in temperate deciduous forest; 2) 13 500 years of red-listed beetle diversity, and 3) the changing cultural values of European forests. Suggestions will be made for the future of forest ecosystem services.

SURVEILLANCE IN ZONOSSES AT ATLANTIC FOREST BOUNDARIES

Martha Brandão

FIOCRUZ

José Luis Passos CORDEIRO, FIOCRUZ; Daniela Dias Araújo ALBUQUERQUE, FIOCRUZ; Renato Orsini ORNELLAS, FIOCRUZ; Carlos José BARBOSA FILHO, FIOCRUZ; Sandro A. PEREIRA, FIOCRUZ; Fabiano Borges FIGUEIREDO, FIOCRUZ

The dynamics of pathogens in the environment is very complex depending of factors as host susceptibility, host-pathogens interactions, transmission's route, abiotic factors influence and many other variables that vary widely introducing further complexity. Reducing public health risks from zoonosis and other health threats at the human-animal-ecosystems interface is not straightforward. Management and reduction of these risks must consider the complexity of interactions among humans, animals, and the various environments they live in, requiring communication and collaboration among the sectors responsible for human health, animal health, and knowledge of the environment. Our study area is at Campus Fiocruz Mata Atlântica that is in an area with disturbed environment and loss of biodiversity, with humans' activity, domestic and wild animals interacting all together near the biggest Atlantic forest fragment at Rio de Janeiro/ Brazil. The Zoonosis Control Program was created to take actions for management of domestic, livestock and wild animals from the campus and its boundaries and also management and care of local people that lives in this area and frequents the Health Care Facility Unit. We visit houses of the communities periodically to collect and recollect samples from domestic animals and livestock. These are the same houses registered in the Family Health Program from Unified Health System in Brazil. Bats, sloths, small rodents and snakes are used as wild animals sentinels once they are the most common species that usually appear around houses in conflict with humans. After two years of surveillance from domestic and wild animals, we do have results for Leishmaniasis, Trypanosomiasis, Esporotricosis, Leptospirosis, Toxoplasmosis, Rabies, Helminths, oral and rectum bacterial fauna in some of those animals. Human cases of Leishmaniasis and Esporotricosis were diagnosed as well.

CONSERVATION GENETICS OF THE WESTERN DERBY ELAND IN SENEGAL: INTEGRATION OF PEDIGREE AND MICROSATELLITE DATA

Karolina Brandlova

Faculty of Tropical AgriSciences, Czech University of Life Sciences Prague

Barbora CERNA BOLFIKOVA, Faculty of Tropical AgriSciences, Czech University of Life Sciences Prague; Pavla HEJCMANOVA, Faculty of Tropical AgriSciences, Czech University of Life

Sciences Prague ; Pavel HULVA, Faculty of Science, Charles University Prague

Less than 200 wild individuals of the critically endangered Western Derby eland (*Taurotragus derbianus derbianus*) live in Senegal. A breeding programme was established in 2000 with six founding individuals (one male, five females) in a fenced reserve. In 2015, the population consists of about 90 individuals living in seven separate herds in the two reserves of Bandia and Fathala in Senegal. Because of the low number of founding individuals in the breeding programme and the resulting high kinship, we compared the results from genealogical and genetic approaches to assess the level of genetic diversity. We used the data from three generations. In F1, the founder contribution was highly biased towards the only founding male, which sired all the offspring. In F2, the founder contributions were more balanced, as the male descendants of founding females entered the reproduction. This resulted in higher gene diversity and lower inbreeding (based on pedigree data) in F2 than in F1. Results of molecular analysis using microsatellite loci confirmed the highest level of heterozygosity and lowest level of inbreeding in the founder generation; however, the implementation of a management strategy was not reflected in the empirical results. The results differed for F2, where empirical values of heterozygosity continued to decrease and inbreeding continued to increase. The allelic richness corresponded with the results of pedigree analyses, reflecting the more equalized founder contributions. We concluded that the overall results for genetic parameters were comparable with other breeding programmes for endangered ungulates. Our suggestions correspond with the Western Derby Eland Conservation Strategy and confirm the need to introduce new founders into the semi-captive population, in order to minimize the risk of inbreeding depression and improve its genetic diversity and suitability for potential reintroduction. The study was supported by CIGA 20135010 and 20134311.

A VIRTUAL SPACE TO JOIN WILDLIFE AND HUMAN HEALTH

Rita Braune Guedes

Fiocruz

Marcia CHAME, Fiocruz

The Center for Information on Wildlife Health (CISS) of Oswaldo Cruz Foundation (Fiocruz) is a virtual space (www.biodiversidade.ciss.fiocruz.br) driven to consolidate in a participatory way, wildlife and human health knowledge, good practices, actions and policies that together can strengthen the conservation of Brazilian biodiversity with quality of life. One of the Center's communication strategies is to be an open space, which stimulates collaborators to publish articles, congresses, events and news on wildlife and human health subjects. The Center integrates two participatory networks:

Wildlife Health and Wildlife Health Laboratory Network that strongly contribute to the site content. In addition, a bimonthly newsletter is sent to a mailing list that includes specialists, students, stakeholders and interested people. Along eleven months, since the Center was established in March of 2014, the website has increased its visitor number totalizing almost 3.000 users from 39 different countries around Latin America, Europe, Asia and Africa. The peak of access until now reflects scientific agenda and the results of the workshops promoted by the Center. Around the total visitors, 47.3% are returning visitors. In addition, the Center strategies to increase and fidelize the users are (i) associate a scientific publication to an easy language article in order to reach different citizens profiles, (ii) publish the Center content on the open media and (iii) host the website at the Fiocruz Portal, a centenary public health institution in Brazil.

MOUNTAIN FOREST BIODIVERSITY UNDER CLIMATE CHANGE: COMPENSATING NEGATIVE EFFECTS BY INCREASING STRUCTURAL RICHNESS

Veronika Braunisch

Institute of Ecology and Evolution, University of Bern

Joy COPPES, Forest Research Institute of Baden-Württemberg

; Rudi SUCHANT, Forest Research Institute of Baden-

Württemberg ; Florian ZELLWEGER, Swiss Federal Institute

for Forest, Snow and Landscape Research WSL ; Raphael

ARLETTAZ, Institute of Ecology and Evolution, University of Bern

; Kurt BOLLMANN, Swiss Federal Institute for Forest, Snow and Landscape Research WSL

Species in mountain environments are expected to face a high risk of range contractions, if not local extinctions under climate change. Yet, many endothermic species are not primarily affected by physiological constraints, but indirectly by climate-induced changes of habitat quality. In mountain forests, where vertebrate species largely depend on vegetation composition and structure, deteriorating habitat suitability may thus be mitigated or even compensated by habitat management. We tested this possibility using four mountain bird species of conservation concern, capercaillie (*Tetrao urogallus*), hazel grouse (*Bonasa bonasia*), pygmy owl (*Glaucidium passerinum*) and three-toed woodpecker (*Picoides tridactylus*), which are considered as indicators for complementary forest structural parameters. Based on species data and environmental information collected at 300 1km²-plots distributed across three mountain ranges in Switzerland and southwestern Germany, we investigated (1) how species' occurrence was explained by climate, landscape, and vegetation, (2) to what extent climate change and climate-induced vegetation changes will affect habitat suitability, and (3) whether these changes could be compensated by adaptive habitat management. Species presence was modelled under current

climate and extrapolated to the conditions of 2050, assuming the moderate IPCC-scenario A1B. Climate variables contributed significantly to explaining species occurrence and expected climatic changes, as well as climate-induced vegetation trends, decreased the occurrence probability of all four species, particularly at the low-altitudinal margins of their distribution. These effects could be partly compensated by modifying single vegetation factors, but full compensation would only be achieved if several factors were changed in concert. The results illustrate the possibilities and limitations of adaptive species conservation management under climate change.

4.12 COMPILING RED LISTS: COULD SDM'S CONTRIBUTE TO BETTER ASSESSMENTS?

Frank Breiner

Swiss Federal Research Institute WSL

Antoine GUIBAN, University of Lausanne ; Michael NOBIS, Swiss Federal Research Institute WSL ; Ariel BERGAMINI, Swiss Federal Research Institute WSL

Red Lists are the most important source of information about the threat and conservation status of single species and biodiversity. Two main criteria of Red List assessments are the absolute geographic range size and its relative change in time. According to IUCN both criteria could be measured by either the extent of occurrence (EOO) or the area of occupancy (AOO). While EOO and AOO include only spatial information, Species Distribution Models (SDMs) also include ecological information to measure range size. In addition, multivariate ordination of the inhabited environment can be used to quantify the realized ecological niche without a direct reference to range size. Here, we test if SDMs and niche size measured via ordination provide additional information on rates of change compared to the standard geographic IUCN scores (EOO, AOO, and α -hulls). We therefore simulated randomly as well as spatially and ecologically directed local extinction events of varying magnitudes (10, 30 and 50%) and tested how accurate the different methods detect these extinctions using occurrence data of 148 vascular plant species in Switzerland. We show that SDMs are not suited to quantify rates of change in contrast to current IUCN scores and niche quantification via ordination. Although SDMs and also niche quantification cannot substitute or "improve" standard IUCN scores, they provide additional information which is helpful to better assess the threat of a species.

FROM BEHAVIORAL ECOLOGY TO CONSERVATION: INVESTIGATING INDIVIDUAL BEHAVIORAL TRAITS AND SOCIAL INTERACTIONS OF PROVISIONED LEMON SHARKS (NEGAPRION ACUTIDENS) AS A TOOL FOR MANAGING SHARK-FEEDING ACTIVITIES

Pierpaolo Brena

USR3278

Johann MOURIER, USR3278 ; Eric CLUA, French Ministry of Agriculture and Fisheries ; Serge PLANES, USR3278

Non-consumptive wildlife tourism is presented as a modern tool for conservation, by providing economic incentives for conserving biodiversity and contributing to enhanced public awareness. In order to ensure the economic viability of the wildlife-watching industry, appetitive stimuli are commonly used to prompt artificial aggregations of emblematic species. In particular, increasingly popular « shark-feeding » operations are being conducted worldwide, albeit with sketchy information on their effects on the targeted species. Deleterious effects on individual fitness have been described in fed terrestrial species, along with behavioural alterations including increased aggression to conspecifics and humans. Such behavioural aspects have not yet been studied among fed sharks, although (1) increased competition between individuals can incur physiological costs and (2) preventing shark bites on humans remains fundamental to promoting shark conservation. Drawing on theoretical behavioural ecology, we investigate individual behavioural traits and social interactions in a group of regularly fed lemon sharks off Moorea, French Polynesia. We use underwater video recording to describe context-dependent social behavior through agonistic interactions towards conspecifics and divers, along with passive acoustic telemetry to monitor individual spatial use. We believe our findings will allow a better understanding of the individual and social behavior of lemon sharks, and inform management plans to ensure the sustainability of shark-feeding activities and their effective contribution to conservation.

194 DEFINING HUMAN WELLBEING FOR CONSERVATION: A SOCIAL SCIENCE FRAMEWORK

Sara Breslow

NOAA Northwest Fisheries Science Center

University of British Columbia ; Brit SOJKA, University of Washington ; Kevin ST. MARTIN, Rutgers University

The wellness of people and nature are interdependent, and thus the notion of human wellbeing has taken root in conservation science. But what exactly is human wellbeing, how is it coupled with environmental change, and how might it be conceptualized for ecosystem assessments? Ecologists and economists have popularized an ecosystem services approach to human wellbeing, and development scholars are measuring subjective wellbeing as an alternative to GDP. Yet neither approach captures the complexities of the human-environment relationship that environmental social scientists have long studied. This paper reports on our effort to define and operationalize human wellbeing for ecosystem-based management. Drawing from the social science literature and an analysis of environmental management priorities, we introduce a conceptual typology of human wellbeing that can be tailored for a range of conservation contexts. Our framework moves beyond the prevailing focus on conditions to include additional dimensions of wellbeing: capabilities and connections, as well as cross-cutting domains, such as equity and justice, certainty and resilience, and the wellbeing of future generations. We illustrate how this general framework can be used to identify focal domains and indicators of wellbeing that serve specific stakeholder, management, and decision-making needs. Ultimately, our goal is to provide a tool to better link conservation strategies to interrelated improvements in human wellbeing.

MOVE IT OR LOSE IT: A SYSTEMATIC REVIEW OF THE MOTIVATIONS, SPECIES, REGIONS, AND OUTCOMES OF NORTH AMERICAN CONSERVATION TRANSLOCATIONS

Typhenn Brichieri-Colombi

Calgary Zoological Society

Axel MOEHRENSCHLAGER, Calgary Zoological Society

A conservation translocation is the intentional release of organisms for the purpose of measurably improving the conservation outlook at the population, species or ecosystem level. We undertook the first systematic review of faunal conservation translocations in North America, a global hotspot for this conservation tool, by reviewing over 2000 articles from 1974-2013. Additionally, we surveyed 230 related authors to understand what motivated their translocations and how they were evaluated. We identified 736 conservation translocation projects on 298 different species and found that translocations were widespread and increasing for all taxa, their frequency was correlated with the number of species at risk per state/province, and reintroductions and reinforcements were more prominent in the US and Canada than in the Caribbean, Mexico, or central America. Moreover, translocated species had a higher

threat status regionally (state/provincial level) than globally (IUCN Red List categorization), suggesting that translocations were motivated by regional priorities rather than global risk. Survey participants identified the reduction of extinction risk at a national, state or provincial level as their main motivation for translocating study species, and most translocation projects were requested, supported and/or funded by government agencies. Thus, we identify an opportunity to explore how local conservation concerns for individual species may affect their global conservation status in the long-term. Translocation projects were generally reported as 'successful,' measured mainly by survival and reproduction of translocated species, population establishment, or an increase in population size. Barriers to success included biological and non-biological factors. We recognize a need to clearly identify the rationale and motivations for conservation translocations and link them with measurable outcomes to aid and ultimately maximize the benefits of translocation projects.

LACK OF PEATLAND SPECIALISTS OF MULTIPLE INDICATOR GROUPS INFORMS FUTURE CONSERVATION PLANNING IN THE WESTERN BALKANS PEATBOGS

Andreja Brigic

Department of Biology, Faculty of Science, University of Zagreb

Jelena BUJAN, Department of Biology, University of Oklahoma ; Antun ALEGRO, Department of Biology, Faculty of Science, University of Zagreb ; Vedran SEGOTA, Department of Biology, Faculty of Science, University of Zagreb ; Mladen KEROVEC, Department of Biology, Faculty of Science, University of Zagreb

Peatbogs are small in size, highly fragmented and unique habitats in the Western Balkans. They are critically endangered due to drainage and especially to the progressive vegetation succession. Ground beetles (Coleoptera, Carabidae) and ants (Hymenoptera, Formicidae), as suitable indicators, were studied by pitfall traps in the isolated Đon mocvar peatbog (Blatuša, central Croatia). The Đon mocvar peatbog is the oldest (preboreal origin) and one of the largest peatbogs in Croatia. The study was carried out at the peatbog centre and at the edges of the peatbog during one growing season. In total, 818 ground beetles representing 37 species, and 11 550 ants representing 25 species were collected, respectively. Species richness and activity density of both taxa were higher at the peatbog edges than in its centre. True tyrphobiotic species (peatland specialist) of both taxa were not found. Tyrphophilous species of ground beetles, such as *Pterostichus rhaeticus* and *P. diligens*, were rare and mostly occurred at the peatbog edges, while tyrphophilous ant species, such as *Myrmica scabrinodis*, was abundant and occurred at the peatbog centre. Most of the species from both taxa were

primarily hygrophilous without a clear preference for peatbogs and most likely colonise the peatbog from surrounding colline belt oak forests. The lack of true tyrphobiontic species in both insect taxa could be explained by the biogeographical dispersal limitations in the Western Balkans and Southern Europe and the significant reduction of suitable habitats for colonisation. We suggest that an evidence-based conservation planning may halt the abandonment of these unique habitats, and ground beetles and ants as indicator taxa can assist in monitoring the effectiveness of those efforts.

DEVELOPING PHYSIOLOGY-DRIVEN POPULATION DYNAMICS MODELS TO ASSESS CLIMATE CHANGE IMPACTS ON KOALAS, EVALUATE KOALA CONSERVATION ACTIONS AND PRIORITIZE THE PROTECTION OF POPULATION REFUGES

Natalie Briscoe

University of Melbourne

Michael KEARNEY, University of Melbourne ; Warren PORTER, University of Wisconsin ; Brendan WINTLE, University of Melbourne

How climate change impacts on species persistence will depend on physiology, landscape, population and dispersal dynamics, and existing stressors such as habitat loss. To generate robust predictions that can form the basis for conservation actions we therefore need an approach that integrates physiological constraints on survival and reproduction with other demographic processes and threats. We outline a modelling framework that addresses this gap by integrating biophysical models with population dynamics models – and demonstrate its application using the koala (*Phascolarctos cinereus*) as a case study. Biophysical models calculate the survival, energy and water requirements of an animal based on daily weather, individual traits and local habitat features. Where data are available on energy and water availability, this approach can be used to capture how climate change will influence vital rates. Biophysical model output can then be integrated with a stage-specific population dynamics model to predict how climate change will interact with other demographic processes and threats to impact population persistence. Our innovative approach overcomes the widely-recognized short-comings of current static, correlative approaches to predicting the impacts of climate change and provides insight into the synergistic effects of multiple threatening processes. It can be used to identify key refugia for populations and to evaluate different management actions. The koala case study also illustrates the benefits of using process-based models that provide insight into the mechanisms through which climate change will influence species persistence: the impact of climate change on koalas is heavily dependent on water content of food (leaves), which

differs between tree species. Selective planting of particular tree species could therefore be a useful management option, and the modelling framework we describe can be used to identify where and when such actions would be most effective.

NOTICING THE ELEPHANT IN THE FOREST: COMBINING OCCUPANCY ANALYSIS WITH SOCIAL SURVEY FOR RAPID ASSESSMENT OF FOREST ELEPHANT STATUS

Stephanie Brittain

Imperial College London

Information on the distribution and abundance of elephants must be available in order to appropriately allocate limited resources and to set conservation goals. However, monitoring over large spatiotemporal scales in forest habitats remains a serious challenge. At the root of this challenge lies tension between monitoring methods that prioritise accuracy, and those that rather emphasise long-term practicality. This trade-off between effectiveness and cost is a pervasive and unresolved problem in biodiversity monitoring. Transect surveys of dung density are the most widely used method for determining the distribution and abundance of forest elephants. This is arduous and as such has only been used in parts of the species' range. Interviewing people who live and work in the forest on the presence of elephants is a potential way of rapidly assessing distribution, collecting information over areas and timescales that cannot be tackled using conventional surveys. In practice, uncertain detectability makes this unreliable, but occupancy analysis allows uncertainty to be controlled for. This rapid survey assessed distribution and trends in forest elephant (*Loxodonta cyclotis*) populations over six years across 30,000 km² of east Cameroon, a survey that may have taken years using transects. This study finds that this method is a reliable and suitable method for a rapid assessment of forest elephant occupancy across a large scale, as a compliment or first stage in a monitoring process.

KEY ROLE FOR NUCLEAR ENERGY IN GLOBAL BIODIVERSITY CONSERVATION

Barry Brook

University of Tasmania

Corey BRADSHAW, The University of Adelaide

We recently published a well-publicised but controversial paper in SCB's flagship journal 'Conservation Biology' in which we argued that environmental scientists need to engage with energy issues more rigorously, and also consider supporting nuclear power to avoid future fossil-fuel dependency and worsening climate change. This call was supported by an 'Open Letter to Environmentalists' that was co-signed by 75 leading conservation biologists and ecologists. In this talk I will

outline the case we made in the paper for a role for nuclear energy (and the broader need for robust energy systems analysis) in biodiversity conservation, and then describe some of the reaction to, engagement with, and criticism of, our proposals, from the broader community and media. In the paper we evaluated the land use, emissions, climate, and cost implications of three published but divergent storylines for future energy production, none of which was optimal for all environmental and economic indicators. Using multi-criteria decision-making analysis, we ranked seven major electricity-generation sources (coal, gas, nuclear, biomass, hydro, wind, and solar) based on costs and benefits and tested the sensitivity of the rankings to biases stemming from contrasting philosophical ideals. Irrespective of weightings, nuclear and wind energy were shown to yield the highest benefit-to-cost ratios. We argued that although the environmental movement has historically rejected the nuclear energy option, new-generation reactor technologies that fully recycle waste and incorporate passive safety systems might resolve their concerns and ought to be more widely understood. Because there is no perfect energy source however, conservation professionals ultimately need to take an evidence-based approach to consider carefully the integrated effects of energy mixes on biodiversity conservation. Trade-offs and compromises are inevitable and require advocating energy mixes that minimize net environmental damage.

TAKING AN INTEGRATED APPROACH TO MINIMIZING HUMAN-WILDLIFE CONFLICT USING A RAPID ASSESSMENT TOOL THAT IDENTIFIES CRITICAL GAPS IN INTERVENTIONS

Ashley Brooks

WWF - Tigers Alive Initiative
Nilanga Jayasinghe, WWF

Conflicts between people and wildlife are occurring with increasing frequency. Human-wildlife conflict (HWC) is complex in nature and involves a diverse array of stakeholders, including the wildlife themselves. Because all elements of HWC management (prevention, mitigation, policy, research/understanding of conflict, response and monitoring) are inextricably linked, management actions should also be integrated. In order to identify the best combination of interventions that can ultimately minimize HWC, WWF has developed a rapid assessment tool that takes an integrated approach to HWC. The tool can be applied anywhere in the world across species to identify the key elements missing in HWC management approaches. The tool will provide practitioners working on HWC with the opportunity to identify critical gaps and the improvements they must make in order to minimize conflict and enhance management actions. This two-part presentation will a) focus on the need for an integrated approach to address HWC and provide an introduction to

the rapid assessment tool, and b) demonstrate results from applying the tool at four sites where WWF is active – two pilot sites address human-tiger conflict, and the other two focus on human-elephant conflict. Results from this assessment will be illustrated further with patterns that have emerged from a wider species-based capacity mapping exercise conducted across WWF's tiger and Asian elephant landscapes.

130-QUANTIFYING THREATS TO GLOBAL BIODIVERSITY THROUGH EXTINCTION RISK ASSESSMENT

Thomas Brooks

IUCN

Stuart BUTCHART, BirdLife International ; Craig HILTON-TAYLOR, IUCN ; Michael HOFFMANN, IUCN Species Survival Commission

The IUCN Red List Categories and Criteria provide a standard system for measurement of species extinction risk. They have been applied to 76,199 species, with the resulting assessments published on The IUCN Red List of Threatened Species. Moreover, repeat assessments have been conducted for all mammals and amphibians (twice) and birds (six times), allowing derivation of Red List Indices of the aggregate rates at which species groups are sliding towards extinction. Over the last decade, standard classification schemes for recording threats and stresses have been developed, along with coding of timing, scope, and severity. These are now required or recommended elements of assessments for The IUCN Red List. The application of these classification schemes opens important new avenues for quantification of human pressures on biodiversity. These include: a) spatial distribution of the number of threatened species facing given threats; b) spatial distribution of the proportion of threatened species facing given threats; and c) spatial distribution of threats that have driven species into higher categories of extinction risk owing to genuine increases in extinction risk. This information is a key input into attempts to model scenarios for biodiversity, and such work is already underway to explore future threats to biodiversity from ecosystem conversion and climate change. The development of methods to model future threats to biodiversity from invasive species, disease, and unsustainable harvest are priority research fronts.

A NEW OPEN-SOURCE SOFTWARE TOOL FOR MORE EFFECTIVE CONSERVATION PLANNING

Jana Brotankova

James Cook University

Bob PRESSEY, James Cook University ; Amelia WENGER, James Cook University ; Ian CRAIGE, James Cook University

We describe the main features of a new, interactive software tool for conservation planning, with initial applications to management of tropical islands in Australia. Island

conservation management is a truly multidisciplinary problem that requires considerable knowledge of ecosystems characteristics, species, and their interactions. Our study sites in the southern Great Barrier Reef (Queensland) and off the Pilbara coast (Western Australia) are characterised by globally- and nationally-significant conservation values and persistent threats to those values, mainly in the form of invasive plants and animals. Management staff and funds are not sufficient to eliminate all threats on all islands. With a limited budget, managers need to select conservation actions according to expected payoffs (in terms of protecting or restoring desired species) versus cost (the amount of resources/money) required for the actions. We wanted to approach real-world complexity in decision-making while building new capabilities that current software systems lack. The new capabilities include: the ability to allocate multiple actions to single areas; temporal explicitness in responses of native species to threats and threats to conservation actions; and dynamic updating of threats, costs and the effectiveness of actions. We describe a working prototype of a new decision-support system, tailored to meet the needs of pest control on islands for conservation managers. The software includes i) a model of the ecosystem and the impact of conservation actions, and ii) a solver selecting the best solutions, and interactivity and flexible around the needs and expertise of the managers.

CHANGES OF THE GRASS AND WOODY COMPONENT ON THE PLATEAU AREAS OF MOUNTAIN ZEBRA NATIONAL PARK: 1980 - 2015.

Leslie Brown

University of South Africa

Hugo BEZUIDENHOUT, South African National Parks ; Peter NOVELLIE, South African National Parks ; Alan BARRETT, University of South Africa

The vegetation of permanently marked plots distributed within plateau grassland of the Mountain Zebra National Park was monitored by means of point surveys for canopy spread cover over a 26 year period spanning from 1989 to 2015. Datasets were collected over five periods (1989, 1993, 2001, 2011, 2015). The observed changes between 1989 and 2001 conformed to some extent to the succession model that forms the basis of veld condition assessment for the Nama-karoo Biome. Annual grasses were abundant after the drought season in the 1980's and decreased with an increase in perennial grasses after a few years. The nature of the rainfall-induced changes differed between different communities with the perennial decreaser grasses in one area never becoming dominant. It seemed that rainfall influenced the vegetation and that grass species react the quickest to rainfall. Total cover for both grass and dwarf shrub species declined in dry years and increased in wet years. The monitoring of these areas was repeated in 2011 and 2015. Above average rainfall years preceded the monitoring.

The prominent and dominant grass and dwarf woody shrub species were analysed with the above hypothesis in mind. It was expected that the perennial decreaser grasses would have increased with the above average rainfall. The new data that was collected did not conform to the previous hypothesis. It seems as though certain grasses change their ecological status during dry and wet periods and that the system may have shifted to a more grassy structure due to overall good rains.

SYMPOSIUM ID 123. CONSERVATION STRATEGIES FOR FOREST MANAGEMENT IN RELATION TO DIFFERING ECOSYSTEM SERVICES SHAPED BY LEGACIES OF PAST LAND-USE.

Guntis Brumelis

University of Latvia

Humans have had tremendous impact on the World's ecosystems and understanding of their historical interactions with nature is required to determine options for management. There is a range of provisioning, regulating, habitat and cultural ecosystem services associated with each ecosystem. Novel ecosystems differing in composition and function from historical ecosystems have developed, which offer important ecosystem goods and services. In view of this, and the impact of climate change, the objective of maintaining naturalness might not even be suitable in some conservation areas. In natural to novel ecosystems, biodiversity has a profound positive effect on the functioning of ecosystems, providing a wealth of ecosystem services for human well-being. Developing spatial planning tools for conservation needs to consider functions of biodiversity in providing ecosystem services, which will depend on regional gradients in human footprint legacies. We describe, for case landscapes in biogeographical regions of Europe, the main drivers of impact on forests and the resulting characteristics of forest landscape. Within these regions we then illustrate how quantitative targets to meet the goal of conservation and enhancement of biodiversity and associated ecosystem services will differ depending on the legacies of past land-use by humans. These range from high non-use existence value in poorly accessible pristine forest, to predominantly wood production and carbon assimilation and storage services in populated but still forested landscapes, to high recreation value in regions with predominantly agricultural land use. We argue that the current and past ecosystem services offered by forests need to be considered in developing biodiversity targets and management plans in a multiple land-use setting. This presentation is based on collaborative work of 30 coauthors and stems from a workshop arranged by the network PRIFOR.

ECOSPACE - A UNIFIED FRAMEWORK FOR UNDERSTANDING VARIATION IN BIODIVERSITY

Ane Kirstine Brunbjerg

Aarhus University

Hans Henrik BRUUN, University of Copenhagen ; Jesper Erenskjold MOESLUND, Aarhus University ; Jonathan SADLER, University of Birmingham ; Jens-Christian SVENNING, Aarhus University ; Rasmus EJRNÆS, Aarhus University

Understanding patterns in biodiversity is an ever-prevalent topic in ecology and a useful framework to gain this understanding is the prerequisite for effective management. Contrary to previous ecological theories, "ecospace" is a holistic concept not constrained to specific species or species groups. We define ecospace as the multidimensional space of conditions and opportunities in which biodiversity develops. Every biotope - regardless of habitat type, area and condition - can be described in terms of its ecospace and we claim that ecospace can serve as a tool for assessing variation in biodiversity and its causes. Our definition of ecospace comprises two levels: 1) Biotope level ecospace encompasses three components: position, expansion and continuity-all affecting biodiversity of a given area (α -diversity). We define position as placement along the classical abiotic gradients, such as temperature and pH, providing an environmental template for biodiversity through 'filtering' processes. Expansion represents organic resources that are not given by position, e.g. the build-up and diversification of live and dead organic matter in the ecosystem. Continuity is defined as the spatiotemporal extension of position and expansion. 2) Landscape level metaspace is an extension of biotope ecospace and comprises variation. Variation is the spatial turnover of biotope ecospace. In general, every position is linked to a set of species from the regional species pool and the larger the expansion of an area the more habitats are available for biodiversity. At larger geographical scales biodiversity also depends on variation in positions and expansion levels. This way, even species poor biotopes with extreme positions (e.g. bogs, foredunes) can contribute to the overall biodiversity. If the concept successfully links physical and environmental factors and biodiversity the model can be used as a flexible and cost-effective predictive indicator for management and conservation.

171-LESSONS LEARNED IN THE FIRST FIVE YEARS: CONSERVATION LEADERSHIP THROUGH LEARNING

Brett Bruyere

Colorado State University

After five years and four iterations of the Conservation Leadership through Learning (CLTL) master's program at Colorado State University in the United States, lessons learned

and best practices emerged to help inform the future direction of the program. CLTL is an applied program focused on training practitioners, though the tradition of graduate work in the department is rooted strongly in research. After five years and four iterations of the Conservation Leadership through Learning (CLTL) master's program at Colorado State University in the United States, lessons learned and best practices have emerged to help inform the future direction of the program. CLTL is guided by values of applied and project-based learning, though the tradition of graduate work is rooted more strongly in research. While this combination provides an opportunity to bridge practice with research, it also presents unique challenges of functioning within a larger university context and culture that is conventional in its instructional delivery. In addition, the term "conservation leadership" is a term lacking a shared understanding about its definition and scope. It can encompass a wide spectrum of skills and knowledge, and therefore, the curriculum for a program in "conservation leadership" can be difficult to settle. In this presentation, best practices and lessons learned related to how these issues have been addressed and navigated within CLTL will be presented, including evaluation results from prior CLTL students and feedback from conservation practitioners about the scope of skills and content in the program.

PATHWAYS TO EVIDENCE BASED POLICY AND PRACTICE IN THE SCOTTISH UPLANDS

Rosalind Bryce

University of the Highlands & Islands

Mark REED, Birmingham City University ; Steve REDPATH, University of Aberdeen ; Xavier LAMBIN, University of Aberdeen

Although evidence-based conservation is widely advocated, evidence from research represents just one of many lines of argument that compete to inform complex decisions in policy and practice. In reality, evidence is often distorted as it is passed from person to person through social networks, and is sometimes misappropriated to achieve the goals of special interest groups. Robust evidence may be overlooked by decision-makers who do not always have the time or expertise to critically interrogate its theoretical, methodological or empirical basis. Instead it is often easier to trust evidence on basis of the trustworthiness of its source, whether that be the quality of the journal it is published in or the credentials of the person who communicates it. As research funders increasingly emphasise the need for research to deliver societal and/or economic benefits, there is growing interest in tracing the pathways through which research influences decisions in policy and practice. However, few studies have focused on the perceptions of those responsible for using this evidence in policy or practice, or analysed the pathways through which this evidence reaches (or is transformed or blocked by) these actors. We addressed these aspects in a case study of the Scottish

uplands. In this presentation, we show, using social network analyses (SNA), the pathways by which evidence is exchanged between stakeholders in upland management. This illustrates the dominance of NGOs in the production and propagation of information received by land managers and policy makers. We discuss the characteristics of research findings that make them more likely to be picked up by stakeholders and the information sources that different stakeholder groups most frequently use. Finally we give the results of a qualitative analysis of stakeholder perceptions of the barriers to the use of research evidence in upland policy and practice and potential ways of overcoming these.

GENETIC VARIATION AT MHC AND TOLL-LIKE RECEPTOR GENES AND THEIR RELATIONSHIP TO DISEASE IN ENDANGERED RED WOLVES AND SYMPATRIC COYOTES

Kristin Brzeski

Louisiana State University

Michael CHAMBERLAIN, University Georgia ; Sabrina TAYLOR, Louisiana State University

Infectious diseases pose a significant threat to global biodiversity and may contribute to extinction events. Endangered populations are particularly susceptible to disease-mediated population declines because they are small and often inbred, lacking the genetic variability necessary to combat pathogens. As such, identifying factors that influence disease susceptibility, such as associations between immunogenetic variation and parasite prevalence, can help predict risk for endangered species. In this study we evaluated if immunogenetic variation or inbreeding influenced disease susceptibility in endangered red wolves (*Canis rufus*) and sympatric coyotes (*Canis latrans*). We assessed both innate (Toll-like receptors (TLR)) and adaptive (major histocompatibility complex (MHC)) immune gene variation, collected immunocompetence data, calculated pedigree inbreeding coefficients, and estimated parasite load to assess: (1) immunogenetic variation, (2) associations between heterozygosity, specific alleles, and haplotypes, and immunocompetence and parasite measures, and (3) how inbreeding influences disease susceptibility. We sequenced 4 TLR genes and 3 MHC genes, and collected immunological and parasite data from 71 canids. Coyotes had higher TLR and MHC variation than red wolves; however we detected coyote introgression which increased red wolf immunogenetic variation over time. Red wolves and coyotes had similar pathogen communities but coyotes had higher parasite diversity. Preliminary results suggest no significant associations between immune gene variation and disease, but further sequence analysis may reveal a stronger relationship. Additionally, red wolves are extremely inbred and may be more susceptible to pathogens compared to the outbred coyote

population. Our study has significant conservation value for endangered red wolves and provides novel results on the implications of reduced innate and adaptive immune gene variation in threatened populations.

COMPARING BIOGEOGRAPHIC PATTERNS OF BUTTERFLIES, ORTHOPTERANS AND VASCULAR PLANTS IN THE SWISS WESTERN PREALPS

Valeria Bucher

University of Lausanne

Manuela D'AMEN, University of Lausanne ; Jean-Nicolas PRADERVAND, University of Lausanne ; Antoine GUISSAN, University of Lausanne

Spatial modeling of community properties is a key tool for better understanding the biogeographic patterns of biodiversity components and their relation with environmental factors. Species richness is the most studied community property but little work has yet been devoted to analyze its different aspects. A particularly interesting question for modeling purposes is the effect of the rare species component on the modeling outcome. In this study, using datasets and species richness models for butterflies, orthopterans and plants in the Swiss western Prealps, we aimed at assessing (i) the influence of the "common/rare" species ratio on the model predictions for each group, (ii) the degree of similarity among the predicted biogeographic patterns of the three groups and (iii) the congruence between their potential diversity hotspots. Three richness models were built per taxon, fitted either on (i) the whole dataset (all species), (ii) the pool of common species (> 30 occurrences), or (iii) the complementary pool of rare species. For each model, we assessed its performance and the predicted richness pattern across the study area, and then identified the emerging diversity hotspots. Our results showed that performance is greater for models fitted on common species for butterflies and plants, but on all species in the case of orthopterans. For all groups, models fitted on all species predicted highest richness at mid-elevation, mostly in slopes facing south. Accordingly, predicted patterns of richness along elevation showed a clear hump-shaped curve for the three taxonomic groups when considering all or common species. Finally, diversity hotspots covered extensive areas for all groups, but overlap of hotspots for the three groups were scarce. In conclusion, richness predictions diverge whether accounting or not for rare species, with usually better model performance observed when these are excluded, likely because they are often more difficult to predict.

141 RESEARCH-LED EVOLUTION OF UK AGRICULTURE ENVIRONMENT SCHEMES TO ADDRESS FARMLAND BIRD DECLINES

David Buckingham

Royal Society for the Protection of Birds

Tony MORRIS, Royal Society for the Protection of Birds

Agri-environment schemes (AES) are the most important large-scale land management tools being used to reverse population declines in widespread farmland bird species. The design of early AES management options was based on autecological studies of declining species. Ongoing bird declines and pressure on governmental spending have necessitated further research to make AES options more effective and affordable and to develop novel solutions to problems that AES were not addressing. In this talk we will review the role of ecological research in the development of British AES options. We will include examples of approaches used in arable farming regions, where knowledge of farmland bird ecology and the development of conservation measures are most advanced. The arable situation will be contrasted with that in livestock-rearing regions, dominated by grassland. In grassland regions, bird declines are qualitatively different, but investigation of the causes and development of solutions are at an earlier stage. In addition to exploring AES measure development, we will present results of large-scale monitoring of the value of AES to bird populations. Limited progress has been made on scaling up the effects of AES measures to estimate the impact of AES on national bird population trends. We will show how this makes it difficult to answer important, practical questions posed by politicians and AES administrators: such as how much land should be managed by AES and where this AES spending should be targeted.

PREVENT HISTORY REPEATING: IDENTIFYING CORAL REEF FISH DISAPPEARANCES TO PREDICT VULNERABILITY TO EXTINCTION

Sarah Buckley

University of Queensland

Tim MCCLANAHAN, Wildlife Conservation Society; Erendira QUINTANA MORALES, Museum National d'Histoire Naturelle; Victor MWAKHA ALATI, Kenya Marine and Fisheries Research Institute; Jatiemo NYANAPAH, Wildlife Conservation Society; Levy OTWOMA, Kenya Marine and Fisheries Research Institute; John PANDOLFI, University of Queensland

Without an understanding of historical baselines, dramatic declines in population abundance and even extinctions can occur undetected. In particular, the historical exploitation and susceptibility of tropical marine species to extinction is rarely investigated. By comparing archaeological records (750- 1500AD) with contemporary catch (1995-2103) and underwater visual censuses (UVC) (1987-2013) from coastal Kenya, we revealed that 81% of the tropical marine fish species that were historically exploited are now absent. We established a list of 45 threatened coral reef fish species by conducting presence/absence tests using combinations of the catch data,

archaeological records, and UVC with the modern species list. We verified the historical decline and disappearance of threatened fish species using 288 interviews with fisher, divers and fish traders and corroborated with UVC (2013-2014). Identifying decline and local extinction of historically exploited species enabled us to predict the contemporary exploited species that exhibit similar vulnerability to extinction using fuzzy logic analysis. Knowledge gained from this research will contribute to ongoing local conservation priorities by raising awareness amongst stakeholders of species at most risk to local extinction. The results are also relevant for species-specific management and prioritization of species for conservation.

IMPORTANCE OF ETHIOPIAN SHADE COFFEE FARMS FOR FOREST BIRD CONSERVATION

Evan Buechley

University of Utah

Cagan H. SEKERCIOGLU, University of Utah; Anagaw Meshesha ATICKEM, Oslo University; Gelaye GEBREMICHAEL, Jimma University; James Kuria NDUNG'U, Front Trail Safaris; Bruktawit Abdu MAHAMUED, Manchester Metropolitan University; Tifases BEYENE, Arba Minch Crocodile Farm; Tariku MEKONNEN, Jimma University; Luc LENS, Ghent University

Coffee is the most important tropical commodity and is grown in high-priority areas for biological conservation. There is abundant literature on the conservation value of coffee farms internationally, but there has been little research on this topic in Africa. Ethiopia is a diverse and little-studied country with high levels of avian endemism, pressing conservation challenges, and where *Coffea arabica* originated. We sampled bird communities in shade coffee farms and moist evergreen Afromontane forest in Ethiopia utilizing standard mist netting procedures at seven sites over three years to evaluate bird species richness, diversity and community structure. Although species diversity did not differ between shade coffee and forest, shade coffee farms had over double the species richness of forest sites and all but one of the nine Palearctic migratory species were captured only in shade coffee. There was greater relative abundance of forest specialists and understory insectivores in forest, demonstrating that little-disturbed forest is critical for sustaining these at-risk bird groups. Nonetheless, all species recorded in primary forest control sites were also recorded in shade coffee, indicating that Ethiopian shade coffee is perhaps the most "bird-friendly" coffee in the world. This is an important finding for efforts to conserve forest birds in Africa, and for shade coffee farmers that may benefit from avian pest regulation and biodiversity-friendly coffee certifications. Biological Conservation Special Issue: Tropical Insectivores

CAUSES AND CONSEQUENCES OF AVIAN SCAVENGER DECLINES

Evan Buechley

University of Utah

Cagan SEKERCIOGLU, University of Utah

The consumption of carrion by vertebrate scavengers has been largely overlooked in ecological studies, in part due to human's aversion to decomposing matter. However, recent research has begun to illuminate its significant and valuable role in ecosystems. The world's 22 vulture species are the only obligate vertebrate scavengers and play a predominant role consuming carrion. Vulture populations have been declining at catastrophic rates in the last few decades and are currently regarded as the most threatened avian functional guild. This is due largely to anthropogenic toxins found in carrion, including the anti-inflammatory veterinary drug diclofenac, poisons used to deliberately kill mammalian carnivores, and lead from spent ammunition. Meanwhile, many facultative avian scavengers—including species of storks, gulls, starlings, ravens and crows—seem less affected by the factors causing vulture declines. In this paper we: (i) use a global database to identify all bird species for which scavenging is a major dietary component, (ii) compile data on the intrinsic ecological traits and extrinsic threats to these species, (iii) use random forest models to identify correlates with extinction risk, and (iv) discuss the implications of changes in abundances of avian scavengers. One hundred and fourteen avian scavenger species were identified from 16 families. Random forest models show that large mass, long generation length, diet specialization and reliance on carrion are strongly positively correlated with extinction risk. Two ecological traits, average mass and scavenger rank, account for a surprising 37% of the variance in extinction risk in avian scavengers. The most important extrinsic threats are dietary toxins, decreasing food availability, persecution, habitat destruction, and, for marine scavengers, fishery bycatch. Rapid declines in vulture populations are expected to have profound impacts on ecosystems and humans, including trophic cascades and disease outbreaks.

MOVEMENT ECOLOGY OF THE GLOBALLY ENDANGERED EGYPTIAN VULTURE NEOPHRON PERCNOPTERUS IN THE MIDDLE EAST AND NORTH AFRICA

Evan Buechley

University of Utah

Emrah COBAN, Kuzey Doga ; Lale AKTAY, Kuzey Doga ; Cagan SEKERCIOGLU, University of Utah

The Egyptian vulture *Neophron percnopterus* is globally endangered and declining throughout its range in Europe, South Asia, and Africa. There have been extensive efforts

to conserve Egyptian vultures in Europe, but very little is known about the ecology, status, or threats to the species in other regions of the world. We summarize data from the first satellite telemetry study on a breeding population of Egyptian vultures in the Middle East. In the past 3 years, we have tagged 13 individuals and fitted them with satellite transmitters in Turkey, Ethiopia and Djibouti. To date, we have collected over 300,000 GPS locations on these birds. This data has provided an unprecedented look at the movement ecology of the species in the Middle East and North Africa, revealing a previously undocumented migration route for the species over the Arabian Peninsula and crossing the Strait of Bab al Mandeb into Africa. To date, these birds have visited nineteen countries, migrated over 4,000 km to their wintering grounds, reached a maximum elevation of nearly 8,000 m, and traveled in excess of 50,000 km in a year. In this paper, we evaluate habitat use in both summer and winter ranges and highlight migratory strategies and routes. This information, coupled with surveys on the ground in Turkey and Ethiopia, has improved our understanding of how these birds use their environment; an important step in targeting conservation actions for this endangered species.

NEST SITE SELECTION AND RISK OF PREDATION IN THE GROUND-BREEDING WOODLARK (LULLULA ARBOREA)

Roman Bühler

University of Bern

Laura BOSCO, University of Bern ; Alain JACOT, University of Bern ; Raphaël ARLETTAZ, University of Bern

The woodlark is a ground-breeding bird, which is listed as a priority species in Switzerland. In Valais, a stronghold of this species, the birds breed in intensively managed vineyards and show a preference for parcels with ground vegetation when foraging and during territory establishment. As a ground-breeder, the species is highly vulnerable to nest predation by avian and mammal predators. The aims of our study were to investigate the effect of ground vegetation on the nest-site preference and to estimate the importance of ground vegetation on nest predation rate. Nest site selection of the woodlark was investigated by comparing woodlark nest sites to the surrounding habitat on two different spatial scales. Here we demonstrate that the woodlark shows a preference for patches of high and dense vegetation within "green" parcels and avoid parcels that have been treated with herbicides. In a follow-up experiment we conducted a study comparing the predation rate between these parcel types, i.e. among parcels with mineral appearance (<20% vegetated area) and green parcels (>40% vegetated area). Artificial nests equipped with one quail egg were distributed pairwise between two adjacent parcels that fulfilled the upper criteria and monitored by trail cameras during 10-12 days. Predation rate was significantly

higher in parcels with mineral appearance and was unrelated to the number of observed predators. These data suggest that conspicuousness of avian nests are decreased in parcels with ground vegetation and that the amount of vegetation can lower the predation risk on ground breeding birds - another piece of evidence for the importance of ground vegetation for a successful conservation of the endangered woodlark in Swiss vineyards.

124-VALUE VERSUS FACT: THE ROLE OF SCIENCE IN IMPLEMENTING THE MITIGATION HIERARCHY AND ACHIEVING 'NO NET LOSS' OF BIODIVERSITY

Joseph Bull

Imperial College London

Astrid VAN TEEFFELLEN, VU University ; Melissa TOLLEY, UNEP-WCMC

To successfully implement policies that seek to achieve 'no net loss' of biodiversity (NNL) or better, alongside economic development, policymakers and practitioners must rely upon a combination of value judgement (values) and scientific research (facts). Conservation biologists will be familiar with this combination. Here, we explore what role values and facts play in the effective delivery of NNL. We outline a general set of value judgements made in developing real-world NNL policy, using examples drawn from this symposium – e.g. whether to allow 'out-of-kind' biodiversity offsets, or permit development within protected areas. To illustrate where subjectivity ends and objectivity begins in implementing NNL policies and designing associated projects, we then give two detailed examples. The first relates to preliminary work undertaken by the UNEP-WCMC in developing an empirical basis for evaluating biodiversity offsets as a mechanism (i.e. asking whether they work, and if so, where and why). This involved mapping the location and type of all biodiversity offsets implemented in Sweden. Second, we describe an exploration of out-of-kind biodiversity offsetting in Victoria, Australia. This required simulation modeling and the implementation of a new policy interrogation framework. Our analysis shows where value judgements are made in allowing offsets to be flexible, and what the ecological outcomes of allowing flexibility might be. Overall, we suggest that important value judgements are made when developing NNL policies and implementing the mitigation hierarchy, but rarely made explicit. We illustrate various means by which conservation biology has contributed to a better understanding of NNL and more robust policymaking – and where it will continue to do so in the future.

SYMPOSIUM 64: USING OPEN INNOVATION FOR CONSERVATION

Paul Bunje

Conservation X Labs[INSTITUTE]XPRIZE Foundation

Global trends in technology and innovation are serving to disrupt industries and fields as diverse as global health and the nature of work. These advances have often led to increasing threats to ecosystems and species. But exponential changes our access to innovation and innovators, specifically through open innovation, also offer the opportunity to harness these changes in order to accelerate conservation efforts. The unprecedented acceleration and democratization of science, technology, and engineering, combined with exponential increase in global connectivity and data, gives us many new powerful tools to address global conservation challenges. Open innovation techniques provide a powerful new toolbox of ways to access the world's best minds and focus them on critical conservation needs. Key tools include prizes and challenges, crowdsourcing, crowdfunding, open analytics, hackathons, and open-source design. By assessing the ways in which tools work and how they can best be applied to different challenges, conservation professionals can rapidly expand both the universe of solutions and the ways in which technology and innovation can rapidly be deployed to counter the destruction of natural systems.

106-THE ROLE OF UNCERTAINTY AND CHANGE IN CONSERVATION CONFLICTS: A GAME THEORETICAL APPROACH

Nils Bunnefeld

University of Stirling

Symposium: NEW AVENUES FOR RESOLVING CONSERVATION CONFLICTS. Conflicts between biodiversity conservation and human livelihoods are increasing in scale and intensity and have been shown to be damaging for both biodiversity and human livelihoods. Research on ecosystem services has shown conclusively that biodiversity underpins ecosystem processes and services to ensure human livelihoods. However, this research fails to address the challenge that arises when stakeholders have competing views on how natural resources (e.g. agricultural crops, wildlife) should be managed. To demonstrate how conservation conflicts can be understood and solved, a game theoretical approach can be applied. For example, in a conflict between farmers interested in protecting their crop from a threatened species and a government agency tasked with providing a favourable conservation status for the species, the outcome of the conflict between these two stakeholders would consistently fall into a prisoner's dilemma situation, in which both gain a smaller benefit than when they both collaborate. Uncertainty in the pay-offs is not usually included in game theory but is common in natural resources and changes the pay-offs of the game. Uncertainty for example

from weather variability could impact both production from agriculture and the population abundance of the threatened species, events that would both reduce food production (crops) and the conservation pay-off (maintaining a viable population of the endangered species) according to some probability of these events happening. Here I show how uncertainty of this situation could shift the game players (farmer, wildlife authority) into a coordination game. Moving interactions between stakeholders with competing objectives from conflict to coordination and eventually collaboration will be a major step towards tackling uncertainty when making decisions in order to improve biodiversity conservation and people's livelihoods.

USING CAMERA TRAPS TO ASSESS POPULATION DENSITY OF TIGER PREY SPECIES

Jenifer Bunty

Clemson University

David TONKYN, Clemson University ; Dale MIQUELLE, Wildlife Conservation Society ; Olga ZAUMYSLOVA, Sikhote-Alin Biosphere Reserve

The conservation of tiger populations is tightly linked to the management and preservation of their prey populations. Prey populations are often elusive and threatened by habitat loss and poaching. We conducted a study to analyze the population density of tiger prey species in the Sikhote-Alin Biosphere Reserve (SABR). The aim of this project was to assess the value of using camera traps to estimate ungulate density. Camera trapping remains a controversial survey method for assessing populations when individuals are not easily identified. When assessing herd animals, the difficulty is compounded by variability in group size and the potential for individuals to be caught in multiple photographs. However, trapping rate (the number of photographs per unit time) has been established as source of information about population density. Rowcliffe et al. (2008) adapted a mechanistic model, which was originally used to describe rates of collision between gas molecules, in order to describe the rates of contact between study animals and camera traps. The adapted model is commonly referred to as the random encounter model (REM). While theoretically sound, this model remains underutilized and undeveloped for many applications. In order to test the utility of the REM on tiger prey species, we compared/contrasted the results with estimates derived from scat analysis. Scat analysis is a widely used and accepted method for studying ungulate population densities and dynamics. Our analysis suggests theoretical and practical adjustments that must be made to the REM when using it to analyze the population density of herd animals. New questions have also arisen which, once answered, will expand the already great potential of using the REM in conservation efforts and as a survey tool.

76-QUANTIFYING SUCCESS FOR BIRD CONSERVATION

Ian Burfield

BirdLife International

Stuart BUTCHART, BirdLife International

Birds are conspicuous, popular, well-known, and consequently are among the most frequent targets for conservation action. In this talk I will highlight three approaches to assessing the impact of such conservation interventions. 1) BirdLife led the development of the Red List Index (RLI) to track trends in the extinction risk of species using data from the IUCN Red List. Calculating the RLI involves determining which species have been downlisted to lower Red List categories owing to genuine improvement in their status. It is then relatively straightforward to identify which of these were driven by conservation action. 2) Conservation action more commonly leads to a species improving in status but insufficiently to qualify for downlisting, or action may avert further declines. We determined examples of the latter by identifying those species that would have gone extinct since 1994 in the absence of conservation action. 3) We also attempted to assess the magnitude of the former phenomenon for one particular type of conservation action: the protection of Important Bird and Biodiversity Areas. We found that among species for which IBAs have been identified, those with a greater proportion of such sites covered by protected areas experienced smaller increases in extinction risk over recent decades: the increase was half as large for species with >50% of the IBAs at which they occur completely covered by protected areas.

FRAGMENTATION, FIRE AND THE POSSUM: SPATIALLY EXPLICIT MODELLING IN NEW ZEALAND'S LARGEST RAMSAR WETLAND

Olivia Burge

University of Canterbury

Dave KELLY, University of Canterbury ; George PERRY, University of Auckland ; Janet WILMSHURST, Landcare Research

New Zealand has lost approximately 90% of its pre-human wetlands and 70% of its pre-human forest cover and legacies of human intervention disrupt natural regeneration even in protected areas. Awarua-Waituna is New Zealand's largest (20,000 ha) Ramsar-recognised wetland and has been subject to clearance, drainage and a heavily modified fire regime. Historically a forested wetland, Awarua-Waituna is considered to be in a stalled succession, with serotinous vegetation and altered abiotic parameters due to the legacy of disturbance. Benefits in favour of reforestation include ameliorating current and historic forest loss both within the site and region-wide, and decreasing the flammability of the wetland, facilitating a return to a more natural fire regime. We used the results of field experiments to parameterise a spatially explicit model of the

interactions between natural and anthropogenic fire regimes, cryptic herbivory, landscape flammability and the surrounding landscape matrix. We then used a combination of the field experiment results and spatially explicit modelling to assess the relative importance of constraints to forest regeneration within the wetland, and assist with management prioritisation. Field experiments revealed cryptic herbivory masquerading as abiotic constraints compounded by fragmentation effects on bird dispersal services. Overall, future wetland scenarios clustered on the key variables of herbivory/predation rates, anthropogenic fire rates and the size and spatial arrangement of seed source. We found herbivory and seed predation was a key parameter of forest regeneration failure within the wetland, affecting both the amount and spatial structure of forest remnants. Field experiments in the study system uncovered previously unappreciated constraints, complementing the ability of spatially explicit models to evaluate succession under multiple management scenarios.

METHODS FOR ELICITING AND COMBINING EXPERT OPINIONS ABOUT FACTS

Mark Burgman

University of Melbourne

Most decisions in conservation biology depend on subjective expert opinion, to some extent. Yet, the methods for acquiring and combining expert judgements are typically naive and untested, creating the potential for unacknowledged biases and inadvertent misunderstandings to cloud decision making. This presentation outlines the latest developments in methods for eliciting judgements from experts about quantities and the outcomes of future events. The performances of approaches are assessed against data and recommendations are presented that lead to generally robust and relatively accurate assessments. The presentation outlines where more work is urgently required.

THE CRANES OF SHANGRI-LA AND THEIR RESPONSE TO SEVENTEEN YEARS OF HABITAT CHANGE IN CHINA'S YUNNAN PROVINCE.

James Burnham

University of Wisconsin-Madison

Matthias BAUMANN, Humboldt University; Heqi WU, Kunming Institute of Zoology

Habitat loss is routinely cited as one of the biggest contributors to the current decline in the world's biodiversity. Wetland loss due to human activities, in particular, is frequently linked threatened or endangered species around the globe. Documented patterns of habitat loss and corresponding declines in biodiversity, however, are often over-simplified and frequently under-represent the nuanced relationships

that exist between human communities and flora and fauna within dynamic wetland ecosystems. Using an alpine wetland in China's northwestern Yunnan Province named Napahai as a case-study, we obtained wintering locations for a threatened waterbird, Black-necked Cranes, over two years with satellite telemetry devices. After creating a land-cover classification map of Napahai from a 2010 SPOT-4 image using a supervised classification method, we determined that wintering Black-necked Cranes used water, wetland vegetation and wetland bare classifications disproportionate to their availability. We then used these methods to classify five Landsat images from 1992-2009 and, using post-classification rules, clumped land-covers into habitat and non-habitat maps. With these maps, we quantified how land-cover and habitat at Napahai changed from 1992-1999 and linked these changes to Black-necked Crane surveys. Contrary to established patterns of human-driven loss of wetlands, our analyses at Napahai show a distinct pattern of habitat increase from 1992-1999, from the construction of water impoundment structures within the wetland. After an airport was built in 1999, impervious urban areas expanded rapidly through 2009. Land-cover patterns are reflected by an increase in cranes from the late 1980's through the late 1990's and then a rapid decline during the early 2000's. These results present a more complete picture of how landscapes change over time and indicate that not all human development equates directly to habitat loss for species of concern.

FORAGING BEHAVIOR OF THREE SYMPATRIC EQUID SPECIES IN THE MONGOLIAN GOBI: A STABLE ISOTOPE APPROACH

Martina Burnik Sturm

Research Institute of Wildlife Ecology

Christian C. VOIGT, Leibniz Institute for Zoo and Wildlife Research (IZW); Ganbaatar OYUNSAIKHAN, Great Gobi B Strictly Protected Area Administration; Petra KACZENSKY, Research Institute of Wildlife Ecology

The conservation and management of threatened and endangered species is increasingly challenged by resource needs of an ever increasing human population. A good understanding of behavioral patterns is an essential element in making better management decisions which may help increase the effectiveness of conservation programs. We studied foraging behavior of three sympatric equid species in the Dzungarian Gobi in southwestern Mongolia: the re-introduced endangered Przewalski's horse (*Equus ferus przewalskii*), the endangered Asiatic wild ass (*Equus hemionus*), and a potential competitor the domestic horse (*Equus caballus*). Using segmentally cut tail hair, a biological archive that contains chemical information about what the animals have been eating in the form of carbon stable isotopes obtained from food, we were able to reveal species specific differences in the

feeding patterns. A stable isotope mixing model revealed that both horse species are hypergrazers that only include higher amount of browse (>20%) in their food under extremely severe environmental conditions. The feeding pattern of the Asiatic wild asses, on the other hand, is highly seasonal switching from being hypergrazers in the summer to mixed-feeders (including up to 65% browse) in the winter when food availability is lowest and competition with other wild and domestic grazers highest. Our results suggest that differences in foraging adaptations facilitate the coexistence of horses and asses in the same habitat, but that competition between Przewalski's horses and domestic horses is likely high, particularly during times of food shortage. Our findings will help optimize resource allocation (grazing permits and winter camp position) between semi-nomadic people and their domestic animals on the one hand and Asiatic wild asses and Przewalski's horses on the other hand and will thus help to improve ongoing conservation strategies.

RESTORING POPULATIONS OF METROSIDEROS ROBUSTA, A ONCE-COMMON NEW ZEALAND HEMIEPIPHYTE

Bruce Burns

University of Auckland

Metrosideros robusta used to be a common emergent tree of many New Zealand forests from which it is today rare; its decline driven by its high palatability to the introduced *Trichosurus vulpecula* brushtail possums. I review evidence of the former abundance of *M. robusta* within New Zealand forests and compare these to its current extent showing its dramatic decline and dieback in many areas. The regeneration ecology of *M. robusta* is complex as it establishes as an epiphytic seedling in natural forests then develops a trunk from roots that reach the ground (i.e., a hemiepiphyte). Natural seedlings occur most commonly on large host trees (> 50 cm diameter) and preferentially on certain host species. I report on an experiment to determine methods to restore hemiepiphytic *M. robusta* populations to forests with limited or no brushtail possums. At Zealandia - Karori Sanctuary, Wellington, New Zealand, in the absence of brushtail possums, the survivorship, and root and stem growth of 200 northern rata seedlings 'planted' on trees as epiphytes were assessed over five years against multiple factors including host species, host diameter, rooting volume, light environment, location on trunk, and aspect. Survivorship was lowest in the summer of the first year due to seedlings drying out, but increased dramatically after this. Survival and root growth were greatest on trees with smooth bark, in seedlings planted with larger rooting volumes, and in intermediate light environments. Stem growth was low in all seedlings until roots had contacted soil, indicating high allocation to root growth at this stage of the life cycle.

Water availability is a key factor limiting growth and survival of juvenile *M. robusta*. Conservation of this formerly key hemiepiphyte species in New Zealand forests will be enabled by controlling brushtail possum populations and strategic location of supplementary seedlings.

A CRASH-COURSE IN CONSERVATION ENTREPRENEURSHIP

Falko Buschke

University of the Free State

Most of us are familiar with the concept of commercial entrepreneurship, which focuses on creating a demand for new products and services. However, there is a newer brand of entrepreneurship – social entrepreneurship – that aims at serving basic, long-standing needs more effectively. Here I briefly introduce the concept of social entrepreneurship within a conservation context. There are several reasons for embracing an entrepreneurial approach to conservation. First, smaller conservation startups can tolerate more risk than conventional conservation organisations and are, therefore, more likely to experiment with innovative solutions to pre-existing problems. Second, some modern conservation problems, such as the need to evaluate, synthesise and summarise the outcomes of past conservation interventions, are amenable to entrepreneurial solutions without needing large organisational structures. Third, novel fundraising tools make launching a conservation startup easier than it has been in the past. Fourth, conventional conservation has traditionally relied on unpaid interns and volunteers, so an entrepreneurial culture offers young conservationists alternative career opportunities. Finally, individuals with certain personality traits, especially those with an internal locus of control, are naturally more suited for entrepreneurial activities. There are already many examples of self-started conservation projects, but these are probably unknown to the broader scientific community. To help embed such startups within mainstream conservation, I introduce an open, online collection of case-studies to inform, and possibly inspire, curious conservation entrepreneurs. Although conservation entrepreneurship will never replace conventional conservation, it may complement existing efforts and ultimately help to protect nature more effectively.

DIFFERENTIAL IMPORTANCE OF PASTURE SIZE AND GRAZING CONTINUITY FOR THE CONSERVATION OF DUNG BEETLES

Joern Buse

University Koblenz-Landau

Martin Slachta, University of South Bohemia ; Frantisek

Sladeczek, University of South Bohemia ; Markus Pung, University

Koblenz-Landau ; Thomas Wagner, University Koblenz-Landau ; Martin Entling, University Koblenz-Landau

Habitat area and continuity are both key issues in conservation biology. Since dung beetles are both functionally important and highly threatened organisms typical of pasture areas, we analyzed how grazing continuity and pasture area affect species richness, functional groups, and threatened species. We used literature and own field data to study a chronosequence of 22 pastures in five Central European countries. Our results show that grazing continuity has a strong positive effect on total species richness especially within the first hundred years of permanent grazing. Richness of habitat specialists increased more strongly with grazing continuity than in generalists. In contrast, the number of red-listed dung beetle species increased strongly with pasture area, leading to higher proportions of red-listed species on large than small pastures. Due to the long time needed for establishment of specialist species, priority should be given to the conservation of existing old pasture areas, and new areas should ideally be connected to source habitats for colonization. To ensure long-term survival of red-listed dung beetles there is a need for relatively large pastures (> 130 ha) or a coherent network of small pastures in a region.

IMPLICATIONS OF PHYSIOLOGICAL TOLERANCES AND EVOLUTIONARY ADAPTATION ON CONSERVATION OF SPECIES AND COMMUNITIES UNDER CLIMATE CHANGE

Alex Bush

CSIRO

Renee CATULLO, CSIRO ; Karel MOKANY, CSIRO ; Simon FERRIER, CSIRO

Species Distribution Models (SDMs) assume that species' occurrences reflect their environmental preferences, but in many cases a species range may not be limited by physiological tolerances, and in addition, those physiological tolerances may change over time. Likewise models that predict turnover in community composition (e.g. Generalised Dissimilarity Modelling: GDM) based on environmental differences in space, may overestimate the rate of change over time. Therefore the capacity for species to tolerate or adapt to climatic shifts has clear implications for our understanding of species potential responses to climate change, and consequently how we evaluate risk and prioritise conservation. We present results from two new methods designed to incorporate estimates of physiological tolerances and adaptive capacity into models of species distributions. To address adaptive capacity for the modified-SDM approach, we used detailed data of the genetics and thermal traits of *Drosophila*, and show how species persistence in the landscape is likely to be affected by the rate of climatic change, the presence of extreme events,

the rate of dispersal, and heritability of traits such as thermal tolerance. A variety of methods can be used to infer adaptive capacity and for large communities like Australian reptiles and plants we used indirect estimates to predict the capacity for diverse assemblages. The modified-GDM approach accounts for such tolerances and highlights where lags in predicted turnover would occur in the future, and therefore where in the landscape there is the least capacity to resist change, and where biodiversity retention may be higher than expected in the future. Under severe climate scenarios change will be inevitable as most species' capacity to resist and adapt is limited. These extended modelling approaches bridge the gap between our knowledge of ecology and physiology, and spatial predictions, to better inform our management actions in the future.

WAVES IN THE FOREST: SPECTRAL ANALYSIS FOR TROPICAL FOREST PHENOLOGY

Emma Bush

University of Stirling

Katharine ABERNETHY, University of Stirling ; Kathryn JEFFERY, University of Stirling ; Caroline TUTIN, University of Stirling ; Lee WHITE, Agence Nationale des Parcs Nationaux ; Nils BUNNEFELD, University of Stirling

Flicking on and off like LED lights at Christmas, the trees of a tropical forest come in and out of flower and fruit in a diverse array of complex cycles. How then in a chaotic natural environment can we recognise and measure these phenological cycles and pull apart the mechanistic and adaptive factors that drive them? Previous work to describe and compare tropical phenology has leaned heavily on qualitative categorisation of phenological behaviour (e.g. continuous, sub-annual, annual, supra-annual), losing information from the raw data and limiting our ability to compare within and between species and detect change. With unique access to thirty years of weather and tree phenology data (750+ trees of 88 species) from Lopé NP, Gabon we are developing spectral time series analyses (based on sine waves) to test links between forest phenology and climatic cycles. Spectral analyses enable efficient use of data to quantitatively identify and assign confidence to dominant cycles. These descriptors (frequency, amplitude and phase) can then be used to test hypotheses of ecological function. Using simulated data and case studies from Gabon we will demonstrate the diversity of cyclic behaviour and synchronisation amongst tropical trees in relation to climate variables, from species whose reproductive cycles are synchronous and ordered around seasonal and annual cycles, to a species that reproduces asynchronously with individuals operating on a 16-18 month cycle. Successful adaptation of forest management to climate change first requires understanding of vulnerability. Current phenology of central African forests is poorly understood and

yet the consequences of change under future climate scenarios will affect animal communities and people depending on the forest. As climate change increases the occurrence of extreme climatic events we show that these tools give us much greater power to identify cascade effects for tree phenology that relies mechanistically on climate signals.

33-NAVIGATING OVERLAPPING AND MULTIPLE ACCOUNTABILITIES IN MULTISCALAR CONSERVATION NETWORKS: LESSONS FROM THE COLLABORATIVE FOREST LANDSCAPE RESTORATION PROGRAM

William Butler

Florida State University

Rachel CHRISTENSEN, Florida State University

This paper examines the interplay between formal and informal accountability in conservation networks through a study of the Collaborative Forest Landscape Restoration Program (CFLRP). Networks are increasingly viewed as preferred avenues for addressing complex environmental problems that cross regional boundaries and operate at multiple scales. CFLRP participants, representing nonprofits, private sector organizations, and public agencies, have developed collaborative networks operating at two scales: landscape scale multistakeholder collaboratives and cross-collaborative networks. Through interviews, field observation, and document analysis, we examine network interactions at both the landscape collaborative scale and at the cross collaborative network scale to gather participant perspectives and explain how network activities are shaping restoration practice on the ground. Utilizing a grounded theory approach, we are especially interested in practitioners' experiences of accountability and responsibility to and with each other. In non-hierarchical network contexts, systems of accountability are less structured and less visible than many contractual intergovernmental or intersectoral relationships. CFLRP participants demonstrate that the principles of felt responsibility and reciprocity afford opportunities for holding themselves and each other accountable. However, individual network participants operate in governmental and regulatory contexts that are constrained by formal monitoring and accountability systems. As a result, when there are competing claims on staff time or resources, it is difficult to prioritize network activities over activities related to regulatory or funder demands. Within this context, we identify how network participants capitalize on the benefits of networks—informality, adaptability, and flexibility—while also maintaining accountability to each other for accomplishing shared goals in conservation and restoration work.

VULNERABILITY OF TURTLE NESTING BEACHES OVER THE NEXT 50-100 YEARS.

Nathalie Butt

The University of Queensland

Scott WHITING, WA Department of Parks and Wildlife ; Kiki DETHMERS, Charles Darwin University

Marine turtles globally are at risk from climate change. We focused on two species that nest across northern Australia, loggerhead *Caretta caretta* and hawksbill *Eretmochelys imbricata*, and parameterized the biophysical characteristics of their nesting beaches in Western Australia, Northern Territory and Queensland. We used climate change projections to identify which beaches may not be suitable for nesting in future. Beaches in all locations are predicted to experience increased maximum temperatures, such that sex ratios will become increasingly female-skewed, and embryo viability will be threatened at beaches in Western Australia and the Northern Territory. Overall, beaches in Queensland are less likely to flood than those in WA and NT, under sea level rise, although all beaches are predicted to experience increases in flooding, and some sites are projected to be below sea level by the end of the current century. Beaches currently not used for nesting, but which may be suitable in future, were also identified, and we suggest that these should come under conservation protection.

RISING TO THE TOP: VOLCANIC AGRO-FOREST PLANTATIONS AND THEIR EFFECT ON THE POPULATION OF JAVAN SLOW LORISES (NYCTICEBUS JAVANICUS)

Francis Cabana

Oxford Brookes University

K.a.i. NEKARIS, Oxford Brookes University

The latest trend in Java's agricultural landscape is labu (*Sechium edule*). These vegetables grow on a lattice framework made of bamboo. The smallest of labu plantations require 110 bamboo trunks with an annual upkeep of 60 more trunks. An important population of critically endangered Javan slow loris (*Nycticebus javanicus*) is being studied in the agroforests of Cipaganti village on Mt. Papandayan, Java, Indonesia. Labu plantations within the study site have increased from 3 to 24 in 2014, and bamboo cover has been reduced by 85%. Bamboo (various spp.) represents critical habitat for the slow loris as it provides preferred sleeping sites. As a nocturnal primate targeted by the illegal pet trade, safe and cryptic sleeping sites are of the utmost importance for their survival. The agroforest mosaic environment is not well connected for the arboreal lorises which are now routinely recorded walking along the ground from tree to tree. Lorises have also been observed using the labu plantations as a bridge between forest fragments. This

study aims to determine if the loss of sleeping sites outweighs the increased connectivity of fragments throughout the study area. The increase in labu plantations and decrease of bamboo patches have been measured every 3 months for the last year. Radio-collared slow lorises ($n=17$) were followed at night to record their ranging behaviour. All occurrences of ground-walking and labu usage were recorded including bout length, distance covered and observed destination. Sleep site locations were recorded once a week for all individuals. Loris habitat was mapped using ArcGIS to quantify the connecting effect of the labu. Results indicate there is a marked decrease in ground-walking as labu plantations become more prevalent. Slow lorises are vulnerable to predation by dogs, cats and owls while on the ground, therefore, the effects of the labu may increase survival.

181 BALANCE AND TRADE-OFFS IN CLIMATE-ORIENTED CONSERVATION PLANNING IN THE EU

Mar Cabeza

University of Helsinki

Conservation is often about trade-offs: trade-offs between biodiversity on the one hand, and economic, social or cultural interests on the other. It often also implies trade-offs between the different biodiversity features we want to protect. Climate change adds yet another dimension to be considered and balanced. This talk will draw on recent studies with a focus on the EU to illustrate a few, often neglected, trade-offs. The impacts of climate change mean that the optimal allocation of conservation resources in the present is likely to be suboptimal for future conservation. Consequently, there is a need for proactive planning given projected climatic changes. Sophisticated methods for spatial conservation planning have been developed to account for the shifting distributions of species under climate change. These approaches often target areas expected to remain climatically suitable for the given species or habitats in question, and/or areas that are expected to receive species tracking climate change, either by functioning as linking corridors or by becoming future distribution cores. Such planning exercises often rely on rather uncertain future projections, giving equal weight to both present distributions and projections. Due to limited resources, this may result in forgoing current conservation needs to preserve uncertain future conservation hotspots. I will present examples of such trade-offs between current and future conservation needs and discuss ways of balancing them while accounting for uncertainties in projections. I will then reflect on whether current EU conservation funding schemes, such as cohesion funds, support near-future conservation needs. I will also discuss additional trade-offs that require consideration when planning for climate change at the EU-level, including mitigation and adaptation trade-offs.

ARE HUMAN-RELATED PROCESSES OR JUST NATURAL PREDISPOSITION THE DRIVERS OF INVASION? AN AUSTRALIAN PERSPECTIVE

Hernan Caceres

The University of Queensland

Matthew MCKINNEY, The University of Queensland ; Salit KARK, The University of Queensland

The distribution of introduced species is influenced by both human and natural factors. Understanding the factors that best predict the establishment of invasive species can help us improve the effectiveness of management strategies. We examined the relative importance of anthropogenic and natural factors in shaping the richness of alien mammals across Victoria, New South Wales, and Tasmania. We developed a database of mammal introduction events and occurrence records of exotic mammals for these territories of Australia, beginning in 1775. We used Hierarchical Partitioning on 50 km² grid squares to identify the relative importance of factors in their modern distribution. The strongest predictor for the number of alien mammal species was native mammal richness. This is consistent with the hypothesis that the presence of habitats with high productivity which support more native mammals also enable the establishment of more exotic mammals. In line with this is the second best predictor for alien mammals richness, which is the greenness of an area, as determined the remotely sensed index NDVI. Thus, the establishment of alien species in South-East Australia is best explained by a combination of environmental and biotic factors.

ADDRESSING SOURCES OF UNCERTAINTY IN CONSERVATION DECISION-MAKING UNDER FUTURE FIRE REGIMES

Natasha Cadenhead

University of Melbourne

Michael KEARNEY, University of Melbourne ; Danae MOORE, Australian Wildlife Conservancy ; Brendan WINTLE, University of Melbourne

Fire regimes will change in the future due to global warming. These changes will impact many species across many ecosystems. However, the magnitude and direction of fire regime changes are uncertain. When predicting the impacts of fire regime change on biodiversity, uncertainty about future fire regimes is compounded by a lack of knowledge about species specific responses to fire. Incomplete process knowledge can be characterised as multiple competing models or hypotheses. Unfortunately, it is not common practice to propagate competing process models in population viability analyses nor in evaluating management options. Here we attempt such a feat, analysing the 50-year viability of the

great desert skink (*Liopholis kintorei*) in central Australia. Metapopulation models can suffer from uncertain predictions about population trajectories and extinction risks. However, the real value of these models is in explicitly teasing out the sources and forms of that uncertainty, highlighting what is possible under explicitly stated assumptions. Metapopulation models enable a coarse ranking of options with transparent risk profiling, providing a defensible strategy for prioritizing management decisions. We evaluated the impact of three future fire regimes on the medium-term viability of the great desert skink, under multiple competing hypotheses about the response of the species to fire. The impacts of the different fire regimes outweighed uncertainty in species-fire responses, making the management objective that was most robust to extinction risk clear; to avoid a regime involving frequent, large fires. This will require intensification of efforts by managers to promote patchy, low intensity fires in times of low fire risk, and to suppress large, summer wildfires. We identified the model and scenario assumptions with the greatest influence on the medium-term viability of the great desert skink and the management options most commensurate with its persistence.

ACOUSTIC TELEMTRY REVEALS CRYPTIC RESIDENCY OF WHALE SHARKS IN A COASTAL AGGREGATION

E Fernando Cagua

University of Canterbury

Jesse E M COCHRAN, King Abdullah University of Science and Technology; Christoph A ROHNER, Marine Megafauna Association; Clare E M PREBBLE, Marine Megafauna Association; Tane SINCLAIR-TAYLOR, King Abdullah University of Science and Technology; Simon J PIERCE, Marine Megafauna Association; Michael Lee BERUMEN, King Abdullah University of Science and Technology

Whale sharks, *Rhincodon typus*, the world's largest fish, are considered highly migratory and have been documented to move large distances. They are most frequently observed at a few predictable seasonal aggregation sites in tropical and subtropical seas. Here, in an aggregation site in Mafia Island, Tanzania, we compare two years of *R. typus* visual survey records to concurrent tracking of 30 acoustically tagged individuals. Sightings revealed a clear seasonal pattern with a peak between October and February, and no sharks observed at other times. In contrast, acoustic telemetry showed that *R. typus* stay year-round in the same area, but utilise a different habitat in the off-season, swimming deeper and further away from shore, presumably in response to prey distributions. This behavioural change masks a cryptic residency that was not detected by visual surveys. Management approaches for most marine planktivorous megafauna are based on the assumption that individuals disperse during the long "off-season". However,

here we demonstrate, for the first time, year-round residency of un-provisioned, individual *R. typus* at an aggregation site with residency patterns comparable to those of smaller and more sedentary elasmobranchs like grey reef and blacktip reef sharks. Our results suggest that conservation measures, in particular for charismatic marine megafauna for which citizen science is usually a primary source of information, should not rely on a single technique to infer the movement ecology of the target species.

SYMPOSIUM #20. GORILLAS IN THE CLOUD: INTEGRATING ELECTRONIC DATA COLLECTION AND A WEB-HOSTED DATABASE TO BETTER STUDY AND PROTECT MOUNTAIN GORILLAS

Damien Caillaud

The Dian Fossey Gorilla Fund

Tara STOINSKI, The Dian Fossey Gorilla Fund

A quarter of the critically endangered mountain gorillas living in the Virunga massif is currently studied by the Karisoke Research Center in Rwanda. Every day, a variety of data – demographic, ranging, behavioral, health – are collected on over 120 gorillas living in 8-10 gorilla groups. Due to the time necessary to enter and clean large amounts of data, the delay between data collection and analysis can be substantial. To reduce this delay and increase the quality and volume the data, we developed an integrated electronic data management system. A custom-made application for tablet computers was created to collect data on the social behavior, activity patterns, health and spatial distribution of the animals. Every day the tablets automatically send the new data to an SQL database hosted on a server in Rwanda. This local database is then synchronized with a Cloud database accessible through a user-friendly graphical interface. Statistical software R is also installed on the Cloud server and allows running a set of standard demographic and network analyses within a few days after the collection of the data. This data management system allows researchers to rapidly detect subtle changes in the social structure and demography of the mountain gorillas and is becoming an important tool for gorilla conservation. The data collection software and the structure of the SQL database are available to the community of behavioral scientists and conservationists and can be tuned to suit a large number of study species and protocols.

FRENCH OBSERVATORY OF LITTORAL NATURAL HERITAGE: A COLLABORATION BETWEEN MANAGERS AND SCIENTISTS TO DEVELOP AN EFFICIENT MARINE PROTECTED AREAS MANAGEMENT STRATEGY

Marion Caille

Réserves Naturelles de France

Aurélien BESNARD, CEFE/CNRS/EPHE ; Emmanuel CAILLOT, Réserves Naturelles de France

The coasts of France are prominent in Est-Atlantic flyway for coastal waterbirds as migrating stopover and wintering areas. Since 1977, France contributes to the International Waterbird Census organized in January by "Wetlands International". In parallel, managers of some French Marine Protected Areas (MPAs) developed a monitoring network to extend this census every month over the year. Created in 2000, this network, named "Observatoire du Patrimoine Naturel Littoral" (Observatory of Littoral Natural Heritage), progressively included unprotected areas. This aims at assessing the efficiency of conservation strategy developed in protected area. The monitoring method was co-constructed with scientists, to mix both feasibility on the field and cost-efficiency and scientific rigor. Method of data collection as well of their analysis was validated by an ad-hoc "Scientific and Technical Committee". All collected data are grouped into a unique database and are used to develop indicators of coastal waterbirds population status. They aims at answering managers' questions about the role of protected sites at different spatial scales (local, regional, national, international) and at helping public policy in implementation of the European Marine Strategy Framework Directive. This observatory is now extending to other thematic, such as survey of intertidal benthic habitats or nursery role of salt marshes for fish, to overcome management challenges and understand littoral ecosystems functionalities. The process of this observatory building and the report of its 14 first years will be presented and discussed.

TEMPORARY WETLANDS: CHALLENGES AND SOLUTIONS TO CONSERVING A "DISAPPEARING" RESOURCE

Aram Calhoun

University of Maine

Kathleen BELL, University of Maine ; David MUSHET, USGS Northern Prairie Wildlife Research Center ; Dani BOIX, University of Girona ; James FITZSIMONS, The Nature Conservancy in Australia

Fluctuating flood/dry cycles and support of unique, highly specialized species assemblages characterize temporary wetlands, including vernal pools, temporary ponds, gilgais, and prairie potholes. As small aquatic features embedded in a terrestrial landscape, temporary wetlands enhance biodiversity and provide valuable aesthetic, biogeochemical, and hydrologic functions. Primary challenges to conserving temporary wetlands include the need to: (1) integrate freshwater and terrestrial biodiversity priorities; (2) conserve entire "pondscapes" defined by connections to other wetlands and terrestrial systems; (3) mitigate economic impact on

landowners when conserving widely distributed, relatively small features that often fall on private ownerships; and (4) work within limited or non-existent regulatory protections. We propose new paradigms for conserving temporary wetlands in increasingly human-altered landscapes that integrate command and control top-down management and bottom-up, collaborative, relatively local approaches driven by key stakeholders. Because all wetlands function as integral landscape components, not singly as isolated entities, the cumulative loss of wetlands, particularly small natural features, is detrimental to ecosystem functions, but not currently part of the conservation calculus. We postulate that alternative regulatory strategies falling midway between individual pool conservation and conservation of landscapes at scales as large as ecoregions are needed to manage small natural features at scales that are ecologically and economically relevant. Flexible conservation strategies that reduce landowner and manager costs while achieving socio-ecological objectives will have the greatest probability of success in maintaining fully functioning landscapes. We can move toward this paradigm by tailoring conservation to local needs through stakeholder-generated solutions coupled with government engagement at multiple levels.

126. A PARTICIPATORY FRAMEWORK TO ASSESS MULTIFUNCTIONAL AGRICULTURE: CASE STUDY AGROBIODIVERSITY IN AGROFORESTRY SYSTEMS OF TOME ACU IN NORTHERN BRAZIL

Daniel Callo-Concha

Center for Development Research (ZEF)

Manfred DENICH, Center for Development Research (ZEF)

The multifunctionality of agroforestry systems was assessed by applying multicriteria and multivariate analyses to identify ecological, agronomic and administrative proxies and integrate these into factors, and evaluate their effects on the overall system performance. This assessment framework was tested in 70 farms in the municipality of Tomé-Açu in the Brazilian Amazon, an area well known for its long-standing practice of agroforestry. The overall goal was to identify management decisions that ensure sustainable production of goods and the provision of ecosystem services, with special emphasis on agrobiodiversity. Three groups of farmers were considered based on their period of settlement, property size, technological know-how, organization and access to the market. The results show that the determinant factors of multifunctional farming are the farmers' technical qualification, good adaptability, environmental commitment and the search for financial profitability. However, the optimization of these factors leads to trade-offs such as a decrease in biomass and woody species diversity and the decline of by-product production. By considering stakeholders' opinions and being adaptable to various demands, the proposed framework

enhances the legitimacy of the results, and may address both the assessment of complex issues and decision-making advising.

ID124_ CAN WE ACHIEVE THE “NO NET LOSS” OF BIODIVERSITY THROUGH MITIGATION BANK SYSTEM? EMPIRICAL EVIDENCES FROM THE FRENCH EXPERIMENTATION

Coralie Calvet

INRA

Claude NAPOLEONE, INRA ; Thierry DUTOIT, CNRS_IMBE ; Harold LEVREL, AgroParisTech

Biodiversity offsetting is promoted as one of the relevant tools to halt the current ecological crisis. As a way to achieve more effectively the “No Net Loss” of biodiversity, mitigation banks are attracting a growing interest from politics at both national and international scales. Whilst this tool is increasingly being used, its ability to reach conservation targets is still debated. We propose thus to investigate the strengths and weaknesses of mitigation banks mechanism from an institutional economics perspective. We used empirical evidences resulting from the analysis of the first mitigation bank implemented in France in 2008 by “CDC Biodiversité”. We carried out a field research study of this bank focusing on four complementary aspects: i) the role of stakeholders in the implementation of the bank, ii) the actual achievement of ecological restoration plan, iii) the dynamics of biodiversity credits sold by the mitigation bank and iv) the influence of the specific institutional framing of this French case study. Our results showed that, from ecological perspectives, restoration actions were successful on short time scale in allowing the return of targeted birds in restored areas. However, strong uncertainties challenge the durability of this recovery over the long term. The economic analysis revealed failures in the organization of the bank questioning the viability of the mitigation scheme over time. Besides, we found evidences for strong influence of the institutional framing on the bank effectiveness. Indeed, we further revealed that the lack of clear and stabilized offsetting rules led to the emergence of opportunistic behaviours resulting from bargaining between stakeholders that tend to jeopardize the objective of biodiversity protection. This analysis allowed us to draw lessons on the mitigation bank mechanism and to conclude on possible improvements of this tool.

OPTIMIZING THE TRADE-OFF BETWEEN LEARNING AND DOING IN PROTECTING SPECIES’ HABITATS

Abbey Camaclang

University of Queensland

Iadine CHADÈS, CSIRO Land and Water Flagship ; Tara MARTIN, CSIRO Land and Water Flagship ; Hugh POSSINGHAM, University of Queensland [INSTITUTE] Imperial College London

Species’ habitats should be identified as accurately as possible to maximize the benefit to conservation and minimize the costs of habitat protection. However, delaying habitat protection to improve accuracy could result in additional habitat loss in the interim. Determining how much time to invest on learning about species’ habitats is therefore important to maximize the accuracy of habitat identification while still allowing for timely protection. To address this question, we expressed the total area of habitats that can be correctly identified as a function of habitat loss and learning over time. We then optimized the trade-off between learning and doing by determining the amount of time spent on research that results in the maximum area of habitat that can be correctly identified and protected. We used linear, hyperbolic, and sigmoid functions to simulate learning over time, and the loss of up to 10% of available habitat area per year to simulate ongoing habitat loss. As predicted, the optimal time to spend learning decreased with increasing rates of habitat loss. When only 1% of habitats are lost per year, the optimal time is determined by the learning rate. For example, given a false positive identification rate of 0.5, the optimal time varied from 15-19 years for sigmoid curves to 5-7 years for hyperbolic curves. However, when habitat loss is 5% per year or greater, the optimal number of years becomes 3 years or less, regardless of the learning rate. This approach to determining the optimal time for learning highlights the need for timely protection when the threat of habitat loss is high, and the benefits of greater accuracy in identification when habitat loss occurs slowly. It can therefore serve as a useful tool for guiding the allocation of conservation resources towards research or habitat protection, for instance, in determining the amount of time to spend on research before designating critical habitats for threatened and endangered species.

EDUCOMMUNICATIVE STRATEGIES FOR THE APPROPRIATION OF THE CONSERVATION OF AMPHIBIANS AND BUTTERFLIES FROM NORTHEASTERN COLOMBIA

Catalina Camargo

Universidad de Pamplona

Fredy SOLANO, Universidad de Pamplona ; Aldemar ACEVEDO, Universidad de Pamplona ; Diego CARRERO, Universidad de Pamplona

The appropriation of environmental education and the communicative divulgation about fauna in Colombia has gained relevance since the country has been positioned as the second in richness of species of butterflies (3,274) and amphibians (771). Few studies concerning fauna have

been reported in Northeastern Colombia, so there is a lack of information, which results in ignorance among local communities. This scenario motivated us to gather the results of research concerning diurnal butterflies and amphibians from the department Norte de Santander, in order to build plans of environmental education that contribute with the conservation, safeguarding and appropriation of the biodiversity, based on the transformation of communication towards social change. Three rural zones associated to ecosystems of Tropical Dry Forest, Sub Andean forest and Paramo where identified and all available literature and photographic material of amphibians and butterflies was classified for each ecosystem in the study area. From an educative perspective we applied 150 semi structured interviews and invested 240 hours to do direct observations in the rural communities to carry out qualitative descriptions. Results from previous scientific research reported 59 species of amphibians and 245 species of diurnal butterflies; also regarding the perception of rural communities it has been identified a low safeguarding of the natural resources and lack of awareness of the species; however, two species, *Evenus coronatay* *Gastrotheca helenae*, exhibit high acceptance among local communities, facilitating their protection and the consequent sustainability of the forest. Aware of the importance of these species in the study area and taking into account the participation of local communities, we designed an strategic plan of communication that could serve as awareness raising agent, in which local knowledge can be integrated and applied towards the preservation of the environment.

DERIVATION OF A HIGH RESOLUTION LAND-COVER MAP OF THE WESTERN SAHARA-SAHEL TRANSITION ZONE FOR LOCAL BIODIVERSITY CONSERVATION

João Carlos Campos

InBIO-CIBIO

José Carlos BRITO, InBIO-CIBIO

Remote Sensing (RS) has proven to be an important tool for conservation, allowing the detection, mapping and prediction of environmental properties and changes. The Sahara desert and the semi-arid Sahel represent two major African ecoregions, and their limits correspond to the transition between the Palearctic and Afro-Tropical biogeographical realms. The western Sahara-Sahel constitutes a major biodiversity corridor between realms due to the moderate climate influenced by the Atlantic Ocean, thus comprising high biodiversity levels, local endemics and high habitat heterogeneity. Such heterogeneity is usually undetected in habitat-related variables derived by RS at global scales. This represents a major limitation for local biodiversity conservation and management, particularly in areas subjected to growing resource exploitation. This study aims to create a high

resolution land-cover map (30x30m) of the western Sahara-Sahel transition zone. A total of 123.000 GPS-control points and associated habitat-descriptive traits (e.g. soil type, water availability) were collected during four overland expeditions to Mali, Mauritania, and Morocco (2011-2014). 242 points were grouped according to habitat traits by hierarchical cluster analyses (HCA) and further implemented in supervised classifications of Landsat 8 images. Results were validated by a set of 20.000 independent points. The extensive field effort allowed collecting a major dataset that was crucial for classifying and validating a high resolution land-cover map of extensive arid and semi-arid regions. The HCA provided an observer-independent method for a priori selection of habitat classes. The land-cover map provided accurate information on habitat distribution in a region where resource assessment represents a major priority. The Land-cover map derived constitutes framework data for understanding local biodiversity distribution and improving the effectiveness of conservation solutions (e.g. reserve design).

THE USE OF AGROFORESTS OF TEAK BY LARGE AND MIDSIZED BRAZILIAN AMAZONIAN MAMMALS IN THE ARCH OF DEFORESTATION

Gustavo Rodrigues Canale

Universidade Federal de Mato Grosso

Angele OLIVEIRA, UNEMAT

Deforestation of tropical forests is globally known as a priority task to biodiversity conservation. Management of agroforestry systems aims to reconcile economic profit and the ecosystems conservation. Some agroecosystems, however, may be less permeable to the fauna community than others. This study assessed the influence of an agroforest of teak on the abundance of large and midsized Amazonian mammals in Mato Grosso, Brazil. Twelve trails, evenly placed in the forest and in the agroforest of teak, were assessed by linear transects (3.5 to 5 km), totalling 485 km of walked trails. We recorded (sights and tracks) 27 large and midsized mammals, seven Orders and 16 Families, including eight endangered species. Only five species sighted (*Ateles chamek*, *Lagothrix lagotricha*, *Dasyprocta azarae*, *Mazama americana* and *Chiropotes albinasus*) were more abundant in the forest. The vulnerable Woolly monkey (*L. lagotricha*) was the most abundant species in the forest (1.8 group/10km), followed by the white-lipped peccary (*Tayassu peccary*) (1.4 group/10km), both were significantly more abundant in the forest than in the agroforest ($p < 0.05$). The capuchin monkey (*Sapajus apella*) was the most abundant species in the agroforest (1.2 group/10km), while the squirrel monkey (*Saimiri sciureus*) was the only species marginally more abundant in the agroforest (0.6 groups/10km, $p < 0.06$). Excluding singletons and doubletons, the crab-eating fox (*Cerdocyon thous*) was exclusively recorded in the agroforest. All in all, most of the community

of large and midsized mammals used the agroforest of teak to move through the landscape and partially support their ecological needs, foraging and feeding on native plants in the agroforest. This agroecosystem, however, seems to not support populations of some endangered species, such as the spider monkey (*A. chamek*) and the woolly monkey (*L. lagotricha*), exclusively recorded in the forest.

159. STOCHASTIC DOMINANCE TO MAKE DECISIONS ABOUT TRANSLOCATIONS WITH RISKY OUTCOMES

Stefano Canessa

University of Melbourne

Terry WALSHE, University of Melbourne ; John EWEN, Zoological Society London ; Michael MCCARTHY, University of Melbourne

Species translocations are often a key component of recovery and restoration plans. However, their expected outcomes are typically uncertain, reflecting our incomplete knowledge of complex and variable natural systems. In some cases, there may be concerns that translocations may do more harm than good. Consider for example the risk of spreading novel pathogens when reintroducing captive-bred species, or the ongoing debate about the potential negative impacts of assisted colonisation. Different attitudes toward risk may lead to conflicting views on whether and how to carry out actions. How can decisions be made in such circumstances? We explore the use of stochastic dominance, a widely applied concept in economic decision-making, for decisions about translocations in the face of uncertainty and risk. We use as a case study the recovery plan for a frog species threatened by disease. Here, the choice of carrying out a translocation or not depends on whether managers prefer to ensure good outcomes or to avoid poor ones. The application of stochastic dominance in conservation can help link risk assessments with decision-making, encouraging a transparent assessment of probabilistic uncertainty and of the preferences and attitudes of decision-makers. These in turn can help ensure rational decisions are made and remove potential causes of stakeholder conflict.

TRACKING DIVERSITY: SWEDISH BIRDS RESPOND TO FOREST ROAD OPENINGS

Paul Caplat

Lund University

Lovisa SOLBÄR, Umeå University ; Åke LINDSTRÖM, Lund University

Road opening is an increasingly recognised threat to biodiversity worldwide. In temperate and sub-arctic forests, however, most of forest management guidelines aim at logging practices themselves (e.g. clear-cutting vs. continuous forestry, green tree retention). An overlooked aspect of forestry is the opening of semi-permanent tracks to allow access to logging sites. In Sweden, forest road openings accounted for 37% of

land-use conversions between 2009 and 2012. Here we assess the impact of road on bird communities in Swedish forested landscapes. Specifically we quantify how changes in road density drive changes in bird abundance and community composition along a latitudinal gradient, accounting for landscape effects and abiotic factors. We develop models within a Bayesian Inference framework that allows flexible model hierarchy and uncertainty quantification. To better account for species habitat requirements we combine several existing land-cover and forest composition layers at 25m resolution, on which is overlaid spatially explicit data on road openings. Bird abundances are derived from a citizen science program, the Swedish Breeding Bird Survey. We show that landscape configuration and road types influence how bird species respond to road openings. Combined with knowledge of the spatial logic underlying road openings, our results allow suggesting road development guidelines to minimize impacts on bird diversity.

SYMPOSIA 188. BARRIERS WITH BENEFITS: THE USE OF IN-STREAM STRUCTURES FOR CONSERVATION OF FRESHWATER BIODIVERSITY UNDER CONDITIONS OF HIGH RISK AND UNCERTAINTY

Samantha Capon

Griffith University

Nick BOND, Griffith University

The detrimental effects of artificial in-stream barriers (e.g. dams, weirs, road crossings, pipelines, etc.) are widely acknowledged. Such structures can prevent fish migration, limit hydrochoric seed dispersal, isolate populations of aquatic fauna and fundamentally alter patterns of hydrologic and biogeochemical connectivity. Removal of barriers is therefore commonly accepted as an appropriate management strategy for the restoration or conservation of freshwater biodiversity in modified systems. Increasing recognition is being given to the potential benefits of in-stream structures, however, particularly in the face of rapid climate change. Through their influence on flows and connectivity, for instance, barriers can create habitats that provide significant refuge from drought or invasive species. The role of artificial barriers in preventing the homogenization of freshwater fauna may also be important where natural barriers (e.g. waterfalls) have been extensively breached by human activities. Additionally, the process of removing in-stream barriers may result in further pressures on already degraded freshwater and riparian ecosystems which could outweigh the likely benefits of barrier removal. Consequently barrier retention, enhancement or construction are now seen, in some situations, as preferable management options. Such actions, however, can be associated with significant costs (e.g. maintenance), considerable risks (e.g. mass failure) and a high probability of perverse outcomes. We present a critical appraisal of the potential benefits of in-stream

barriers in the conservation and restoration of freshwater ecosystems. We assess the risks involved and evaluate a range of case studies to identify the conditions under which artificial barriers are likely to contribute to, rather than threaten, ecological outcomes.

THE BIODIVERSITY AND DEVELOPMENT RESEARCH AGENDA OF THE UNITED STATES AGENCY FOR INTERNATIONAL DEVELOPMENT

Sara Carlson

USAID, Forestry and Biodiversity Office

Andres GOMEZ, ICF International ; Diane RUSSELL, USAID, Forestry and Biodiversity Office

The United States Agency for International Development (USAID) is one of the world's major conservation donors. The Agency's recently launched Biodiversity Policy cements its commitment to conservation and articulates a vision of biodiversity as a critically important foundation for human welfare, intricately connected to other development sectors, and fundamental to meeting its development goals. A new Research Policy commits the Agency to evidence-based programming to improve outcomes and contribute to the global knowledge base. In this context, USAID designed a systematic, strategic, operations-focused, and collaborative process to define and prioritize the most critical questions in the area of biodiversity conservation in support of its development objectives. This Agenda seeks to 1) build the evidence base for the links between biodiversity conservation and development outcomes in key sectors; 2) improve the effectiveness of conservation programs and projects; and 3) advise on the generation and use of evidence in conservation project design and adaptive management. While not limited to Agency sources, the Agenda draws on the rich storehouse of data and experience from within the Agency and calls attention to the knowledge resources available therein. We describe the process that led to the Agenda, its conceptual framework, the main themes and priority research questions identified, and suggest avenues for future collaborative engagement by a variety of stakeholders.

WOOD FUNGI DECOMPOSITION INCREASED BY HEAT SHOCK

Fredrik Carlsson

NAT

Mattias EDMAN, NAT ; Bengt Gunnar JONSSON, NAT

Wood fungi are present in the majority of dead wood on the forest floor, and are regarded as the main decomposers in boreal forests. The role of Wood fungi in ecosystem carbon cycling is not fully explored, however as main decomposers they have an impact on Carbon release, from wood to the surrounding air. In this context, it is important to understand

how wood fungi metabolism is regulated in relation to different conditions, since changes in for example temperature and humidity as well as different disturbances can have a significant influence on the release of CO₂. In the present study we investigate the effect of heat shock on decomposition rate in 18 species of wood fungi. Ten of the species can be seen as associated with forest fire while the other eight has no such association. Heat shock time and temperature was calibrated to match the conditions of a forest fire. We found a triggered increase in fungi decay rate after heat shock, and this response was more pronounced in the fire-associated group. In some species the decomposition rate increased by up to 1000%. How relevant this response is on a carbon cycling at a larger scale is not within the scope of the present study, but it shows that decomposition levels can be heavily modified by environmental trigggers, such as in this case, a forest fire.

TOURISM AND CONSERVATION: THE IMPORTANCE OF CONTEXTUAL ANALYSIS AND STAKEHOLDER INVOLVEMENT

Lina Caro

University of Cambridge

Alison GUNN, Fauna & Flora International

Protected areas can face major challenges in achieving a financial sustainability due to economic, politic and legal conditions. Securing long-term funding is one of the most challenging targets to meet, particularly in countries with complexities such as low government investment, supportive law enforcement and corruption. Besides, conventional funding streams often fluctuate impeding the development of sustainable financial strategies. Environmental problems in Ometepe Island Biosphere Reserve, Nicaragua, are largely related with financial shortfalls that impede effective law enforcement, management and conservation planning in the island. Although tourism provides an important source of incomes for the locals, little is invested in conservation and in 2011 only 0.004% of the national budget was invested in all PAs in Nicaragua. Consequently, this expenditure has been inadequate to supply basic needs, including salaries for rangers, environmental education, protection and monitoring activities, and general equipment. It is important to explore innovative funding mechanisms for PAs that can be sustainable in time and independent from government budgets. In particular, tourism user fees (TUFs) are site-based mechanisms that often capture significant revenues necessary for PAs' management and conservation. However, these revenues are not enough on its own to ensure a sustainable financing strategy. Thorough analysis of the contextual factors that may enhance or undermine a sustainable financing strategy in Ometepe revealed that coordination, partnership, leadership, and governance abilities are critical in creating a

sustainable financing niche to ensure stakeholder involvement, cooperation and collaboration.

122 SPATIAL TRADE-OFFS BETWEEN AGRICULTURAL PRODUCTION AND ECOSYSTEM SERVICES IN THE TROPICS

Luis Roman Carrasco

National University of Singapore

Growing global demands for food and biofuels are providing strong economic incentives for deforestation across the tropics. Much of this deforestation is poorly planned due to the lack of information on the spatial distribution of benefits and costs of deforestation. To inform sustainable land-use policies at the landscape level, a spatially explicit analysis of the trade-offs between agricultural benefits, carbon emissions and losses of ecosystem services due to tropical deforestation was performed. The results show that the economic externalities of destroying tropical forests and their associated ecosystem services are at least of a similar magnitude to the direct economic benefits derived from agriculture. The analysis identifies areas that present high potential agricultural gains and low ecosystem services losses, where payment for ecosystem services programs would not be able to halt deforestation, areas that presented low agricultural gains and high ecosystem services and should have not been converted to agriculture. Clarifying the spatial distribution of economic net losses and gains resulting from deforestation can help identify optimal areas for conservation and agriculture thus informing pantropical conservation planning.

SEASONS OBSERVATORY - COLLABORATION BETWEEN CITIZENS AND SCIENTISTS

Jennifer Carré

Associtaion Tela Botanica - GDR PARCS

Isabelle CHUINE, CNRS - GDR PARCS ; Camila LEANDRO, Associtaion Tela Botanica - GDR PARCS

In partnership with Tela Botanica, CNRS has developed the Seasons Observatory program to collect phenology data on the various animals and plants. These data will allow researcher to provide indicators of the effect of climate change and to feed studies in this field. Indeed, climate change is having, and will have, strongly effects on the seasonal rhythms of plants and animals. This changing is having serious consequences in terms of ecosystem functioning, food chains, the survival of certain species, and the geographic distribution of species. Seasons Observatory is a fruit of the collaboration between research teams, citizens, associations and local authorities in advancing climate effects research. This project is a program of participatory science that federates 3160 citizens. This program has two levels: a national level and a local level with 9 relay

observatory. He is a great citizen awareness device through action and is very accessible through collaborative Web tools we are developing. These collaborative Web tools allow us to collect data online and they are free. Also we make an available website to citizens. This website is a true place of resources and exchanges for raise awareness and education of citizens. In this session we will present the results of this project, and open the discussion on the usefulness of these programs in dialogue with civil society.

DIVERSITY OF DIURNAL BUTTERFLIES (PAPILIONOIDEA) IN A HIGH ANDEAN LANDSCAPE FROM NORTHEASTERN COLOMBIA AND ITS IMPORTANCE FOR CONSERVATION

Diego Carrero-Sarmiento

Universidad de Pamplona

Cristobal RIOS-MALAYER, Universidad de Pamplona

Butterflies (Papilionoidea) are functional insects when developing studies of diversity and conservation. Heterogeneity of landscapes and ecosystems position Colombia as the second richest country in terms of species of butterflies with 3274 species reported. Despite of such richness there is a lack of knowledge regarding the diversity patterns of Andean butterflies. Our main aim was to estimate the diversity of butterflies' communities in 8 localities in northeastern Colombia, located at altitudes between 2700 and 3300m. To sample the butterflies we established 7 stations per locality, placed 100m apart from each other in an altitudinal gradient. One transect of 200m x 50m was also established and used to actively search for butterflies from 09:00 to 16:00 hours using an entomological net. In addition we used 6 Van Someren-Rydon traps baited with decomposed fish. Our sampling resulted in a total of 448 hours with entomological net and 1792 with traps. We found 762 individuals, belonging to five families (Nymphalidae, Hesperidae, Pieridae, Lycaenidae and Papilionidae), 30 genera, 55 species, 13 subfamilies and 9 tribes. Twenty five species belonged to the subtribe Pronophilina, the richest and with highest level of endemism including: *Altopedaliodes tamaensis*, *Pedaliodes reyi*, and *Idioneurula erebioides*; the next richer families were Hesperidae, with nine species, and Pieridae, with eight species. Sampling stations located between 2900m and 3100m of altitude where the most diverse, exhibiting diversity order 1D with ranges of species between 22 and 27, represented by genera like: *Pedaliodes*, *Altopedaliodes*, *Corades* and *Idioneurula*, associated to transitional life zones between High Andean Forest and Paramo. Our results show the importance of these Andean Highlands as refuge and reserve of unique species of butterflies, which are key to understand the ecological process that will finally allow us to identify, select and establish priority areas for conservation.

49-ARE SPECIES TRAITS USEFUL FOR PREDICTING PRIMATE SPECIES RESPONSES TO HABITAT LOSS AND FRAGMENTATION? A REVIEW

Xyomara Carretero-Pinzon

The University of Queensland

Thomas DEFLEER, Universidad Nacional de Colombia ; Clive MCALPINE, The University of Queensland ; Jonathan RHODES, The University of Queensland

Habitat loss and fragmentation are the main threats of primate species worldwide. We conducted a review of published literature about the effects of habitat loss and fragmentation to quantify the effect of habitat loss and fragmentation on primates and whether this depended on species' traits. The effect of habitat loss and fragmentation on five response variables (density, parasite prevalence and diversity, presence, genetic diversity and behaviour), were extracted from 130 papers and were compared across six species traits (diet specialization, social organization, body size, home range, group size and dispersal ability). There is no evidence that the effect of habitat loss and fragmentation varies across species traits. Density and parasitic prevalence and diversity were positively correlated with habitat loss and fragmentation. On the other hand, species presence and genetic diversity were negatively correlated with habitat loss and fragmentation. Behavioural responses (time spent in resting, moving and feeding activities) didn't show a detectable effect of habitat loss and fragmentation. Therefore, although some studies hypothesize that species traits can be used as a guide to determine primate species susceptibility to habitat loss and fragmentation, there is little evidence to support this from primate literature at present.

ARE MIXED TROOPS AFFECTED BY HABITAT LOSS AND FRAGMENTATION? AN EXAMPLE FROM COLOMBIAN PRIMATES

Xyomara Carretero-Pinzon

The University of Queensland

Habitat loss and fragmentation are the main threats of biodiversity worldwide. Habitat loss and fragmentation affects the area and resources available to primate species thus affecting their interactions with other sympatrical species. Mixed troops are associations of species, which can be ecologically similar, which associate during long periods of time, moving and feeding together. Several hypotheses have been proposed to explain mixed troops formations in primates, including a parasitic knowledge of spatial resource distribution and reduction of predation rates. Mixed troops formation has not been studied in the context of habitat loss and fragmentation and how these landscape processes can affect

this species type of interaction. The aim of this study was to evaluate the effects of habitat loss and fragmentation on mixed troops formation using the Colombian squirrel monkey (*Saimiri cassiquiarensis albigena*) and black-capped capuchins (*Sapajus apella*) as an example in two areas (one continuous and one fragmented). Mixed troop formation data was collected using scan sampling method every five minutes in both sites, during four months in each site (369 hours in the continuous and 423 hours in the fragmented site). The frequency of mixed troop formation was lower in the fragmented site compared with the continuous site. A higher frequency of mixed troop formation was observed in the dry season for the continuous site, contrary to the findings for the fragmented site for the same season (less frequency of mixed troop formation in the dry season). An exploration of landscape variables and site variables in order to determine the effects of habitat loss and fragmentation in the frequency of mixed troop formation for these species was made.

ASSESSING FUNCTIONAL HOMOGENIZATION OF BIRD COMMUNITIES IN MANAGED AND UNMANAGED FORESTS USING MULTI-SPECIES OCCUPANCY MODELS

Eduardo Carrillo-Rubio

Cornell University

Functional homogenization of biological communities, caused by disproportional population declines and a shift towards domination by generalist taxa, is one of the most ruinous consequences of environmental degradation. Species loss dilutes species-habitat relationships, altering the functionality of ecological systems. As degradation effects are expected to worsen from increasing human pressure and climate change, understanding how biological communities respond and are shaped by disturbances has never been more important. In this study we assessed the effects of logging on habitat relationships and specialization of forest bird communities using occupancy models to estimate species-specific occurrence probabilities as a function of forest stand characteristics while accounting for imperfect detection. We used data from a 2 year breeding bird survey of managed and unmanaged forests in the Sierra Tarahumara region of México. Our findings showed that logging degradation has favored generalist species and a shift towards functional homogenization. Degraded forests dominated by dense stands of small diameter trees (<0.3 m) were species-poor and contained mostly generalists; whereas stands with higher diameter values supported more species and habitat associations. Based on these results, predictions of lower species richness, generalist prevalence, and decreased function from degradation were generally supported. Compared to recent efforts that derived implicit conclusions about

specialization based on the relative apparent occurrence of species among different habitat types, our approach allowed us to develop unbiased species-specific covariate models to formally investigate specialization and quantify the relationships between true species occupancy and habitat gradients. Our findings could be used to inform decision-makers to enhance conservation and management outcomes, and project the consequences of management interventions on biological communities.

171 LEARNING BY DOING: LESSONS LEARNT THROUGH BUILDING CONSERVATION LEADERSHIP VIA PROJECT GRANTS AND AWARDS, INTERNSHIPS AND MENTOR SUPPORT.

Marianne Carter

Fauna & Flora International

Requiring self-initiative, experiential learning is one of the most powerful tools available to build skills and knowledge. 'Having a go' at a complex conservation activity with guided support, and an opportunity for reflecting on that, is a very effective way for building conservation leadership capacity. When an individual shows a spark of initiative, and as a result receives a 'leadership boost' (a training opportunity, a chance to be part of a peer-to-peer network, recognition and profile-raising, or some additional financial or technical resources, for example) we have found this support assists their progression to the point where they are quickly encouraging and inspiring others to join them as they guide and influence positive change. Over time we are developing more ways to better target our limited resources on maximising this effect for conservation gain. FFI has learnt a great deal through support of long-term tailored local and national conservation training and mentoring and also through several global initiatives that target conservation leadership development and aim to scale up our capacity to deliver effective conservation on the ground. Although clearly there is no single magic formula, we believe investing in talented individuals and maintaining strong, effective institutions and networks equals effective and sustained conservation.

THE KEYS TO COEXISTENCE: REALIZING THE POTENTIAL FOR INTEGRATING LARGE CARNIVORES INTO MULTI-USE LANDSCAPES

Neil Carter

University of Maryland

John LINNELL, Norwegian Institute for Nature Research ; Meredith GORE, Michigan State University ; Amy DICKMAN, Oxford University ; J. Baird CALLICOTT, University of North

Texas ; Vidya ATHREYA, Wildlife Conservation Society ; Nicolas LESCUREUX, Norwegian Institute for Nature Research

Many iconic large carnivore species, such as wolves, tigers, and bears rely heavily upon unprotected land as well as reserves. There is therefore a pressing need to integrate large carnivore presence into multi-use landscapes. Sharing landscapes with carnivores can potentially confer many benefits to people, but the negative impacts and conflicts associated with large carnivores often make attaining coexistence challenging. The lack of a clear, consistent, and comprehensive conceptualization of coexistence is among the biggest obstacles. A vague conceptualization of coexistence hinders efforts to implement coexistence strategies and, once implemented, evaluate effectiveness. Furthermore, without a common understanding of coexistence, people with opposing views toward carnivores will be unable to engage in a meaningful dialogue. Here, we explore and clarify important ecological, economic, and societal aspects of human-carnivore coexistence. Examining the coexistence concept from multiple perspectives allowed us to identify three key dimensions: the 1) potential for sharing landscapes based on biophysical and behavioral characteristics of both people and carnivores; (2) societal choice to realize that potential based on norms, attitudes, and knowledge; and (3) implementation of large carnivore conservation in shared landscapes through various institutions, policies, and practices. We also outline an operational framework of human-carnivore coexistence, based on the above three key dimensions and accessible to policy makers and managers. Coexistence is not an automatic consequence of cohabitation; rather, a central and novel theme concerns the extent that coexistence requires mutual adaptations by both wildlife and humans and by different groups of people in those three dimensions. We conclude by discussing ways in which the theory and practice of coexistence can be advanced using our proposed framework.

MODELLING THE COMBINED EFFECTS OF HABITAT HETEROGENEITY AND ROADS ON LANDSCAPE FUNCTIONAL CONNECTIVITY IN A MEDITERRANEAN FOREST CARNIVORE

Filipe Carvalho

Research Center in Biodiversity and Genetic Resources (CIBIO/InBio-UE), University of Évora

António MIRA, Research Center in Biodiversity and Genetic Resources (CIBIO/InBio-UE), University of Évora ; Pedro BEJA, EDP Biodiversity Chair, Research Center in Biodiversity and Genetic Resources (CIBIO/InBio), University of Porto, Campus Agrário de Vairão,Vairão; Rafael Carvalho, Research in

Biodiversity and Genetic Resources (CIBIO/InBio-UE), University of Evora

Landscape functional connectivity is likely shaped by a combination of factors, including the spatial heterogeneity of habitats and the distribution of infrastructures such as roads networks. These joint effects are poorly understood due to the shortage of empirical information on the environmental features affecting movement behaviour in human-dominated landscapes. We aimed to assess how spatial habitat heterogeneity and roads influence functional connectivity in a forest carnivore, the common genet. We used VHF radiotracking to collect movement data on 22 genets in a mixed forest-agricultural landscape of southern Portugal. We used information-theoretic model building and multimodel inference to develop path selection functions (PathSFs) discriminating between observed and random paths in relation to environmental variables. PathSFs were used together with land cover information to produce conductance surfaces. Genets showed preference for moving within forest patches and close to riparian habitats, and strongly avoided open agricultural land. The probability of movement declined with increasing road density, but increased with the proximity of culverts, viaducts and bridges. Landscape connectivity was favoured by large forest patches, and by the presence of riparian areas providing movement corridors within open agricultural land highly resistant to genet movement. Roads reduced connectivity by dissecting forest patches, but had less effect on riparian corridors due to the presence of crossing structures. Spatial habitat heterogeneity shaped the extent, location and configuration of areas most permeable to genet movement. The road network dissected the forest habitats, creating obstacles in areas otherwise permeable to animal movement.

POPULATION SIZE ESTIMATE AND VEGETATION CORRELATES OF NEST ABUNDANCE OF THE WESTERN CHIMPANZEE IN LAGOAS DE CUFADA NATURAL PARK, GUINEA-BISSAU

Joana S. Carvalho

Centre for Environmental and Marine Studies
Christoph F.J. MEYER, Centre for Ecology, Evolution And Environmental Changes ; Luís VICENTE, Centre for Environmental and Marine Studies ; Tiago A. MARQUES, Centre for Research into Ecological and Environmental Modelling

Rapidly growing global demand for natural resources within chimpanzee ranges continues to rise. Chimpanzee depend on effective conservation strategies that mitigate the impacts from the numerous threats they are facing. Among those are harmful anthropogenic activities, including commercial logging, industrial agriculture or mining, all of which contribute to the ongoing reduction of suitable habitat as well as

population sizes for chimpanzees. For Guinea-Bissau, robust estimates of population size and density are lacking, despite the country's importance as a refuge for Pan troglodytes verus at its westernmost margin of distribution. Using distance sampling and nest count methods, we assessed the population density and size of P. t. verus at Lagoas de Cufada Natural Park (LCNP). We further examined how quantitative vegetation characteristics are linked to chimpanzee nest abundance. Chimpanzee density was estimated at 0.22 nest builders/km² (95%CI 0.08-0.62), corresponding to 137 (95%CI 51-390) chimpanzees, the lowest density reported for any protected area in Guinea-Bissau. Zero-altered generalized mixed model showed that nest abundance was negatively correlated with plant species diversity and positively related with availability of smaller-sized trees, both characteristics of dense-canopy forest, the least available suitable habitat. Further, lower nest abundance was associated with greater floristic richness and larger variation in floristic composition, vegetation characteristics of open-canopy forest and savannah-woodland. Given the importance of LCNP as refuge for this flagship species, our findings can help device conservation guidelines for the management of its chimpanzee populations and remaining suitable habitats. Moreover, our population size estimate make a valuable contribution to the urgently needed reassessment of the conservation status of chimpanzees, whose reclassification to critically endangered is overdue (Walsh et al. 2003, Nature).

PERIODICALLY HARVESTED CLOSURES: POTENTIAL OPTIMAL FISHERIES MANAGEMENT STRATEGY

Paul Carvalho

California Polytechnic State University San Luis Obispo

Periodically harvested closures (PHCs) are a form of community-based fisheries management often implemented within customary fishing grounds throughout the Pacific. Communities, and their co-management partners that advocate the use of PHCs, have broad objectives of fishery sustainability and conservation. However, PHCs are designed more specifically to increase harvest efficiency, and for opportune occasional exploitation of protected stocks to support local social events. Despite their prevalence, the effectiveness of PHCs for simultaneously achieving these objectives remains uncertain. To assess PHC functionality, we developed a bioeconomic fisheries model that included fish behavior, and quantified how PHC open-closed schedule affects harvest efficiency (catch-per-unit-effort), biomass

conservation and sustainable fishery yield. We also compared PHC effects with the effects of non-spatial and no-take marine reserve harvest regulations – forms of conventional management often heralded as optimal in well-managed and over-fished systems, respectively. Optimal PHC design was sensitive to overharvesting; regardless PHCs were more effective at achieving the multiple objectives than either conventional method. Key to the results is the fishers' ability to reduce fish wariness and increase catchability in PHCs targeting finfish using strategic harvest schedules. These findings challenge the dogma that PHCs are simply a cultural legacy to be accommodated by contemporary fisheries science, and instead place PHCs center stage as a potentially optimal fisheries management strategy.

134 USING MARXAN TO INCORPORATE CLIMATE CHANGE IN CONSERVATION PLANNING

Silvia Carvalho

CIBIO/ InBIO

Given the present biodiversity crisis, safeguarding biodiversity in protected area networks and monitoring its change through time, have been established as major international goals. Climate warming challenges our approach to building protected areas' systems and monitoring networks, because it is likely to drive accelerating shifts in species ranges and the projections of those future species distributions are uncertain. Marxan is the most commonly used decision support tool for identifying priority conservation areas. It selects a minimum set of planning units necessary to represent a minimum pre-established amount of conservation features by the minimum cost. In this talk I will exemplify how a modified version of Marxan - Marxan with probabilities – can be used to identify priority conservation areas given uncertain future species distributions. This modified version deals with the inherent uncertainty in probabilistic distribution data, assuring that species' occurrence targets are met with a selected level of confidence. Finally, I will exemplify how Marxan can be used to design biodiversity monitoring networks, optimized to track species range shifts derived by climate change.

BEHAVIORAL AND PHYSIOLOGICAL EVALUATION OF ANTHROPOGENIC EFFECTS ON CANIDS IN THE BRAZILIAN CERRADO

Stacie Castelda

George Mason University

Frederico LEMOS, Universidade Federal de Goiás ; Elizabeth FREEMAN, George Mason University ; Fernanda AZEVEDO,

Cerrado Mammals Conservation Program ; Nucharin SONGSASEN, Smithsonian Conservation Biology Institute

The Brazilian Cerrado is the largest savannah in South America. However, over the past 40 years it has been severely altered and is now a mosaic of cattle ranches, agricultural fields and Cerrado fragments. Three canid species: the hoary fox (*Lycalopex vetulus*), crab-eating fox (*Cerdocyon thous*) and maned wolf (*Chrysocyon brachyurus*) are sympatric in this ecosystem. The objective of our study was to use behavioral and physiological measures to quantify and evaluate how anthropogenic activities are influencing the canid communities. We selected the smallest Cerrado canid, the hoary fox, as our model species. Over 100 hours of continuous focal behavioral observation and 20 serum and 125 fecal samples were collected from a sample population of 24 radio-collared hoary foxes in human modified and fragmented Cerrado habitat in Goiás state, Brazil. Our results indicated that all individuals of our hoary foxes study population were denning and foraging in overgrazed cattle pastures in proximity to human establishments. Interactions between hoary foxes and crab-eating foxes were more common than interactions between hoary foxes and maned wolves. These interactions varied from visual awareness of each other to hoary fox chasing crab-eating fox, crab-eating fox displacing hoary fox from a food resource, hoary fox vocalizing at maned wolf near denning pups, and hoary fox escaping maned wolf predation. More importantly, however, hoary foxes were frequently vigilant for cattle, domestic dogs, trains, and noise from homes. Preliminary analyses suggest that serum and fecal metabolite profiles reflect the frequency of vigilance behavior. Finally, our results indicated that the hoary fox was an ideal model species for advancing our understanding of the impacts of human activities on canid communities and provided the crucial information needed for establishing appropriate conservation plans for the region and sympatric carnivores worldwide.

HUMAN-CANID CONFLICTS ON CATTLE RANCHES IN CENTRAL BRAZIL

Stacie Castelda

George Mason University

Frederico LEMOS, Universidade Federal de Goiás ; Elizabeth FREEMAN, George Mason University ; Michael GILMORE, George Mason University ; Fernanda AZEVEDO, Cerrado Mammals Conservation Program ; Ricardo ARRAIS, Cerrado Mammals Conservation Program ; Nucharin SONGSASEN, Smithsonian Conservation Biology Institute

Among the terrestrial mammals, carnivores are the most threatened species and are also the most challenging to conserve. Attitudes towards, experiences with, and economic losses often reflect the degree of conflict between humans

and carnivores. Therefore, assessing attitudes and experiences of people living with wildlife is critical in the development of conservation strategies. We used interviews to assess local knowledge of Cerrado canids, whether predation events affected attitude towards these species and if, in return, local attitudes influence their livestock management practices. An opportunistic sample of 50 ranchers living in and around the Cerrado Mammal Conservation Program study area in the Limoeiro region of southeast Goiás, Brazil participated in structured interviews. Results of our study highlight that many ranchers were not able to differentiate between the crab-eating fox (*Cerdocyon thous*) and hoary fox (*Lycalopex vetulus*) and misidentified when they were active, their social structure, and feeding behaviors. Only half of the respondents liked seeing wild canids on their property and preferred that the animal stayed away from their house. All respondents identified domestic fowl predation by the maned wolf (*Chrysocyon brachyurus*), crab-eating fox, or hoary fox as the main source of conflict. Those who lost domestic fowl were more concerned about the frequency of the attacks rather than the actual number livestock lost. Only half of the properties used some form of enclosure at night to protect against predation. However, all the respondents who sold chickens or eggs as a source of income had some sort of roosting structure or closed them in at night. Finally, most respondents identified a chicken coop as the most expensive form of livestock management practice, but those who used the coop considered them as an investment. Collectively, this information will be used for developing strategies for improving local support for canids.

A CENTURY OF GENETIC CHANGE IN TWO AMERICAN PIKA POPULATIONS IN THE SIERRA NEVADA OF CALIFORNIA

Jessica Castillo

Oregon State University
Clinton EPPS, Oregon State University

Rapid, contemporary climate change over the past century has already resulted in local extinctions and detectable changes in patterns of occupancy for a number of species. In addition to shaping future habitat suitability, climate change is expected to impact dispersal ability and therefore population connectivity, further complicating predictions of range shifts and species viability. This is particularly true for species with low dispersal ability inhabiting naturally fragmented landscapes. One such species is the American pika (*Ochotona princeps*), which in addition to its reliance on highly specialized, patchy habitat, is also particularly sensitive to relatively small increases in ambient temperature. In this study we characterized historic and contemporary genetic diversity and population structure in two populations of American pikas in California: Lassen Volcanic National Park where the northern Sierra Nevada and

southern Cascade Range meet (1923-1926, and 2010-2011), and Yosemite National Park in the central Sierra Nevada range (1915 and 2012-2014). We found no significant changes in genetic diversity in either study area, suggesting stability in population size over the last century. However, we detected changes in population structure in Yosemite National Park, suggesting increased isolation of particular regions within the study area. Our results provide an important benchmark for long-term genetic monitoring of these populations. Our results also emphasize that maintaining functional connectivity, particularly for populations that are characterized by a metapopulation structure, should be a management priority in the face of rapid climate change.

MEASURING PROTECTED AREAS REPRESENTATIVENESS UNDER CLIMATE CHANGE SCENARIOS: A CASE STUDY OF THE COLOMBIAN CARIBBEAN REGION

Luis Guillermo Castro

Humboldt Institute
Clara Matallana, Humboldt Institute

Climate change is considered one of the main drivers of biodiversity loss at a national and global level. Protected Areas are considered as one of the more effective strategies to adapt to climate change. The objective of this study was to define a methodology that allows to identify the potential of each protected area to preserve species under different climate change scenarios. For doing so we propose to use potential distribution models of species to assess conservation objectives of protected areas, in order to identify which areas can serve as climate refuges for more species inside and outside protected areas. This methodology was applied in a study case in the Colombian Caribbean region, using distribution models for five species (*Aotus lemurinus*, *Leopardus wiedii*, *Synallaxis fuscorufa*, *Basileuterus conspicillatus* and *Pristimantis megalops*.) under current conditions and under the A2 and B1 scenarios defined by Intergovernmental Panel on Climate Change (IPCC) Fourth Assessment Report. The results allow to analyze how much of the species distribution area will remain inside protected areas, and to define new conservation priorities under climate change scenarios, where most of the species would share its distribution. Our aim is to apply this methodology for the whole country protected area system.

122 PRIORITIZING LEVELS OF ACTION EFFORT TO ACHIEVE COST-EFFECTIVE TRADE-OFFS IN CONSERVATION MANAGEMENT: A FRESHWATER CASE STUDY

Lorenzo Cattarino

Australian Rivers Institute, Griffith University

Virgilio HERMOSO, Australian Rivers Institute, Griffith University ; Josie CARWARDINE, CSIRO Ecosystem Sciences ; Mark KENNARD, Australian Rivers Institute, Griffith University ; Simon LINKE, Australian Rivers Institute, Griffith University

In order to protect biodiversity using the limited resources available to conservation, it is critical to identify trade-offs between achieving ecological outcomes and meeting social and economic objectives. Systematic Conservation Planning provides an approach for identifying these trade-offs, by prescribing the nature and spatial location of conservation management actions to address threats to biodiversity, while minimizing costs. Substantial gains in cost-effectiveness can be obtained by prescribing the specific level of effort to allocate to an action to remediate a threat to a species. However, due to the limitations of previous methodological approaches, the spatially-explicit prioritization of levels of conservation effort has received little application. Here, we present the first implementation of a novel approach for prioritizing conservation effort in a cost-effective and spatially-explicit way. We developed an optimization framework to prioritize the specific level of effort to allocate to different actions to improve species persistence. We applied our framework to prioritize the level of effort to allocate to 4 different actions that remediate major threats to freshwater biodiversity, in the Daly River catchment, Northern Australia. We used expert-elicited information on the responses of 140 freshwater species to different levels of effort of the different actions, and the management cost of different actions. Our framework also accounts for river connectivity, by ensuring that levels of action effort are prescribed in sites that are located along the river network. Our analysis reveals the priority areas in the Daly where specific levels of effort, for different actions, are prescribed, to secure the long-term persistence of freshwater biodiversity, at the minimum cost. Sitting at the forefront of systematic conservation planning, our approach represents an innovative and robust way to achieve trade-offs in conservation science.

IS BIRD FRIENDLY® COFFEE ALSO MAMMAL-FRIENDLY? ASSESSMENT OF MAMMAL DIVERSITY IN COFFEE FARMS OF CHIAPAS, MEXICO

S. Amanda Caudill

Smithsonian Institution

Robert Rice, Smithsonian Institution

Biodiversity-friendly coffee certifications, such as the Smithsonian Institution's Bird Friendly® coffee, provide a viable way to protect wildlife habitat while providing a financial incentive to farmers. Most studies related to these certifications focus on avian habitat requirements and it is not known whether these standards also apply to other wildlife, such as mammals, that inhabit the coffee landscapes. We

assessed the non-volant mammalian fauna and their associated habitat requirements in 23 sites representing forest, Bird Friendly® shade, conventional shade, and sun coffee habitats in Chiapas, Mexico. We used Sherman trap-grids to measure small mammal abundance and richness, while camera traps were set for medium-sized and large mammals. We detected 18 species of mammals, representing 11 families. We found the coffee farms in this region to provide an important refuge for mammalian wildlife. Species richness was significantly higher in Bird Friendly® coffee sites than other coffee habitats and was either higher (small mammals) or not significantly different (medium-sized mammals) than forest study sites. No significant difference was found in small mammal abundance among the habitat types. Medium and large mammals were present in sites with larger, more mature shade trees associated with, but not required by Bird Friendly® certification standards. However, lower strata vegetation (5 cm to 1 m tall), the only vegetation parameter found to increase abundance and richness for small mammals, is not specified in the Bird Friendly® standards. Our findings suggest that although the standards devised for avian habitat do benefit mammals, requirements specific for mammals could be included that would enhance the coffee habitat for mammals that inhabit these coffee landscapes.

MAPPING OPPORTUNITIES AND CHALLENGES TO EUROPEAN REWILDING

Silvia Ceausu

Studies (IVM), VU University Amsterdam ; Henrique M. PEREIRA,

German Center for Integrative Biodiversity Research (iDiv)

Wilderness has evolved into a conservation approach that includes an ecological dimension besides the original ethical and esthetical value. Wilderness areas have been shown to provide important supporting, regulating and cultural services and they are fundamental to the survival of many threatened species. We use wilderness mapping to highlight the opportunities and challenges associated with the restoration of natural habitat in Europe through rewilding. In the context of continuous European farmland abandonment, rewilding has been proposed as a management option for the areas of decreasing human presence. Ecological rewilding is the management of abandonment farmland that aims to minimize human interventions and favor self-regulating ecosystems. The ecosystem trajectories in areas of abandonment depend on the extent of the alterations produced by cultivation and policy responses. We map artificial night light, human accessibility, proportion of harvested primary productivity

and deviation from potential natural vegetation in projected abandonment areas in Europe for 2040. We discuss trajectories of ecological rewilding based on the different wilderness metrics configurations and the current protected area networks in Europe. Areas of disagreement between wilderness metrics are more likely to require management actions to facilitate the return to natural systems. One of the most important metrics that seems to affect rewilding potential is the deviation of current vegetation from natural vegetation patterns. A high proportion of projected abandonment is also located in or around NATURA 2000 sites, which have management goals directed at maintaining many human-managed habitats. Thus rewilding is likely to be slower in these areas though research indicates that recovery of species and vegetation continues despite management interventions. Finally, we discuss European rewilding in the worldwide context of responses to land-use change and anthropogenic modifications.

ACCELERATED MODERN HUMAN INDUCED SPECIES LOSSES: ENTERING THE SIXTH MASS EXTINCTION

Gerardo Ceballos

Universidad Nacional Autónoma de México
Anthony D. BARNOSKYB, Department of Integrative Biology and Museums of Paleontology and Vertebrate Zoology, University of California, Berkeley; Andrés AGUAYO, Instituto de Biología, Universidad Autónoma de México; Robert M. PRINGLE, Department of Ecology & Evolutionary Biology, Princeton University; Todd M. PALMER, Department of Biology, University of Florida, Gainesville, FL; Paul R. EHRLICH, Department of Biology, Stanford University

The oft-repeated claim that Earth's biota is entering a sixth "mass extinction" episode depends on clearly demonstrating that current extinction rates are far above the "background" rates prevailing outside of the five previous mass extinctions. We compare a recent background rate for fossil mammals, which is at least twice as high as most previous estimates, with conservative assessments of the number of extinctions in the past five centuries. Even under these extremely restrictive assumptions, the average rate of vertebrate species loss over the last century are up to 70 times higher than the background rate. Extinction rates have increased from the 17th century to present. Depending on the vertebrate taxa, the number of species that became extinct in the last century or so, would have taken from 1,100 to 9,700 years to become extinct under background rates. The exceptionally rapid loss of biodiversity over the last few centuries indicates that the sixth mass extinction is underway. Averting it may be possible through intensified conservation efforts, but that window of opportunity is rapidly closing.

95-CAN SPECIES TRAITS INFLUENCE THEIR VULNERABILITY TO ROAD IMPACTS?

Ana Ceia-Hasse

Centre for Ecology, Evolution and Environmental Changes, Faculdade de Ciências da Universidade de Lisboa[INSTITUTE] German Centre for Integrative Biodiversity Research (iDiv) Halle-Jena-Leipzig[INSTITUTE] Centro de Estudos do Ambiente e do Mar, Universidade de Aveiro
Trina RYTWINSKI, Geomatics and Landscape Ecology Research Laboratory, Department of Biology, Carleton University; Henrique M. PEREIRA, German Centre for Integrative Biodiversity Research (iDiv) Halle-Jena-Leipzig[INSTITUTE] Institute of Biology, Martin Luther University Halle-Wittenberg

Roads are a major threat to global biodiversity. Roads and traffic can affect wildlife populations in three major ways, by: (1) increasing mortality, (2) decreasing habitat amount and quality; and (3) fragmenting populations into smaller subpopulations, which are more vulnerable to local extinction. Species vulnerability to roads and traffic can be influenced by their life history traits and behavior towards roads, e.g., road attraction or road avoidance. Several studies indicate that species with lower reproductive rates and/or higher mobility are more vulnerable to negative road effects. Species that do not avoid roads or that are disturbed by traffic are also negatively affected. For instance, larger mammals with large home ranges, low reproductive rates and low natural densities, birds with larger territories, and all amphibians and reptiles are vulnerable to negative road impacts. Furthermore, simulation models predict that population abundance should not be reduced by roads for species with small territories and movement ranges, and high reproductive rates, such as many small mammals and birds. Explicitly combining extrinsic factors of threat and intrinsic species traits will allow moving from a descriptive to a mechanistic, biologically sound evaluation of threats. For example, modeling studies predict that species with low population growth rates and large minimum area requirements for population persistence can be negatively affected even in regions of low road density. Identifying which traits increase vulnerability to roads and traffic can help direct mitigation efforts towards the species that are most vulnerable. Also, strengthening the link between empirical knowledge and models will help to obtain a refined understanding of the impacts of roads and traffic across species and regions.

DO COMMUNICATION AND INFORMATION PROJECTS MATTER? - EFFECTIVENESS OF

Joanna Cent

Jagiellonian University

Agata PIETRZYK-KASZYŃSKA, Jagiellonian University ;
Malgorzata GRODZIŃSKA-JURCZAK, Jagiellonian University ;
Justyna GUTOWSKA, Jagiellonian University

Effective conservation requires not only sound biological and conservation science, but also good relationship with stakeholders and their engagement in actual conservation activities. This need is well recognized among both conservation scientists as well as policy makers. For example, European Union's biodiversity policies support financially not only direct conservation activities, but also educating and informing the public about the nature and the need for its protection. Although it is difficult to assess a precise contribution of education and information to the conservation outcomes, there is a need for evaluation of their actual results. Education and information campaigns require vast funding, however the benefits for the conservation are often unclear. We investigated the effectiveness of such campaigns in a case study project funded within LIFE+ INF program. "Natura Mission" LIFE INF project is conducted in Poland comprising several activities aimed at improving environmental awareness on Natura 2000 network among key stakeholders groups, local communities and general public. Special attention is given to conflict mitigation both on local level and in general all over the country. The project has been systematically evaluated at all of its stages (including ex ante, mid-term and ex post evaluation). Evaluation research provided information about stakeholders needs and opinions, used in planning project's activities, such as workshops, media campaign and consultancy. Likewise, assessing success or failure of the project's activities is based on the evaluation research. The evaluation shows differences in reaching stakeholders who are land users or land owners in one or more Natura 2000 areas, local societies and general public. Also, the funding program requirements create inflexibility of project activities that results in allocating time and efforts for less effective activities

HEGGEHOG AS AN ISLAND INVADER: A GENETIC PERSPECTIVE

Barbora Černá Bolfíková

Czech University of Life Sciences Prague
Miroslava LOUDOVÁ, Charles University in Prague ; Adam KONECNY, Masaryk University ; Kristýna ELIASOVA, Charles University in Prague ; Pavel HULVA, Charles University in Prague

The crucial steps in biological invasions, related to the shaping of genetic architecture and the current evolution of adaptations to a novel environment, usually occur in small populations during the phases of introduction and establishment. However, these processes are difficult to track in nature due to invasion lag, large geographic and temporal scales compared with human observation capabilities, the frequent depletion of genetic variance, admixture and other

phenomena. In our study, we used hedgehogs from the genus *Erinaceus* as model taxon for studying genetic background of invasion process. We compared genetic and historical evidence related to the invasion of the West European hedgehog to New Zealand, where they affect many local endemic species. We also included selected European islands with different timing of hedgehog introduction to compare genetic signatures of colonization histories. Historical information from New Zealand indicates that the species was initially established on the South Island. A molecular assay of populations from Great Britain and New Zealand using mitochondrial sequences and nuclear microsatellite loci proposed that the population of the North Island was most similar to that of the native area and showed greatest reduction in genetic variation caused by founder demography and/or drift. This evidence indicated the location of the establishment phase. The hypothesis was corroborated by data on climate and urbanization. The molecular and historical approaches have different explanatory power and the possible biases influencing the description of particular aspects of invasions, and we advocate the integration of the two types of approaches in invasion biology. The work was supported by Charles University grant GAUK 702214.

BIODIVERSITY MONITORING IN MOUNTAIN ECOSYSTEMS: A MULTI-TAXA APPROACH

Cristiana Cerrato

Institute of Atmospheric Sciences and Climate, National Research Council
Cristina MOVALLI, Val Grande National Park ; Luca PEDROTTI, Stelvio National Park ; Enrico VETTORAZZO, Dolomiti Bellunesi National Park ; Emanuel ROCCHIA, University of Milano Bicocca ; Antonello PROVENZALE, Institute of Geosciences and Earth Resources, National Research Council, ; Ramona VITERBI, Gran Paradiso National Park

Elevational gradients are natural laboratories to study species diversity and community level responses along patterns of environmental variation. Understanding how multiple taxa respond to elevation along the same gradient, as well as how the same taxa respond to different elevational gradients, is still an important and urgent task in conservation biology. In this framework, in 2012-2014, 6 Italian Parks (4 National Parks and 2 Regional Parks), located in the Alpine Region and covering its natural variability, shared a common protocol to study animal biodiversity in mountain ecosystems. Along 24 altitudinal transects, for a total of 132 sampling stations, ranging from 550 to 2700 m a.s.l., seven taxonomic groups were monitored (Coleoptera Carabidae, Coleoptera Staphylinidae, Araneae, Formicidae, Orthoptera, Lepidoptera Rhopalocera, Aves), using semi-quantitative standardized, easy to apply and cheap sampling techniques. Such protocol has been developed in order to be repeated every 5 years (2 ys monitoring – 4 ys stop; next session 2018-2019). We focused on recognizing

common points and differences between geographic areas and altitudinal zones. In this framework, we decomposed β -diversity into its nestedness and turnover components and we quantified the proportion of variation due to different factors (climate, habitat, altitude, spatial component). We observed that both climate and altitude have a fundamental role in shaping the observed communities, but at the same time a well-defined proportion of the variation depends on the geographical position of each protected areas, showing how each of them has its peculiar faunistic composition. We also identified the (group of) species characteristic of different areas and habitat types. To identify the parameters influencing species' distribution across large spatial scales represent an important tool for estimating current conservation value and obtaining a baseline against which measure future changes.

WETLAND RESTORATION AND AQUATIC BEETLES: COMMUNITY AND SPECIES LEVEL RESPONSES

Cristiana Cerrato

National Research Council

Silvia GHIDOTTI, University of Milano Bicocca ; Luca CRISTIANO, Civic Museum of Natural History ; Ramona VITERBI, Gran Paradiso National Park ; Massimo MEREGALLI, Turin University

Alpine wetlands represent a rare and fragile biotope in the European Alps, often altered by human activities, which strongly modify the water table, with negative effects on the biota. In 2013-2014, Gran Paradiso National Park (NW Italy) begun a restoration project in a transitional peat bog (6 ha, 2100 m a.s.l.), impacted by grazing and drainage channels. The restoration project consists of the exclusion of grazing and the positioning of small mobile dams, to reduce the channels effect and whose height can be manually regulated depending on the seasonal water table level. The effects of these activities have been tested, using aquatic beetles (Coleoptera Dytiscidae, Coleoptera Hydrophiloidea) as a target group. A sample of 23 ponds has been selected and each of them characterised measuring the amount of water, its seasonality and the water chemistry. The responses of aquatic beetles have been tested at two levels. At first, we evaluated if the ponds host communities with different faunal composition and which ponds' characteristics are the most influential one. We observed big differences in community composition, suggesting the importance of micro-habitat management. Secondly, we measured seasonal population dynamic and movements of two selected species (*Agabus congener* and *Agabus solieri*, Coleoptera Dytiscidae). A mark-release-recapture protocol has been developed. During each bi-monthly session, the captured specimens were permanently marked with an alphanumeric code, printed on water-proof paper and pasted over one elytra, and then immediately released in field. Such mark didn't reduce the flight ability of the specimens and allowed us to follow their movement through the humid area, during all the

season. We marked more than 600 specimens but we observed a low amount of movements, mainly executed by walking through the mud. Our results can offer important suggestions for the management of alpine humid areas.

SOCIAL PERCEPTION OF ALIEN SPECIES IN THE TUSCAN ARCHIPELAGO NATIONAL PARK (ITALY)

Jacopo Cerri

Game and Wildlife Conservation Trust

Francesca GIANNINI, Tuscan Archipelago National Park ; Michele GIUNTI, NEMO society ; Elena TRICARICO, University of Florence

Biological invasions are worldwide recognized as one of the most relevant threats to biodiversity and ecosystem services. Islands are particularly vulnerable to this phenomenon, and several heavy invasions were reported in these ecosystems. Being humans the first cause of introductions, an understanding of the social perception is critical to effectively tackle the problems associated with invasive alien species (IAS). The Tuscan Archipelago National Park, composed by seven main islands, was established in 1996. It is located in Central Italy, between the Ligurian and Tyrrhenian Sea, and several projects were conducted to preserve the local biodiversity and control the IAS, particularly alien plants. During 2012, within the Strategic project Co.R.E.M. ("Cooperation of ecological networks in the Mediterranean area", cooperation program Italy-France 2007/2013), we interviewed 237 local people to evaluate their knowledge and social perception on IAS present in Park. The majority of the people (90%) knew the term alien species, but they were not able to indicate an invasive one or did not consider invasive some well-known invasive species. Most local people (93%) bought alien plants because they are beautiful and more resistant than native ones, and did not know that some are highly invasive. They mostly stood up for managing IAS through eradication programs, controlling their trade, and establishing a sort of "black list" (95%), but, oddly, they were not willing to attend dissemination events on the topic (62%). Overall, they did not think IAS are the most important environmental problem for the Park (63%). It thus emerges that more dissemination programs are needed to increase the local awareness on the topic, and make proactive the people on IAS management.

185: ADAPTIVE STRATEGIES FOR MANAGING A METAPOPULATION OF CRYPTIC SUMATRAN TIGERS WITH DECLINING CONNECTIVITY

Iadine Chades

CSIRO

Yann DUJARDIN, CSIRO ; Arthur LE RHUN, CSIRO ; Guillaume CHAPRON, Swedish University of Agricultural Sciences ; Eve

MCDONALD-MADDEN, University of Queensland ; Sam NICOL, CSIRO

Threatened species are difficult to detect, with the consequence that many populations go extinct without us noticing. Deciding whether to continue investing in the protection of a threatened population that is already extinct could lead to a waste of scarce resources, while giving up too soon could lead to species' extinction. Finding the best strategy becomes even more difficult when managing metapopulations of cryptic threatened species with uncertain and changing connectivity over time, because with the right connectivity, individuals might have a chance of recolonising a declining population and saving it from extinction, but with poor connectivity, that population is unlikely to persist. Using a case study of Sumatran tigers, we study when uncertain and changing connectivity between sub-populations warrants implementing an adaptive management strategy. We solve this decision problem using a novel tool from Artificial Intelligence. While decision tools are often criticized for the complexity of their solutions and inaccessibility to stakeholders, our approach makes it possible to find the simplest adaptive management strategy that also maximises the chance of persistence of threatened species. By avoiding overly-complex adaptive management strategies, whilst still accounting for uncertainties, decision-makers can ensure that limited conservation funds are spent adequately. In doing, so we hope to contribute to bridging the gap between conservation decision science and practitioners.

DIVERSITY OF RHIZOBIA ASSOCIATED WITH LOCAL LUCERNE IN THE OASIS ECOSYSTEMS OF TUNISIA

Oumaima Chaieb

National Agronomic Institute of Tunisia[INSTITUTE]National Agricultural Research Institute of Tunisia[INSTITUTE] Research Regional Center of Oasis agriculture
Sihem BEN MAACHIA, Research Regional Center of Oasis agriculture ; Bouaziz SIFI, National Agricultural Research Institute of Tunisia

Abstract In arid ecosystems of Tunisia, oases are faced to high levels of land degradation exacerbated by climate change impacts. Alfalfa (*Medicago sativa* L.), the most important forage crop of oasis ecosystem can contribute to the improvement of soil fertility and soil conservation. As well, it can contribute to the maintenance and regeneration of the crops through a symbiotic nitrogen fixation. Both alfalfa and its nitrogen fixing symbiotic bacteria are affected by different abiotic stresses such as salinity, drought and high temperatures. Improvements in biological nitrogen fixation could be achieved through selection of native tolerant strains of nitrogen-fixing bacteria Rhizobia to these abiotic stresses. The study of natural nodulation showed that it depends of physicochemical factors

of soil and agricultural practices. Phenotypic characterization of 68 bacteria isolated from root nodules of local *Medicago sativa* plants growing in 28 soils of arid oases was studied. All strains can resist in high and low temperatures. 90% of strains were able to grow at pH ranging from 5 to 9, tolerate a high salt concentration 500 mM of NaCl and grew at a maximum temperature between 35 and 45° C. The rhizobia were very diverse with respect to their cross-nodulation patterns, as well as their physiological and biochemical properties. Almost all isolates shared the ability to nodulate with alfalfa. 10% of the strains were highly effective. The R38 stain claimed that was the highly efficient and classified astolerant to osmotic stress and moderately tolerant to nitrate stress. The strains which were highly effective in nitrogen fixation at the same time could intensively solubilize phosphates. The results obtained suggest that the phenotype of these rhizobia might have evolved to adapt to the local arid conditions. Keywords: Alfalfa, Rhizobia, Diversity, Nitrogen fixation, Abiotic stress, Phosphate solubilization

SPATIAL PRIORITIZATION IN COASTAL ECOSYSTEMS RESPONDING TO CLIMATE CHANGE

Debbie Chamberlain

University of Queensland

Hugh POSSINGHAM, University of Queensland ; Stuart PHINN, University of Queensland

In the design of marine protected areas we need to not only incorporate both the influence of connectivity and climate change, but also the effect of climate change on connectivity. We use a structured decision-making approach to determine suitable development and management options to safeguard a productive near shore fishery while accommodating climate change and the associated human responses. Most ectothermic marine species are operating at or near their thermal limits. Ontogenetic ecosystem connectivity has important consequences for reef and coastal organisms that have nursery habitats detached from reproductive populations. Increased ocean temperatures are expected to accelerate larval development, potentially leading to reduced pelagic durations and earlier settlement behaviour. The spatial scale of connectivity for planktivorous larval movement is predicted to be reduced leading to a convergence in dispersal distances. To develop robust plans for conservation, species-specific analyses explicitly defining responses to environmental change are incorporated into prioritization. Candidate areas are identified and by applying complementarity, areas are selected among the candidates. By incorporating demography and dispersal, mechanistic modelling and time-series analysis in remote sensing, we are developing a spatially coherent network for species dispersal and persistence under changed climatic conditions by maximizing the conservation benefit for the lowest cost. We use the Zonation spatial

prioritization software framework and apply our plan to the Mackay/Whitsunday NRM Region of Central Queensland employing feature specific connectivity. Parametisation is with environmental and physiological data using the iconic species *Lates calcarifer* an economically important species in near shore tropical regions.

WATER RESERVOIRS AND THEIR IMPLICATIONS IN THE CINEGETIC MAMMALS DISTRIBUTION IN THE SEMI-ARID: CONTRIBUTIONS TO THE CONSERVATION OF THE SERRA DA CAPIVARA NATIONAL PARK, SOUTHEASTERN PIAUÍ, BRAZIL

Marcia Chame

Oswaldo Cruz Foundation

Luiz Flamarion OLIVEIRA, Rio de Janeiro Federal University

The Serra da Capivara National Park (PNSC) - a World Heritage Site, is a 130,000ha area at the Caatinga Northeastern Brazil. There are no perennial watercourses at the PNSC and water is available only in man-made or natural reservoirs. We study the implications of water reservoirs over 20 cinegetic mammal species. All 443 reservoirs in the park area were classified by the species use, landscape and habitat components. The animals' use of the reservoirs was evaluated by ordination analysis, NMS, MRPP, Indicator Species Analysis. The presence or absence of each sample, species and land cover classes was transformed in occurrence favorability index by "Beals Smoothing". These values were transposed to the polygons of land cover classes, generating maps of occurrence favorability of all 20 studied species. The analysis identified three different groups related to the distinct environment conditions: i) *Mazama gouazoubira*, *Puma yagouaroundi*, *Leopardus tigrinus*, *Dasyprocta aff. nigriclunis* and *Cerdocyon thous* are distributed throughout the high dense scrubby Caatinga of the plateau area of the Park; ii) *Alouatta caraya* e *Sapajus libidinosus* are restricted to the forests of the interior of the deep canyons and; iii) *Panthera onca*, *Dasyopus spp.*, *Euphractus sexcinctus*, *Conepatus semistriatus*, *Tamandua tetradactyla* and *Kerodon rupestris* are distributed in corridors formed by a set of land cover patches. *Tolypeutes tricinctus*, *Callithrix jacchus*, *Procyon cancrivorus*, *Pecari tayassu*, *Mazama americana* showed no preferences. Great predators overlapped distribution, excluded small carnivores and short distance between the reservoirs is more important than the size of them, especially for the jaguar, while the large reservoirs are important points for the deer. These highlights the efforts made by the Foundation Museum of American Man (FUMDHAM), in and out of the park, since this is the most significant area for conservation in the region, specially the most targeted by hunters.

SISS-GEO: A PLATFORM FOR COLLABORATIVE CITIZEN-DRIVEN MONITORING OF WILDLIFE HEALTH

Marcia Chame

Fiocruz

Douglas Augusto, Fiocruz ; Eduardo KREMPSE, LNCC ; Livia ABDALLA, Fiocruz ; Helio BARBOSA, LNCC ; Luiz GADELHA, LNCC

SISS-Geo, a georeferenced information system on wildlife health, is a Brazilian initiative for prevention and prediction of threats to animal and--by consequence--human healths. Recruiting a group of professionals to track events concerning wildlife is expensive and clearly does not scale to large areas like the vast Brazilian territory. Aware of that, SISS-Geo takes the modern and increasingly popular approach of leveraging the collaborative effort of citizens to help monitoring wildlife health. Uncommon or abnormal wildlife occurrences observed by the volunteers can be promptly informed to SISS-Geo through a mobile application. Occurrences describe the observed situation, such as locality, involved animals and their conditions, and once received by the system they are grouped according to whether or not they represent the same event--for instance, when the occurrences are spatially and temporally connected. The next phase relies on a previously built regression model, which will process the just characterized wildlife event and predict its severity. High-severity events represent potential threats and therefore are immediately communicated to specialists for close inspection and confirmation. Roughly speaking, a prediction model works by evaluating linear and non-linear rules and relationships among variables derived from the event's occurrences. As one can guess, the effectiveness of SISS-Geo strongly depends on how accurate the model is. In order to obtain highly accurate models, SISS-Geo employs state-of-the-art machine learning techniques to automatically train and update the model, based on the growing data from the confirmation of past predictions. The prediction models, in particular the symbolic ones, also serve to the purpose of giving insights on what makes an event more or less severe. This can aid specialists to come up with more effective measures to preserve wildlife health and biodiversity.

FEATHERED FRIEND OR FEATHERED FOE? BIRDS LOVED AND HATED BY URBAN RESIDENTS

Brendan Champness

Federation University Australia

Dave KENDAL, University of Melbourne ; Grant PALMER, Federation University Australia ; James FITZSIMONS, The Nature Conservancy

Little is known about urban residents' opinions of the birds with which they share their streets and gardens. As urbanisation increases, this information could predict future conflicts between birds and humans in suburbia. In south-

eastern Australia, urban bird communities are comprised of numerous conspicuous generalist species and some woodland species where suburban and urban fringe habitat is suitable. Twenty participants from an Australian city were shown photographs of local bird species and asked to separate the photographs according to whether they liked or disliked the bird. The photographs included local urban and woodland birds which each participant had previously indicated were familiar to them. Greater than 75% of participants liked nine species of birds, including the Laughing Kookaburra, Australian Pelican, Crimson Rosella, Rainbow Lorikeet and Superb Fairy-wren. Many of these species are prominent and easily sighted within the suburbs of south-eastern Australian cities. Behaviour and colour seemed to be primary factors in these decisions. No species were disliked to such a degree, however half or more of participants disliked the Australian Magpie and Australian Raven, citing swooping, scavenging or "pest" status as reasons for disliking a species. Overall, colour, behaviour and personal experience with a species seemed to drive residents' reactions to local birds. These results suggest species which are useful for promoting community engagement in urban conservation programs, and those which are less useful. However, the lack of reaction to small woodland passerines (those in urban fringe habitats susceptible to population declines), suggests that despite awareness of their presence, local residents know relatively little about these species. Conservation agencies and scientists, it seems, can do much more to inform suburban residents of these birds and promote their conservation.

147 ESSENTIAL BIODIVERSITY VARIABLES FOR CONSERVATION NEEDS - OPPORTUNITIES FOR CITIZEN SCIENCE

Mark Chandler

Earthwatch Institute

With recent changes in technology and the ability to reach and interact with much wider audiences than ever before, Citizen Science is becoming an increasingly trusted and integral part of future scientific research, particularly in terms of data collection. With limited budgets for paying scientists and government-sponsored environmental monitoring, engaging citizens to help with ground-based monitoring efforts and reporting of rare events will be the only way of covering much of the planet's environments. This talk will examine how CS can contribute to ongoing efforts in biodiversity monitoring, e.g. through increased monitoring of data on key species and systems in a standardized manner, collection of information on Essential Biodiversity Variables (EBVs), or in reaching key constituencies who would benefit biodiversity observation networks through their involvement.

RECENT RANGE CONTRACTION OF THE ENDANGERED PYRENEAN DESMAN (GALEMYS PYRENAICUS) IN THE FRENCH PYRENEES

Anaïs Charbonnel

CNRS; UMR 5245; CNRS; EcoLab (Laboratoire Ecologie Fonctionnelle et Environnement)[INSTITUTE]Université de Toulouse; INP, UPS; EcoLab (Laboratoire Ecologie Fonctionnelle et Environnement)[INSTITUTE]Conservatoire des Espaces Naturels Midi-Pyrénées
Pascal LAFFAILLE, CNRS; UMR 5245; CNRS; EcoLab (Laboratoire Ecologie Fonctionnelle et Environnement)[INSTITUTE] Université de Toulouse; INP, UPS; EcoLab (Laboratoire Ecologie Fonctionnelle et Environnement) ; Marjorie BIFFI, CNRS; UMR 5245; CNRS; EcoLab (Laboratoire Ecologie Fonctionnelle et Environnement)[INSTITUTE]Université de Toulouse; INP, UPS; EcoLab (Laboratoire Ecologie Fonctionnelle et Environnement) ; Frédéric BLANC, Conservatoire des Espaces Naturels Midi-Pyrénées ; Mélanie NEMOZ, Conservatoire des Espaces Naturels Midi-Pyrénées ; Laetitia BUISSON, CNRS; UMR 5245; CNRS; EcoLab (Laboratoire Ecologie Fonctionnelle et Environnement) [INSTITUTE]Université de Toulouse; INP, UPS; EcoLab (Laboratoire Ecologie Fonctionnelle et Environnement)

The Pyrenean desman (*Galemys pyrenaicus*) is a threatened semi-aquatic mammal endemic to the mountain streams of the Pyrenees and the Iberian Peninsula. We compared an historical (1985-1992; 637 sites) and a current (2011-2013; 1222 sites) sampling conducted in the French Pyrenees to update the distribution of this species and highlight potential range shifts. After simulating the river flow across the entire stream network using the hydrological model Soil and Water Assessment Tool, we applied a consensus of Species Distribution Models to predict habitat suitability both in the historical and current periods while accounting for climatic (i.e., rainfall and temperature), hydrological (i.e., river flow) and land-use changes between the two periods. The Pyrenean desman range has strongly contracted all over the French Pyrenees with mean occurrence probabilities shifting from 0.70 (\pm 0.27) to 0.32 (\pm 0.17) for historical and current periods, respectively. We showed that the distribution of the Pyrenean desman is mainly constrained by climatic and hydrological factors, suggesting that this species is sensitive to modifications of these environmental factors. As climate change in the French Pyrenees is associated with warmer temperature and lower annual rainfall, this appears as a severe threat for the Pyrenean desman as streams with high temperature and low rainfall were highlighted not to be suitable for this species. Additionally, the place left to move to new climatically suitable habitats is strongly limited for this mountain species. However, the observed range contraction was much higher than the one projected when including only land-use, climatic and hydrological changes that have occurred during the two time

periods. This finding thus suggests that other factors, such as stream local habitat or biotic interactions (e.g. recent range expansion of invasive and native predators) may play an important role in the recent reported decline of this threatened species.

A TREE-RING PERSPECTIVE ON THE IMPACT OF CLIMATE CHANGE ON NORTH AMERICAN TREE GROWTH

Noah Charney

University of Arizona

Flurin BABST, University of Arizona ; Ben POULTER, Montana State University ; Sydne RECORD, Bryn Mawr College ; Brian ENQUIST, University of Arizona ; Valerie TROUET, University of Arizona ; Margaret Evans, University of Arizona

The fate of forests in a warming world is of major ecological, societal, and economic concern. Forests play a key role in the combined carbon-water-nutrient cycle, including important ecosystem services and feedbacks to the climate system. Historically, forests have been an important carbon sink because of an excess of net primary production (NPP) compared to ecosystem respiration, but the future of this carbon sink is increasingly in question, as NPP may decline in a warming world. We assessed how climate change will affect growth in North American forests, using an extensive network of tree-ring observations to calibrate the relationship between tree growth and climate. In particular, we parsed the effect of changing climate ("exposure") from changing sensitivity to climate ("sensitivity"). The effect of shifting climate sensitivity offsets much of the growth increase that would otherwise be projected for northern latitude forests due to warming. That is, much of the positive effect of 21st century warming on growth rates in temperature-limited forests is counteracted by the degree to which those forests become precipitation-limited in the future. All else being equal (i.e., assuming constant species composition, stand structure), we forecast the net effect of changing climate on North American tree growth rates to be a reduction between -5% and -17% by the second half of the 21st century, with the strongest reduction of growth rates associated with the most carbon-intensive emissions scenario. Geographically, the strongest reduction of growth rates is forecast for interior western parts of the U. S. and Canada, highlighting the vulnerability of these forests to climate change. Our gridded forecasts, based on empirically-determined climate-growth relationships, adds to the emerging evidence questioning the ability of future forests to mitigate global carbon emissions.

194 BEST AVAILABLE SOCIAL SCIENCE FOR ENVIRONMENTAL DECISION-MAKING

Susan Charnley

United States Forest Service

Courtney CAROTHERS, University of Alaska ; Terre SATTERFIELD, University of British Columbia ; Karma NORMAN, NOAA Northwest Fisheries Science Center ; Melissa POE, NOAA Northwest Fisheries Science Center ; Jamie DONATUTO, Swinomish Indian Tribal Community ; Sara BRESLOW, NOAA Northwest Fisheries Science Center ; Arielle LEVINE, San Diego State University

A number of laws, rules, and policies direct federal natural resource managers in the United States and other countries to consider the "best available science" in natural resource management decision-making. Yet rarely do these laws, rules, and policies provide managers and others with guidance on how to define or evaluate what the "best available science" is, or how to use it. Attempts to fill this gap have focused on the best available natural science. This paper provides insights for natural resource managers and others on how to assess and integrate the best available social science (BASS) into environmental decision-making to comply with best available science mandates, based on the experience of authors that have been involved in such efforts. We offer some definitions and standards for BASS, and compare and contrast them with those for natural science. We comment on how qualitative data, and traditional and local ecological knowledge, might be considered in best available science efforts – both sources of social science information that natural resource managers may have difficulty evaluating and using. We then provide two case examples – one from the U.S. Forest Service, one from the National Marine Fisheries Service – of how these federal agencies have attempted to integrate best available social science into natural resource management decision-making. Insights for improving best available science efforts drawn from these cases include: the need to identify at the outset what the key management questions are for which best available science is needed; to consider the social dimensions of the questions (rather than assume there aren't any) and assemble a team from the start that includes social scientists having the appropriate expertise; to determine how natural and social science will be integrated early on; and to work closely with decision-makers to deliver the scientific information needed in a meaningful and usable way.

TIGERS OF INDIA ARE AT RISK OF GETTING DISEASES FROM DOGS

Vratika Chaudhary

Clemson university

David TONKYN, Clemson university

In highly populated countries like India dogs thrive on human leftovers and live in densely packed human habitations and breed successfully multiple times a year. They are reservoirs for diseases like rabies, canine distemper virus (CDV), canine

parvovirus, canine adeno virus, tuberculosis etc. Apart from public health concern free ranging/ semi owned dogs, which are often unvaccinated, pose a serious threat to health of livestock and wild carnivores. CDV is the second most common cause of death due to infectious disease in domestic dogs and is emerging as a global health concern for endangered wild carnivores. In 1990s in Serengeti National Park, there was a steep decline in African lion (*Panthera leo*) population caused by CDV epidemic that was later found to be caused by spillover from domestic dogs. My study site is in Kanha Tiger Reserve, a deciduous protected area for endangered species such as tigers (*Panthera tigris*) in central Indian highlands. Most of the dogs that are found in Kanha Tiger Reserve are of communal ownership. They are seen to frequent the tiger reserve and they come in frequent contact of the wild carnivores. There is very little information available on the demography or population size of these dogs. Based on our surveys it was determined that these dogs are largely unvaccinated and suffer from general poor health conditions. In this study we conducted seropositivity surveillance of feral dogs and wild carnivores of the region. We have also studied odds ratio of infection at carnivore metacommunity level, genetic composition of the pathogens that jump species and are found both in feral and wild carnivores. Based on our ongoing study we can conclude that tigers and other wild carnivores of the region are at a risk as feral dogs act as reservoir communities for these infectious diseases.

INFECTION FROM DOGS: EMERGING THREAT TO WILD CARNIVORES

Vratika Chaudhary

Clemson university

David TONKYN, Clemson university; A.b. SHRIVASTAVA, CWFH

In many parts of the world, domestic dogs pose a significant though often overlooked threat to protected wildlife. In countries such as India, dogs thrive on human leftovers and can form large populations that move freely among towns, agricultural fields and protected areas. These free-ranging or semi-owned dogs are generally unvaccinated and can serve as reservoirs for rabies, canine distemper virus (CDV), canine parvovirus (CPV), canine adenovirus (CAV), and tuberculosis, which threaten humans, livestock and wildlife. For example, domestic dogs are believed to have been the source of a CDV epidemic that ravaged lions in the Serengeti National Park in the 1990s. More generally, CDV is the most common cause of death from infectious diseases in domestic dogs, and is emerging as a global health concern for endangered wild carnivores. We are studying the role of semi-owned dogs around the Kanha Tiger Reserve in central India as reservoirs of CDV and other diseases that threaten protected carnivores including tigers (*Panthera tigris*). Our surveys found that most of these dogs are communally owned, largely unvaccinated,

and in poor health. Still, they reach high densities and frequently enter the Reserve where they come in contact with wild carnivores. Our preliminary studies found that 85% of the dogs were sero-positive for CPV, 43% were positive for CDV and 52% were positive for, CAV representing past infections and not necessarily current infectivity. None were sero-positive for rabies, though infected individuals would be expected to die quickly and not be detected. We opportunistically examined samples from various wild carnivores, and are comparing the genetic composition of pathogens that jump species and calculating the odds ratio of infection at the carnivore metacommunity level. Our work to date suggests that tigers and other wild carnivores are at a risk from diseases carried by these feral dogs.

BEYOND TRADITIONAL PROTECTED AREAS: CONSERVATION LANDSCAPES TO ENSURE ECOLOGICALLY-RELEVANT AND COST-EFFICIENT LAND PROTECTION

Alienor Chauvenet

University of Queensland

Nathalie PETTORELLI, Institute of Zoology, ZSL; Guillaume CHAPRON, Swedish University of Agricultural Sciences; Matthew BECKER, Zambian Carnivore Programme; Sarah DURANT, Institute of Zoology, ZSL; Georgina MACE, University College London; Noelle KUMPEL, Conservation Programme, ZSL; Clare DUNCAN, Institute of Zoology, ZSL; Jonathan BAILLIE, Conservation Programme, ZSL

Protected areas (PAs) play a key role in global biodiversity conservation, being generally thought to safeguard biodiversity and help support local and regional ecosystem functions. Yet, an overwhelming majority of PAs are <5km², limiting their ability to prevent further biodiversity loss and to contribute towards securing key ecological processes and the provisioning of ecosystem services at scales relevant to dependent human communities. Here we propose a new approach to halting biodiversity loss, which could be achieved through multiple-use landscapes rather than strict protection. This paradigm shift in land protection and management relies on the identification of Conservation Landscapes (CLs), which are defined as areas able to sustain viable populations of the widest-ranging terrestrial species and help secure ecological processes. We describe a cost-benefit approach to identifying CLs to maximise biodiversity conservation outputs while minimising the long-term costs. Specifically, benefits are defined in terms of richness and representativeness of all species and threatened species; we index long-term costs using the Human Footprint as a proxy for opportunity cost, and the potential for climate to change as a measure of increases in future costs and pressure. We show through a case study in East Africa that the current reserve system does not encompass

all the most cost-effective conservation areas. In the light of the recommendations from 2014 IUCN World Parks Congress, we believe such options should be considered by wildlife management authorities when deciding on how to expand the current conservation areas network.

EVALUATING THE IMPACTS OF A SEAGRASS CONSERVATION EDUCATION PROGRAMME ON THE COMMUNITY'S ECOLOGICAL UNDERSTANDING AND PERSPECTIVES OF SEAGRASS CONSERVATION: A CASE STUDY IN PENANG, MALAYSIA.

Jiun Xiang Cheah

UNIVERSITI SAINS MALAYSIA

Leela RAJAMANI, UNIVERSITI SAINS MALAYSIA

Community-based approaches in marine conservation has been increasing in importance especially in developing countries where conservation funds are limited. However, information on the effectiveness of community participation in conservation education is also limited. This paper presents a case study of community involvement in a seagrass education programme in Penang, Malaysia. The education programme consists of two components, seagrass education and seagrass monitoring. The seagrass education uses diagrams, seagrass photos and informal conversations to disseminate information of seagrass biology, seagrass ecology, threats to seagrass and its conservation to the local community. To improve further their understanding, the community are invited to participate in a six-months seagrass monitoring using photo-library method. This method was adopted using Kutser et al (2007) to visually estimate seagrass dry weight using a photo-library of classes of different seagrass biomass. A catalogue of photo-library consisting seagrass photos and its corresponding biomass will be developed for the reference of the community during the fieldwork. Individual semi-structured interview surveys will be conducted before and after the seagrass education programme. Both the interview surveys will ask questions on general understanding on seagrasses, seagrass monitoring method, and perspectives towards seagrass conservation. The post interview surveys will also include questions on community opinions towards the seagrass education programme and lifestyles changes. The programme targets local fishermen, boat operators and university students. This study aims to assess the impacts of a seagrass education programme on the community's ecological understanding and perspectives of seagrass conservation.

HUMAN-WILDLIFE COEXISTENCE IN QOMOLANGMA (MT. EVEREST) NATURE RESERVE: CONFLICT AND RECOMMENDATIONS

Pengju Chen

Everest Snow Leopard Conservation Center[INSTITUTE]

Beijing Forestry University

Yufang GAO, Everest Snow Leopard Conservation

Center[INSTITUTE]Yale School of Forestry & Environmental Studies

Livestock depredation by large carnivores is increasing in Qomolangma (Mt. Everest) Nature Reserve, Tibet Autonomous Region of China. We conducted an assessment of local resident's interactions with wildlife, and evaluated the compensation scheme adopted by local authorities. We collected quantitative and qualitative data using multi-methods. We gathered 9,193 conflict records over 2011-2013 to analyze predation patterns. We interviewed government officials and local residents to understand perceptions about causes of conflict and effectiveness of the compensation program, including community participatory mapping to get local knowledge and perspective. We found snow leopards (*Panther uncia*), lynxes (*Lynx lynx*), dholes (*Cuon alpinus*), and wolves (*Canis lupus*) were major predators. The snow leopard tended to take yak and cattle, whereas lynx and dhole selected sheep and goat. Conflicts showed spatial and temporal patterns as different towns were impacted by different predators, mostly from March to July. Most respondents (68%) attributed causes to wildlife population growth, and only 6% blamed improper herding practices, while 7% said it was due to livestock population increase. The compensation scheme was flawed in virtually all aspects - evidence collection and verification, public involvement and communication, standards and procedures setting, resources allocation, implementation, monitoring and evaluation, and in its inability to terminate unsuccessful activities. Local residents and government officials highlighted different weaknesses of the management problem, due to their different identities, demands and expectations. We showed that human-wildlife conflict management can greatly benefit from an integrated, adaptive approach that targets the key aspects of the complex, interconnected social and management process at based in the conflict. Our recommendations sought to offer reduced conflict, improved conservation, and open, more effective management.

133 HOW BUDDHIST VALUES DRIVE ORGANIC FARMING IN TAIWAN

Li-Yi Cheng

Tse-Xin Organic Agriculture Foundation

Through organic farming, adapting a vegetarian diet, and planting trees, the Buddhist concepts of love and compassion are applied as part of our daily life by Tse-Xin Organic Agriculture Foundation (TOAF). The development of organic farming is the earliest and the most comprehensive of TOAF's efforts which began by introducing the purpose for organic farming through various educational camps and encouraging

farmers to convert to organic farming. TOAF also helps consumers and farmers understand why eating and planting organic food is healthy for people while promoting care for the many other living entities in agricultural fields. Through organic farming, the Buddhist disciple can practice love and compassion that builds a co-existing and cooperative relationship between people, other species, and the natural environment. TOAF involves the participation of not only Buddhists but also many others in the society to become healthier, to enrich their spirituality, and to demonstrate love and compassion which are shared universal values. Case studies of organic farmers and consumer behaviors will be discussed with the hope of drawing upon this shared value and inspiring love and compassion for all.

BEHAVIORAL CROWDING: IMPACT OF PROVISION OF EXTRINSIC BENEFITS ON ENVIRONMENTAL BEHAVIOR

Ashwini Chhatre

Indian School of Business

Arun AGRAWAL, University of Michigan ; Elisabeth GERBER, University of Michigan

We provide evidence that the foundational assumption motivating conservation interventions that seek to simultaneously address rural poverty and resource or habitat degradation is flawed – namely that providing material benefits to local residents shall persuade them to change behavior deemed to improve conservation outcomes. Evaluating the impact of a prototypical Integrated Conservation and Development intervention in the Indian Himalayas, we find that households who received material benefits through the program changed their behavior in environmentally unsustainable ways compared to matched counterparts who did not receive benefits. We use data on grazing and firewood use on 1432 households from before the start of the program in 2006 and at the end of in 2011, distributed equally across villages that received the program and those that did not. We further find that providing private material benefits to support rural livelihoods has the worst impact on behaviors related to open grazing of cattle in local forests and use of firewood for domestic energy also collected from local forests. On the other hand, households participating in creating public goods through the program reported slightly positive change in behaviors, though this is not statistically significant. In a related finding, we also report an adverse effect of the program and its activities on the intrinsic motivations of participating individuals to protect the environment. Our results not only corroborate existing critiques of ICDPs, but provide quantitative evidence about their adverse effects under certain conditions. This manuscript is part of a set of contributed papers organized by L. Glew, M. Mascia, and D. Miller. If accepted, please include this presentation in the program at the end.

A TREE IS A TREE? EFFECTS OF DIFFERENT TREES ON VEGETATION IN AGROFORESTRY STRIPS

Lucie Chmelíková

Technische Universität München

Harald SCHMID, Technische Universität München ; Sebastian WOLFRUM, Technische Universität München ; Kurt-Jürgen HÜLSBERGEN, Technische Universität München

High future demand for biomass will likely enhance fast growing tree plantations. Agroforestry, a corresponding sustainable agriculture practice, has many favourable properties. However, effects on biodiversity are little known. The aim of this study was to evaluate richness and composition of vascular plants in relation to different tree species in agroforestry strips. Data was collected at Scheyern research station located in southern Germany. In 2009 four short-rotation coppice systems comprising three 8.25 m wide tree strips were planted. Each strip consists of three double rows spaced 1.5 m apart. After first harvest in February 2013, vegetation was recorded in May 2013 and September 2014 in 140 plots (0.75 x 1.5 m). Sampled tree species included black alder (*Alnus glutinosa*), black locust (*Robinia pseudoacacia*), poplar Max 3 (*Populus maximowiczii* x *Populus nigra*), willow Inger (*Salix triandra* x *Salix viminalis*) and a mixture of regionally common hedge trees. Sites with different trees showed different plant species composition and richness. In 2013, 36 species belonging to 19 families were recorded. The most frequent families were Poaceae, Fabaceae and Polygonaceae. In 2014, the number of species increased to 40 from 21 families, mostly Asteraceae, Poaceae, Rosaceae and Fabaceae. The highest species richness was recorded in willow for 2013 and black locust for 2014. In both years, poplar showed lowest species richness. Legumes and forest species, which were not present at sites with black locust and black alder, favoured few nutrients in soil and low light availability. The most species were hemicryptophytes. Weed species, annual species and species with ruderal strategy disappeared with time. Six years after plantation typical species for natural hedgerows appeared. Plant species richness and composition thus suggested little limitation by nutrient availability, but more by light conditions due to tree species characteristics and location within strips.

GIVE THEM DESSERT: INCREASING BENEFICIAL INVERTEBRATES IN WHEAT AGROECOSYSTEMS

Beth Choate

Allegheny College

Jonathan LUNDGREN, USDA-ARS, North Central Agricultural Research Station

Wheat is grown worldwide on approximately 520 million acres and provides 20% of calories and protein consumed across the globe. Sustainable and efficient management of wheat

is essential to reduce negative environmental impacts and ensure necessary food supplies. Cereal aphids are responsible for reducing wheat yields; however, management against these species is rare, particularly in North America. Generalist predators may contribute to reducing cereal aphid numbers and prevent significant damage to crops. A two-year field study was conducted in South Dakota spring wheat aimed at identifying the arthropod communities throughout wheat fields and the role of non-prey foods in enhancing these communities. Plots of spring wheat were planted and surrounded by alfalfa borders to evaluate the effects of diverse cropping systems. Borders were treated with high and low inputs of sucrose to mimic plants with extrafloral nectaries. The arthropod complex in wheat was diverse with 103 taxa identified. Sentinel bird cherry-oat aphids were placed on wheat plants and predator gut-content analysis employed to identify specific predators. The role of a sugar in enhancing predator communities and the role of predators in reducing aphid communities provides important guidelines toward creating a self-sustaining wheat agroecosystem.

BIOLOG & BIOLIB, MOBILE & WEB SPECIES MAPPING APPLICATIONS AIMING AT PUBLIC

Karel Chobot

Nature Conservation Agency CZ

BioLog and BioLib are two species occurrence mapping applications in the Czech Republic. BioLog is an Android app replacing the field notepad by using the advantages of mobile technologies (mapping, location, time, and media) for gathering the species observations by public. The app has been originally developed by Nature Conservation Agency of CZ as a mobile device for their experts, but it is open to public use. The data collected via BioLog are public, and after validation procedure imported to the central Species Occurrence Database, the official instrument of nature conservation authorities, but also as a source of data for research purposes. BioLib is a web page originally intended as taxonomically structured photo gallery of all species, but the branch of citizen science: mapping of species of mammals, amphibians, reptiles, dragonflies and selected species of beetles and spiders has evolved. Although created as an independent project, the data flows are recently also connected to the Species Occurrence Database. Both applications are examples of good practice of use of citizen science in both nature conservation practice and research. <http://biolog.nature.cz> <http://www.biolib.cz/>

PREDICTING THE IMPACTS OF SEA LEVEL RISE ON SEA TURTLE ROOKERIES IN LOW-LAYING ISLANDS: A CASE OF CONDAO ARCHIPELAGO (VIETNAM)

Cuong Chu

Vietnam Academy of Science and Technology

Martin DAHL, Department of Ecology, Environment and Plant Sciences, Stockholm University

Vietnam is the most vulnerable country in Southeast Asia to sea level rise, which is expected to be 0.5–1.4 m through 2100. Approximately 80% of green turtle (*Chelonia mydas*) nesting in Vietnam is on the Con Dao Islands. In this study, we used three climate change scenarios to estimate the loss of nesting area on the Con Dao Islands beaches (n = 5) in relation to predicted sea level rise through 2100. Previous studies have not considered the seasonal nature of turtle nesting and monthly tidal fluctuations. To address this gap, we estimated the impact of sea level rise for each month separately during the nesting season. Beach profile measurements and digital elevation models were used for simulation of sea level rise. The nests in 2011 defined the nesting area. Our results showed that the period June–August would experience the lowest impact (17–36% loss of nesting area by 2100), and October–November the highest impact (43–56% loss by 2100). This result matches with the nesting activity in 2011, which was highest between June and August when the beach is at its maximum width. Tide data showed that June to August also had the lowest tidal impact during 1980–2009. We concluded that rising sea levels today and in the future have the potential to reduce nesting space, lower breeding success, and cause an increase in conspecific nest destruction on the Con Dao Islands. To predict the impact of sea level rise, monthly variations must be considered because nesting activity is seasonal.

133. IDEA TO ACTION: THE EMERGENCE OF FAITH-BASED CONSERVATION IN THE EASTERN HIMALAYAS AND EAST AFRICA

Dekila Chungyalpa

Yale University

The results of qualitative and quantitative research on faith-based conservation projects established by Tibetan Buddhist leaders in the Eastern Himalayas and the Catholic Church in East Africa that were supported by the Sacred Earth Program at WWF between the period of 2009 and 2014 are the focus of this presentation. Two different sets of questions are explored: (1) Does environmental advocacy from senior faith leaders lead to measurable pro-environmental behavior change at the institutional level and (2) is there also a comparable attitude change among individual monastics? Findings from the two case studies demonstrate that an environmental call to action from senior faith leaders can result in pro-environmental behavior among their religious institutions and communities. The more specific the call, the more efficacious and tangible the pro-environmental behavior is. At the same time, distinguishing between individual attitude change and

institutional behavior change is important because regulations at an institutional level do not necessarily lead to or imply an attitude shift at the individual level. Without the engagement and support of middle-tier monastic managers, the initial faith-based environmental effort can be unsustainable as a management model. The religious institutions with strong physically present leadership and that receive consistent capacity building efforts are the most successful in reaching their own environmental goals and engaging their wider communities.

AUGMENTATION OF THE CRITICALLY ENDANGERED SPECIES, *ALOE SAUNDERSIAE*

Brigitte Church

Ezemvelo KZN Wildlife

Sharon LOUW, Ezemvelo KZN Wildlife

Aloe saundersiae which occurs in Kwazulu-Natal South Africa is an endemic, critically endangered plant with a very restricted range and very specific habitat requirements. The species was not afforded any formal protection and the area of occurrence fell below the conservation target. At the initiation of this project in 2003 there was only one extant population with two subpopulations. As introduction to a protected area was one of the recommended interventions in the recovery plan, a modelled distribution of the species was used to select three sites in a protected area for a trial introduction. Adult plants grown *ex situ* from seed collected from the natural site were planted in suitable microsites within the three selected sites. The quantitative measures of success at each site are based on the number of surviving introduced plants, the number of progeny that reach reproductive maturity, the number of inflorescences produced per year and the number of new seedlings per year. Results after 10 years of monitoring show varied success at the three sites. Adult survival rate varied from 74% to 43%. Although flowers, seeds and seedlings have been produced at all sites only one site has completed a full life history cycle in which progeny have flowered and produced seeds and seedlings. Despite this, current interventions including this introduction programme have improved the status of the species through an increase in area of occurrence from 0.76km² to 9.58km² and an increase in area of occupancy from 0.75km² to 2.25km². Recommendations for ongoing monitoring and management to secure this species are made.

HUMAN-WILDLIFE CONFLICT IN EASTERN TURKEY: GAINING PERSPECTIVE FROM COMMUNITY SURVEYS

Mark Chynoweth

University of Utah

Emrah COBAN, KuzeyDoga Society ; Cagatay ALTIN, Celal Bayar University ; Cagan SEKERCIOGLU, University of Utah

Human dimensions of wildlife management are critical to the success of a wildlife management program. The input of stakeholders at the local level can help determine how a conservation organization can mitigate potential human-wildlife conflicts. In the Sarikamis-Allahuekber Mountains National Park and surrounding forests in eastern Turkey's Kars province, large carnivores are facing increasing threats due to human activity. Villagers in this area have an integral relationship with the forest, which provides firewood, grazing areas and recreational opportunities. The main threats to large carnivores in the region include unchecked development, habitat loss and fragmentation, illegal resource extraction, and direct persecution. To provide a comprehensive conservation and management plan, the KuzeyDoga Society is conducting long-term monitoring of large carnivores, including a community outreach program. As part of this program, we are conducting community surveys in villages surrounding the national park to understand the opinion of local villagers concerning large carnivore presence, wildlife management, and designation of protected areas. We conducted 682 surveys in 2010 and 267 surveys in 2014 at 29 villages surrounding the national park. Seventy-seven percent of respondents see wildlife on a regular basis in the area immediately surrounding their village, and 53% of these people consider these interactions harmful. However, the majority of survey respondents are aware of ecotourism as an economic opportunity (63%) and have a desire to participate in future wildlife ecotourism opportunities (74%). These and other results of this survey provide guidance for the KuzeyDoga Society to further develop their community outreach program and sustain populations of brown bears, gray wolves, Caucasian lynx and other wildlife species in eastern Turkey.

CONSERVATION IN A COMPLEX WORLD: MODELLING THE BOREAL FOREST-CARIBOU COMPLEX SYSTEM, A CASE FOR ABM SIMULATION

Fabian Cid Yañez

UBC

Lael PARROTT, UBC ; Frédéric RAULIER, Université Laval ; Daniel FORTIN, Université Laval ; Guillaume LATOMBE, Monash University

Conserving populations of boreal caribou (*Rangifer tarandus caribou*) in Canada is of paramount ecological and cultural importance. Caribou can be considered a fine filter for the ecological integrity of the boreal forest, also culturally important as many communities rely on caribou as symbol or source of food. Additionally, the ultimate cause of caribou's threatened status is the human encroachment and habitat loss caused by recreational, industrial and forest activities.

Therefore, connecting the social and ecological systems to help manage caribou conservation becomes a key aspect for defining conservation strategies. In this case, our objective is to provide forest planning decision makers with a decision support tool that could help them assess the viability of forest management strategies under caribou conservation goals. For doing so, an Agent-based model (ABM) of caribou movement and interactions is setup to test forest planning strategies. The model captures movement data from telemetry observations for two other species: moose (*Alces americanus*) and wolves (*Canis lupus*). The resulting movement sub-models allow the species to interact in a fairly dynamic environment for a given period of time. Functional responses and population dynamics can emerge from these interactions. Some difficulties for the model arise when fitting scales of different ecological processes. To overcome these challenges, landscape structure is quantified and movement sub-models derived accordingly. A prototype model will be presented and the validation process discussed to simulate movement and dynamics in future managed landscapes. The goal is to derive process-pattern relationships to facilitate caribou self-sustainability and estimate trade-offs between the management production and conservation objectives.

A BEFORE-AFTER-CONTROL-IMPACT (BACI) STUDY OF THE SAPODILLA CAYES MARINE RESERVE IN BELIZE

John Cigliano

Cedar Crest College

Richard KLIMAN, Cedar Crest College

The Sapodilla Cayes Marine Reserve (SCMR) was established in 1996 at the southern end of the Mesoamerican barrier reef to protect and replenish local fisheries. The SCMR is divided into three zones of varying levels of protection: a General Use Zone (GUZ), where commercial extractive activities are allowed but managed; two Conservation Zones (CZ), where no commercial extractive activities are allowed (subsistence harvesting is allowed in one of the zones); and a Preservation Zone (PZ), where entry is prohibited except with a special permit. Enforcement began in April 2010. The goal of this project was to conduct a before-after-control-impact (BACI) study to determine if the conservation goal of the reserve was being fulfilled for queen conch (*Strombus gigas*). We collected pre- and post-enforcement data (n=3 yrs each) on density, size (total length), and age (lip thickness; queen conch are considered subadults with lips <5mm and adults with lips ≥5mm) of conch in shallow-water (<3m) aggregations in both control/unprotected (GUZ, n=3) and impacted/protected (CZ, n=6) sites. We found no significant BACI effect for density (P=0.6724), size (P=0.2910), or age (P=0.5817) with all sites included. We also found no significant effect when single impacted sites were compared to control sites. However, there

are signs of recovery. Conch returned to one site that did not have conch within 5 months of enforcement and we observed for the first time conch laying eggs in shallow water. The lack of a BACI effect is likely due to the parallel response of control and impacted sites. This likely occurred because the few fishers that regularly fished the SCMR left once enforcement began, essentially turning the entire reserve, including the GUZ, into a protected area. We conclude that enforcement is likely having a positive effect but additional and regular monitoring is required to confirm this conclusion.

A PLAYBACK EXPERIMENT ON THE EFFECTS OF NATURAL ENERGY EXTRACTION NOISE ON WILDLIFE: THE PHANTOM NATURAL GAS FIELD.

Elizeth Cinto Mejia

Boise State University

Christopher J.w. MCCLURE, Peregrine Fund ; Jesse Rex BARBER, Boise State University

Energy infrastructure and related extraction activities are expected to more than double in the western US in the next few decades. Gas extraction activities negatively impact wildlife abundance and diversity. For instance, avian abundance and species richness are reduced near gas compressor stations. No work has experimentally parsed the role that compressor station noise alone plays in these impacts. We have recreated the noise component of natural gas compressor stations, a prominent element of extraction fields, using speaker arrays at four sites in a shrub steppe habitat and simultaneously monitored four control sites. We present preliminary results demonstrating that noise affects the distribution of birds, bats, and insects. Ongoing work is focusing on how noise might impact trophic relationships in sage steppe ecosystems

TRANSITION TO SUSTAINABILITY: AN ECOSYSTEMS-BASED APPROACH TO MODELING URBAN METABOLISM

Ioan Manuel Ciumasu

Institute of Innovation for Transition to Sustainability - INTRAS

Kalliopi NTANOU, Institute of Innovation for Transition to Sustainability - INTRAS ; Teodora KOOS-MORAR, Institute of Innovation for Transition to Sustainability - INTRAS [INSTITUTE] Institute of Innovation for Transition to Sustainability - INTRAS

Urban systems embody, as a human community scale, the current contradiction between development and nature conservation goals at planetary scale. According to the systemic understanding of sustainability, any economic system is a sub-system of a social system which is itself a subsystem of a natural system in which is embedded and on which is dependent. This nested inclusion relationship means

that sustainable development requires that ecological issues must be given priority in policy and management, followed by social issues and then by economic issues. However, the public opinion favors an opposite order: it demands that economic problems are solved first, followed by social issues, with environmental issues being left at the end. In this communication, we propose a way forward through a holistic eco-city reference model (ECRM) that reviews and extends the notion of urban metabolism to include ecological, social and economic aspects. The model is formulated as a composite algorithm that aggregates information and knowledge from various fields of science (starting with environmental quality parameters) into a set of holistic parameters that policy-oriented, the most important being the city resilience, city footprint and city livability. System complexities and limitation of knowledge are being addressed through recently developed concepts in sustainability studies. A set of sustainability filters (SF) – environmental, social and economic – accounts for the systemic order of priorities. The notion of Urban Sustainability Nexus (USN) is used to manage the interdependencies between landscape, water, energy and transport within cities. Using this model, we show that, in the pursuit of better and sustainable living in cities, citizens can assimilate better principles of nature conservation. We anticipate that urban ecosystems and biodiversity are key themes in the transition to sustainable development, because they facilitate interaction between experts and public.

SYMPOSIUM 188: BARRIERS TO BIODIVERSITY IN FLUVIAL ECOSYSTEMS” RELYING ON HISTORICAL ECOLOGY TO PLAN THE RECOVERY OF THE EUROPEAN EEL

Miguel Clavero

Estación Biológica de Doñana-CSIC

Virgilio HEMOSO, CEMFOR-CTFC Forest Sciences Center of Catalonia

Energy infrastructure and related extraction activities are expected to more than double in the western US in the next few decades. Gas extraction activities negatively impact wildlife abundance and diversity. For instance, avian abundance and species richness are reduced near gas compressor stations. ARE AUSTRALIAN'S JUST OBSERVERS TO SHOREBIRD POPULATION DECLINES BEING DRIVEN FROM OVERSEAS?

Robert S. Clemens

University of Queensland

Greg A. SKILLETER, University of Queensland ; Richard A. FULLER, University of Queensland

The conservation of non-breeding habitats for migratory species is critical for the long-term viability of populations. However, for highly mobile or migratory species, population increases or decreases at a local scale may or may not be related to local conditions. Local conservation efforts, monitoring effectiveness, and our understanding of the costs and benefits of taking conservation actions at local habitats are confounded when species populations may have declined due to factors outside those local habitats. Migratory shorebirds that visit Australia during the non-breeding season are declining rapidly, and by analysing count data we discover three more species that can be added to the list of those showing widespread declines. Local shorebird population declines are most rapid at both ephemeral wetlands, which are filling more intermittently or disappearing altogether, and many large wetlands reliant on freshwater flows which are decreasing in water quality or increasing in salinity. Using a continental citizen science count data set we investigated why some local populations are faring better or worse than others, and find important geographic variation including greater declines in the south for some species. We also discover a strong negative correlation between predicted inland suitability and coastal abundance of four shorebird species, suggesting a combination of markedly different habitats is used during the non-breeding season further confounding local scale analyses. Finally, we explore whether this dynamic habitat suitability is related to population changes as management increasingly dampens the pattern of wetland availability. With growing evidence that shorebird population declines are driven by habitat loss in East Asia, we show here that variation in conditions in the non-breeding areas in Australia also may play a role.

SYMPOSIUM ID: 76. CAN PAYMENTS FOR ENVIRONMENTAL SERVICES CONSERVE HABITATS AND ALLEVIATE POVERTY AT THE SAME TIME? A CASE STUDY FROM NORTHERN CAMBODIA.

Tom Clements

Wildlife Conservation Society

E.j. MILNER-GULLAND, Imperial College London

The potential impacts of Payments for Environmental Services (PES) and Protected Areas (PAs) on environmental outcomes and local livelihoods in developing countries are

contentious and have been widely debated. The available evidence is sparse, with few rigorous evaluations of the environmental and social impacts of PAs and particularly PES. We measured the impacts on forests and human wellbeing of three different PES programs instituted within two PAs in northern Cambodia, using a panel of intervention villages and matched controls. Both PES and PAs delivered additional environmental outcomes: reducing deforestation rates significantly in comparison with controls. PAs increased security of access to land and forest resources for local households, benefiting forest resource users, but restricting households' ability to expand and diversify their agriculture. PES impacts on household wellbeing were related to the magnitude of the payments provided: the two higher-paying market-linked PES programs had significant positive impacts, whereas a lower-paying program that targeted biodiversity protection had no detectable effect on livelihoods, despite its positive environmental outcomes. Households that signed up to the higher-paying PES programs, however, typically needed more capital assets and hence they were less poor and more food secure than other villagers. Therefore, whereas the impacts of PAs on household wellbeing were limited overall and varied between livelihood strategies, the PES programs had significant positive impacts on livelihoods for those that could afford to participate. Our results confirm theories that PES, when designed appropriately, can be a powerful new tool for delivering conservation goals whilst benefiting local people.

MAKING A DIFFERENCE: THE IMPACT OF SEED CONSERVATION AND TRANSLOCATION ON THREATENED PLANT RECOVERY

Anne Cochrane

Department of Parks and Wildlife

Leonie MONKS, Department of Parks and Wildlife ; Andrew CRAWFORD, Department of Parks and Wildlife

Implementing effective conservation strategies is essential to stem the loss of global biodiversity. Seed banks deliver one of a number of important strategies for supporting the conservation of threatened plant species. Seed banks collect, evaluate and store seeds under conditions that minimise seed deterioration as an insurance against species or population loss. Adequate collections of viable seed with a broad genetic base are required to provide effective support for conservation activities such as threatened species translocation. The goals of translocation are to increase plant numbers, create or maintain self-sustaining populations and ideally down-grade a species from its threatened ranking, thereby positively affecting the conservation status of the species. Evaluating the success of each step of the translocation process, from seed germination through to survival of reproducing adults on the ground, can help prioritise and set targets for future seed collection. Here we highlight the benefits of integrating ex situ seed storage

and plant translocation programs to help provide for better conservation outcomes. We use Western Australian examples to illustrate how translocation supported by seed conservation is making an important contribution towards improving conservation status of a wide range of threatened species across this unique global biodiversity hotspot.

THRESHOLDS OF CHANGE IN A MULTI-USE CONSERVATION LANDSCAPE OF SOUTH AFRICA: HISTORICAL LAND-COVER, FUTURE TRANSFORMATION AND ENVIRONMENTAL DECISION-MAKING IN THE KRUGER TO CANYONS BIOSPHERE RESERVE

Kaera Coetzer

University of the Witwatersrand

Edward T F WITKOWSKI, University of the Witwatersrand ; Barend F N ERASMUS, University of the Witwatersrand

Biosphere Reserves (BRs), as multi-use conservation landscapes, exemplify the landscape mosaic approach to environmental decision-making. With dual biodiversity conservation and sustainable development objectives, they provide a long-term perspective that aims to improve the relationship between traditional conservation and sustainable use; providing local communities with options to sustainably manage environmental resources into the future. South Africa has six BRs listed with UNESCO's Man and the Biosphere Programme (MaB), with the Kruger to Canyons Biosphere Reserve (K2C) in north-eastern South Africa, one of the largest globally. K2C is a spatially structured socio-ecological system, with important economic sectors and world-renowned protected areas proximal to extensive, mostly rural, human populations engaged in informal livelihood practices. In this study, time-series remotely-sensed data (1993 – 2006 – 2012) was used to track landscape transformation across the subregion, analysing spatial changes in cover relative to the theoretical MaB concept. The focus is on changes in the scale of land-cover change (spatial extent, rate, intensity of change) across the analysis period, simulating future changes to 2018 and 2024. Results indicate that the spatial distribution of these land-cover changes bear little regard for the prescriptive BR zonation and the relative limitations on 'use' that typifies successful BR implementation. The increased rate of change in the recent observation period (2.3% versus 5.7%) poses challenges for landscape management, with future predictions of escalating transformation likely to undermine BR sustainability long-term. Consequently, the thresholds for scheduling proactive management action have been identified, allowing for timely detection of unfavourable transformations while practical options for intervention remain.

159 - AN ANALYSIS OF PLANT CONSERVATION TRANSLOCATIONS IN EUROPE

Bruno Colas

Université Paris Sud [INSTITUTE] Univ. Paris Diderot
Juan FERNANDEZ-MANJARRES, CNRS - Univ. Paris Sud 11

Alternative views for managing biodiversity oppose on the one hand the conservation of extant biodiversity at all costs, and on the other hand, the management of landscapes to allow evolution continue while accepting extinctions. These views question our conception of wilderness, but they are not mutually exclusive although tools for reconciling them are not easily available. One management option that seeks to manage endangered populations and may also target landscape restoration is species translocation. We focus here on conservation translocation which consists in the deliberate movement of organisms from one site for release into another, for a conservation benefit at the levels of a population, species or ecosystem (cf. IUCN). We have set up a database of more than 800 conservation translocations of plants and animals in Europe over the last 150 years. Parallel to the presentation of Thévenin et al. (this symposium), which focuses on animals, we present here some results on plants from the database. First, we compared translocated species with all plant species in Europe to see whether translocated species consist of a particular subset of taxonomic groups (genera and families), life forms (herbs, shrubs, trees...), and other life history traits (pollination syndromes). We also identified the types of translocations that have been undertaken, according to the IUCN typology for conservation translocations (reinforcement, reintroduction, assisted migration). We compared the frequencies of the different translocation types in plants and examined possible differences with animals in the light of differences in dispersal abilities. Lastly, we discuss the demographic survey and the viability of translocated plant populations, and the need for more long-term demographic data.

99. URBANISATION AND GREEN-SPACE - INFLUENCES ON HUMAN WELL-BEING, BIODIVERSITY KNOWLEDGE AND CONSERVATION SUPPORT.

Debbie Coldwell

University of Sheffield
Karl EVANS, University of Sheffield

There is a vast amount of literature on the well-being benefits people get from spending time in nature. It is also widely assumed that greater nature engagement may lead to increased biodiversity knowledge and willingness to protect it. There is thus rising concern that urbanisation will increasingly disconnect people from nature, reducing the benefits delivered by green-spaces as well as conservation support.

This talk presents results of household surveys conducted in six urban areas across England across the full range of the socio-economic spectrum present in each area. These data inform understanding of how people perceive urbanisation and green-space, and how at a local scale these influence human well-being, biodiversity knowledge and interest in environmental protection.

GENETIC DIVERSITY IN RINGED SEALS (*PUSA HISPIDA*) FROM THE BALTIC SEA AND THE ADJACENT LAKES

Bethany Cole

University of Lincoln
P UKKONEN, University of Helsinki; O KARLSSON, Swedish Museum of Natural History; Malgorzata PILOT, University of Lincoln

Ringed seals (*Pusa hispida*) rely on ice for breeding and foraging, so winter ice cover is vital. The southern location of the Baltic, Lakes Ladoga and Saimaa ringed seals may render them vulnerable to climate change effects, combined with human disturbance from ships, fisheries, and pollution, which may affect their recovery from the 1970's bottleneck. Modern ring seal populations from Ladoga and Saimaa lakes, landlocked for nearly 10,000 years, have reduced genetic diversity, which may be due to both long-term genetic drift and the recent bottleneck. Mitochondrial DNA was sequenced from ancient and modern ringed seal samples, and aligned with published sequences. Nucleotide diversity of Baltic ringed seals decreased from 0.037-0.038 in 1850-1925 to 0.032 in 2000-2012. Ancient ringed seals (14,000-3,000 BP) had lower nucleotide diversity (0.029) compared to modern Baltic populations. This could be an underestimation due to the small sample size (N=11), but may also suggest that initial colonisation of the Baltic was followed by subsequent gene flow from genetically diverse sources. Spatial analysis showed high nucleotide diversity (0.044-0.049) in different parts of the Baltic Sea: Bay of Finland, Bay of Bothnia and Archipelago Sea; 8.6% of haplotypes were shared among these colonies. Comparatively low nucleotide diversity was found in Lake Ladoga: 0.028 and Lake Saimaa: 0.027, reflecting strong genetic drift. Lake Saimaa shared 2 haplotypes (9.5%) with Lake Ladoga and the Baltic, while Lake Ladoga shared 5 with the Baltic and 1 with Lake Saimaa (19% altogether). Some shared haplotypes were only found in museum specimens, implying recent bottlenecks further increased levels of genetic differentiation among these populations. Overall, these results suggest recent bottlenecks could have caused a larger loss of genetic diversity in the Baltic and adjacent lake populations than genetic drift acting on these populations since their founding in early Holocene.

134 MARXAN'S ROLE IN PARTICIPATORY PLANNING PROCESSES

Heather Coleman

PacMARA

Norma SERRA-SOGAS, PacMARA ; Jeff ARDRON, PacMARA

Marxan spatial planning software supports systematic conservation and resource use planning. It is best known as a decision support tool to aid the development of marine protected area networks, but is just as applicable to other systems and scales. Using Marxan or Marxan with Zones, planners can identify an efficient system of management areas that represents a suite of targets for a minimal socioeconomic "cost." Many challenging decisions are inherent to solving this problem, including setting targets for each feature, determining appropriate socio-economic input values, and working with stakeholders to understand the role and outputs of a decision support tool. Technical considerations for successful Marxan use in participatory planning processes are also under-discussed, considering the popularity and wide usage of the tool, and good practices in both areas deserve more attention. Teaching managerial-level and technical Marxan courses internationally has provided us with insight into challenges and problems faced by Marxan users in any context. This presentation will include current good practice considerations for Marxan as part of a participatory planning process.

WHICH NATURAL AREAS DO WE MOSTLY VISIT? IMPLICATIONS ON CONNECTEDNESS WITH NATURE AND RESTORATION

Agathe Colléony

Centre d'Ecologie et des Sciences de la Conservation, UMR 7204 Muséum National d'Histoire Naturelle

Anne-Caroline PRÉVOT, Centre d'Ecologie et des Sciences de la Conservation, UMR 7204 Muséum National d'Histoire Naturelle ; Susan CLAYTON, College of Wooster

Much research effort has been done to explore the effects of natural areas on human health, well-being and environmental concern. However, with urbanization, biodiversity crises and western way of life, the opportunities to experience nature rarefy, and the growing disconnection of people with nature jeopardizes global conservation efforts. It is therefore extremely important to know which kind of nature are mostly preferred and used by individuals, before building sustainable conservation and pro-nature managements. In this paper, we present results on nature connectedness and nature habits of 2744 French adults, based on the exploration of questionnaires coming from three complementary data sets: 1126 students from various disciplines, 1172 adults from a virtual game community, and 446 zoo visitors. We explored the type and

frequency of natural areas they visit mostly, the place they have grown up, and their connectedness with nature, i.e. the extent to which an individual feels being part of the natural environment. We found significant differences between the three groups in the type of natural areas they visit mostly. For instance, gamers mentioned significantly more their personal natural areas (e.g. their own garden), and zoo visitors were more concerned with animal presence in natural areas (e.g. zoos). However, in all the three groups, the forested areas are largely more mentioned than other natural areas, suggesting a common appealing for forests in these populations. Mediation effects of connectedness with nature on the relationship between place of childhood and natural areas' visits are clarified. These results are discussed in light of restorative aspects of nature, the potential of nature to reduce cognitive fatigue and other sources of stress. Finally, consequences of this result in terms of landscape management and education are examined.

TENSION, CELEBRATION AND FAIRNESS OF HUNTING PRACTICE IN THE ETHNOZOOLOGY OF NEWFOUNDLAND MOOSE

Cory Collins

Memorial University of Newfoundland

The Eurasian elk or moose is an invasive species on the island of Newfoundland, having been introduced via extremely small founder populations in 1878 and 1904. Moose create problems for the regeneration of balsam fir and hardwoods and appear to have negative affects on certain birds and lichens in Newfoundland, and reduce its hopes for a sustainable forestry industry. At the same time, however, moose and their hunting have been meaningfully integrated into Newfoundlanders' cultural identities and a system of traditional knowledge, centred in part around notions of 'fairness' of relations between species, has developed in tandem. I examine the dynamics of these relationships and knowledges using interviews with moose hunters, moose meat consumers, moose-vehicle collision victims and their families as well as secondary literature. I find that this ethic of hunting and the entrenchment of moose as a cultural identifier in Newfoundland exist in uneasy tension with increasing moose-vehicle collisions but are also reinforced by amused interest in episodes where moose wander into urban centres.

SNAPPING TURTLE (CHELYDRA SERPENTINA) HOME RANGE ANALYSIS IN AN OPEN RIVER SYSTEM: IMPLICATIONS FOR CONSERVATION AND HARVEST REGULATIONS

Benjamin Colteaux

Virginia Commonwealth University

Derek JOHNSON, Virginia Commonwealth University

The snapping turtle is an iconic large-bodied reptile native to freshwater lakes and rivers in the eastern United States. Increased commercial harvest pressure on these turtles has raised concern about the sustainability of the species. Understanding the movement patterns and home range of snapping turtles is critical for making informed conservation decisions. In particular, a snapping turtle's home range can be used to infer size- and sex-specific movement patterns, habitat use, conspecific interactions, and population density. Historical accounts of snapping turtle demography is based almost exclusively on lake habitats, yet the majority of commercial harvest pressure is exerted on river and estuarine systems, which offer greater public access to trappers. Here we estimate seasonal home range sizes for 23 snapping turtles within the Chickahominy watershed, Virginia, USA. We found that average home range size was larger during the summer (1.04 ha), than during the spring (0.25 ha) or autumn (0.44 ha) sessions. On average males had larger home ranges than females, both overall (4.22 to 3.50 ha) and seasonally (ranging between 18 – 38% larger). Home range size was not correlated with body mass. Additionally, we found that home ranges were unexpectedly smaller, but overlapped more, in this open river system compared to findings from lake environments. Their sedentary nature may expose this riverine snapping turtle population to increased risk of overharvest as a large number of turtles can be more easily trapped in congregations over a relatively small area. Repopulation following a commercial harvest event may also be difficult due to the limited dispersal ability shown by this population. These results suggest that effective snapping turtle management should include the prevention of extirpating local populations as a conservation priority.

THE ROLE OF ZOOS IN ATTITUDES TOWARDS BIODIVERSITY AND THE REINTRODUCTION OF NATIVE WILD CARNIVORES TO THE UK: RESULTS FROM A PILOT STUDY

Adriana Consorte-McCrea

Canterbury Christ Church University

Ana FERNADEZ, Canterbury Christ Church University ; Alan BAINBRIDGE, Canterbury Christ Church University ; Dennis NIGBUR, Canterbury Christ Church University

Our research investigates the role of zoos in forming attitudes towards biodiversity and towards wild carnivores (European lynx *Lynx lynx*, and pine marten *Martes martes*), native to the UK within historical times, which have been considered for reintroduction, to inform species conservation strategies in the UK and Europe. The project being developed by an interdisciplinary team (wildlife conservation, psychology, education) employs a mixed methods approach, based on an

expanded version of the Theory of Planned Behaviour and on personal narratives. Research suggests that experiences with animals in zoos encourage empathy, through personal connection, which facilitates greater concern towards biodiversity. IUCN guidelines state the need for public support to establish viable, free-ranging populations in the wild, therefore, carnivore restoration benefits from an understanding of human dimensions. The reintroduction of carnivores to their native habitats may help regulate ecosystem dynamics. Carnivores carry a rich cultural and historical heritage that makes their reintroduction even more relevant. The first of the pilot studies taking place in Kent (Spring 2015) uses focus groups and interviews. Results will be discussed in the light of findings about attitudes towards lynx and pine marten and their conservation and potential reintroduction in the UK; how attitudes relate to knowledge, to socio-demographic variables (age, gender, place of residence), and to zoo membership. Results will inform the design of questionnaires and interviews to be carried out in north-west England and Scotland. A nuanced understanding of local people's attitudes towards native carnivores allows for a cost-effective way to identify and address points of conflict between them and wildlife, and saves time. A baseline survey of attitudes will enable the evaluation of the effect of the deployment of future plans for environmental education on attitudes of interest groups.

91-GETTING SCIENTIFIC EVIDENCE USED IN PRACTICE: PROGRESS, BARRIERS AND SOLUTIONS.

TITLE: ACHIEVING CONSERVATION SCIENCE THAT BRIDGES THE KNOWLEDGE-ACTION BOUNDARY

Carly N Cook

Monash University

Michael B MASCIA, Conservation International ; Mark W SCHWARTZ, University of California ; Hugh P POSSINGHAM, University of Queensland ; Richard A FULLER, University of Queensland

There are many barriers to using science to inform conservation policy and practice. Conservation scientists wishing to produce management-relevant research must balance this goal with the imperative of demonstrating novelty and rigor in their science. Decision makers seeking to make evidence-based decisions must balance a desire for knowledge with the need to act despite uncertainty. Generating science that will effectively inform management decisions requires that the knowledge created be salient (relevant and timely), credible (authoritative, believable, and trusted), and legitimate (developed via a process that considers the values and perspectives of all relevant actors) to both researchers and decision makers. This paper outlines some of the challenges for those hoping to generate conservation science that achieves all three of these information characteristics, and highlights some of the

successful ways creative scientists and decision makers have found to facilitate science that will inform management. We discuss examples of effective solutions to generating science that crosses the knowledge-action boundary including: boundary organizations (environmental organizations that span the boundary between science and management), embedding research scientists in resource management agencies, creating formal links between decision makers and scientists at research-focused institutions, and innovative training programs for conservation professionals. The success of these, and other, approaches to generating boundary-spanning science hinge on incorporating mechanisms for promoting communication, translation, and mediation across the knowledge-action boundary. Learning from current successes can help conservation science become a more effective boundary science, which both advances scientific understanding and contributes to decision making.

USING THE POLICY SCIENCES ANALYTICAL FRAMEWORK IN THE ASSESSMENT, IMPLEMENTATION AND MONITORING OF ADAPTIVE ECOSYSTEM-BASED APPROACHES TO RESOURCE MANAGEMENT

John R Coon

University of New Hampshire[INSTITUTE]University of New Hampshire

Mimi L BECKER, University of New Hampshire[INSTITUTE] University of New Hampshire ; Thomas LEE, University of New Hampshire

Biological diversity and ecosystem resilience are undoubtedly eroding and the deterioration of ecosystem functions is likely accelerating at a global scale, with potentially catastrophic social consequences if current trends are not significantly mitigated. There is a growing sense that traditional scientific management approaches are failing, and may in fact be making the problems worse. Despite growing popularity of various iterations of adaptive management there is little sign that stress on ecosystem function is abating. While many continue to cite the need for adaptive management, there exist few real-world examples of institutional arrangements designed for the sustainable regulation of natural resource protection and use. Absent the capacity to implement and monitor an ecosystem approach to restore ecological integrity and human sustainability, environmental policy decision makers and managers will not succeed in addressing critical environmental problems. We propose a tool that has the capability of assessing existing governance while fostering a successful adaptive approach. We rely upon the analytical framework of the Policy Sciences to derive characteristics that would be representative of an "ideal" adaptive, ecosystem-based approach to management. We argue that management

regimes that most closely resemble the ideal governance characteristics proposed in this study will show greater progress toward restoration and goal achievement than projects that differ greatly from the ideal. Our proposal fosters an intelligence system derived from the use of monitoring indicators that will trigger adaptive responses if trends for critical functions are moving away from goals. The governance regime that existed in the Great Lakes Basin during the early years of the Great Lakes Water Quality Agreement efforts of the 1970's and 1980's and a more recent regime in the Bay of Fundy/Gulf of Maine watershed are then compared with the ideal characteristics.

97. CAN CITIZEN SCIENCE MOTIVATE SCIENCE-BASED RATHER THAN EMOTION-BASED MANAGEMENT DECISIONS FOR SONGBIRDS IN A RESIDENTIAL LANDSCAPE?

Caren Cooper

North Carolina Museum of Natural Sciences

Larson LINCOLN, Clemson University; Mark HAUBER, Hunter College

Citizen science has the potential to coordinate and inform public stewardship of songbirds for a positive cumulative impact. We focused on public efforts to enhance nesting by native passerines and control invasive competitors. In the United States, many people try to prevent the non-native house sparrows' attempts to breed. Given insufficient data to directly assess the efficacy of management options, and the clear need for citizen science participation to fill the data gap, we created The House Sparrow Project to assess the decision-making process of citizen scientists. Using web-based surveys, we investigated two questions: (1) What are the primary factors influencing citizen scientists' choice of management actions for minimizing sparrow breeding? (2) Does citizen science participation increase the likelihood that management decisions are guided by scientific evidence (science-based) rather than personal experience and affect (emotion-based)? We found that emotions and personal experience matter tremendously in this system. The best predictors of lethal management were firsthand contact with House Sparrow damage, antipathy associated with specific House Sparrow encounters, and general feelings about House Sparrows. Using pre-post surveys we found changes in management orientation varied with level of project engagement. Support for emotion-based management decreased during the project among participants who engaged at medium or high levels, and increased among low-level participants. We characterize changes among participants with low engagement as counterproductive "onlooker effects," potentially important given the ubiquity of skewed engagement of citizen science programs. Insights from this study deepen understanding of the affective and cognitive drivers of backyard management

and highlight the complexity of using citizen science to fill a data gap and support participants in achieving desired conservation outcomes.

CLIMATE REFUGIA AND BIODIVERSITY CONSERVATION IN AN ERA OF ANTHROPOGENIC CLIMATE CHANGE

Laura Coristine

University of Ottawa

Paul GALPERN, University of Calgary ; Andrew PLOWRIGHT, University of British Columbia ; Juan ZULOAGA, University of Ottawa ; Cassandra ROBILLARD, University of Ottawa ; Emily ACHESON, University of Ottawa ; Rosanna SOARES, University of Ottawa ; Jeremy KERR, University of Ottawa

Climate refugia maintained populations of some species during periods of paleoclimatic change and could mitigate extinction risks during anthropogenic climate changes. Because both climatic variability and rates of change can cause species' populations to shift or disappear, the rate of climate change and the magnitude of climatic variability within refugia should be lower than in surrounding areas if climate refugia are to provide biologically significant shelter for species. Using long term, high resolution climate data across the most intensively observed regions of North America, we identify areas where relative variability and rates of change are low despite the substantial climatic shifts observed subsequent to 1975. Rate and interannual variability of climate are assessed, at multiple spatial scales (ranging from 2800 to 230,000 km²) using mean annual temperature and precipitation seasonality data from 1975-2010. There are significant areas distributed across much of continental North America that have, to date, shown potential as climatic refugia. However, the utility of these refugia hinges on whether they are distributed across areas with high species diversity or coincide with existing or potential protected areas. Climate refugia overlap with such areas is limited, suggesting that species vulnerabilities may be greatest where refugia are most limited in their extent.

INDICATORS OF ECOLOGICAL CHANGE: AN INTER-SITE COMPARISON OF A CONCURRENT MONITORING OF WILDLIFE OCCURRENCE AND HUNTING ACTIVITY IN CENTRAL AFRICA

Daniel Cornelis

Cirad

Nathalie VAN VLIET, CIFOR ; Nicolas GAIDET, Cirad ; Jean-Claude N'GUINGUIRI, FAO ; Robert NASI, CIFOR ; Alain BILLAND, Cirad ; Sébastien LE BEL, Cirad

Choosing and adapting wildlife management options ideally requires appropriate and affordable information on trends in animal populations and offtakes over several years. In

African tropical forests, most studies have been documenting separately wildlife abundance, offtake and consumption of bushmeat. In addition, most site-level assessments were so far implemented using different methodologies, thus limiting the potential for meta-analysis at inter-site level. Yet, measuring concurrently spatial patterns of wildlife occurrence and hunting activities at different sites along gradients of human pressure (land conversion, human density) may provide a useful basis to identify indicators of non-sustainability of hunting, and to help predict temporal trends at site level. In this study, we implemented a standard protocol aiming at assessing bushmeat use and availability over 6 hunting grounds located in the Congo Basin (Gabon, Congo, and Democratic Republic of Congo). This preliminary diagnostic was conducted to evaluate the feasibility of testing community-based hunting approaches in the framework of a FAO/GEF project. For this purpose, we mapped the contours and the principal features of every hunting ground, and characterized the management rules, wildlife resources, hunting practices, offtakes and consumption. Results of the comparison between sites show how indicators of game species availability (e.g. species diversity, abundance indices, etc.) and resource use (e.g. catch per unit effort, ratio between small and large body-sized species, composition of the catch, etc.) vary in contexts of contrasted hunting pressure. We discuss their respective relevance as a basis for implementing evidence-based wildlife management strategies through adaptive management.

49-HABITAT FRAGMENTATION EFFECTS ON BIODIVERSITY SERVICES REVISITED- EFFECTS OF FOREST EDGE FORMATION ON INSECTS AND PLANTS

Tatiana Cornelissen

Universidade Federal de Sao Joao del Rei

Insects and plants are major components of terrestrial ecosystems and insects have the potential to alter plant population dynamics, community structure and ecosystem functioning through their effects as herbivores. Recently, habitat fragmentation has turned into one of the most important threats to biological diversity and a common feature of habitat fragmentation is a sharp increase in the amount of induced or artificial edges, exposing plant and animal populations in fragmented habitats to ecological changes associated to edge formation. We reviewed the evidence for the effects of fragmentation on insects and plants by conducting a meta-analysis for the effects of artificial forest edge formation on insect herbivore abundance, herbivore richness and plant herbivory, with data pooled from 31 studies and 159 independent comparisons. Edge formation exhibited strong effects on plant herbivory rates, as plants on edges exhibited about 70% more damage than plants in

interior patches. Edges also increased herbivore abundance by 14% and herbivore richness by almost 65%. Effects of edge formation were stronger for Lepidoptera (mainly caterpillars were evaluated) and Orthoptera. Edge effects were also stronger for forested ecosystems compared to open habitats and for temperate regions. Because the studies here evaluated did not simultaneously evaluate bottom-up and/or top-down factors, the mechanisms responsible for the patterns found cannot be properly addressed, although variation in host plant chemistry and/or relaxation of pressure exerted by natural enemies can be suggested as potential factors explaining variation in herbivory between edge and interior habitats. Higher herbivory rates on edge habitats, as shown by our meta-analytical review, have the potential to alter community composition and should be studied in detail to unravel its effects on ecosystem functioning.

COMMUNITY RESILIENCE AND ADAPTION IN A CHANGING ARCTIC: POLICY CHALLENGES AND OPPORTUNITIES FOR MARINE MAMMAL SUBSISTENCE USERS

Leslie Cornick

Alaska Pacific University

The Arctic is the sentinel for climate change on several fronts – tangible changes to ecosystems are observable in real time, including the opening of the Northwest Passage, the loss of seasonal sea ice and shore fast ice, and increased interest in off-shore oil and gas development, shipping and tourism. Indigenous communities in several Arctic nations (e.g., United States, Canada, Norway) rely on the subsistence hunting of marine mammals as a significant component of their food security and cultural life ways. Changes in ocean temperatures and ocean acidification may alter the timing and distribution of marine mammal prey, which may then alter migration and residence patterns. Changes in seasonal sea ice and shore fast ice have already altered behavior and accessibility of ice seals, walrus and polar bears, and make large whale hunting from shore more dangerous. Increased development of offshore oil and gas and shipping increase the risk of oil and other contaminant spills and ship strikes. In order to continue to harvest these resources safely and reliably, indigenous communities must consider how to adapt to the shifts that climate change continues to bring to the region. In order to preserve coastal communities, policy makers in Arctic nations must consider indigenous rights as they develop policies for sustainable Arctic development and conservation. Treaty rights, co-management agreements, and regular and genuine stakeholder engagement are critical for these communities to adapt to a changing Arctic climate and maintain the subsistence practices that sustain them, for both food security and cultural preservation. Using Alaska as a case

study, this presentation will address the current challenges and opportunities for coastal communities that rely on marine mammal subsistence, define the current state of relevant Arctic policy, and make recommendations for policy makers and communities to preserve access to these critical resources.

SYMPOSIUM 65: CITIZEN SCIENCES FOR MONITORING BIODIVERSITY IN HABITAT STRUCTURED SPACES

Camille Coron

Université Paris Sud

Christophe GIRAUD, Université Paris Sud ; Clément CALENGE, Office National de la Chasse et de la Faune Sauvage ; Romain JULLIARD, Museum National d'Histoire Naturelle

Our aim is to estimate the abundance of a common species, using data coming from different citizen science programs. Space is divided into sites and we estimate relative abundances of several species between any two sites by combining standardized and opportunistic datasets. Species detecting probability, and site observation intensity are also estimated for each dataset. More practically, a second step consists in considering space habitat structure and taking into account the respective preferences of observers and of each observed species for each habitat. The model for the behavior of observers is different for each dataset. We estimate abundances, habitat preferences and observation efforts, and study the role of opportunistic data in improving the accuracy of these estimations.

POTENTIAL BENEFITS AND TRADE-OFFS BETWEEN BIODIVERSITY CONSERVATION AND BIOFUEL PRODUCTION WHEN USING MICROALGAE PRODUCTION FARMS

Diego Felipe Correa

University of Queensland

Hugh POSSINGHAM, University of Queensland ; Hawthorne BEYER, University of Queensland ; Skye THOMAS-HALL, University of Queensland ; Peer SCHENK, University of Queensland

Ongoing population growth and increasing energy demands pose further pressures on resource consumption and on biodiversity conservation. Biofuel production systems have been proposed as a more sustainable alternative for energy production in comparison to the use of fossil fuels. However, several studies discuss the potential negative environmental effects of biofuel production; which include loss of biodiversity in areas where native ecosystems, cropland and pasture mosaics are transformed for extensive monocultures. Recent advances in production technologies have shown that microalgae cropping can be a suitable

alternative for biofuel production, as result of its high yield potential per unit area. This could result in better optimization of land use for biofuel production, increasing the potential of biodiversity conservation. Additionally, algal cultivation is possible in areas with low precipitation levels, which have been negatively related to areas with high biodiversity values. Here, we review the potential benefits and trade-offs between biofuel production and biodiversity conservation when using microalgae production farms, comparing the environmental impacts between microalgae production ponds and extensive crops for biofuel production, taking into account differences on land use change. This research could lead to a better understanding on how the production of biofuel in smaller areas can relate to the conservation of native biodiversity at regional scales.

MEASURING AND MAPPING THE DIGITAL SALIENCY OF BIODIVERSITY

Ricardo Correia

Universidade Federal de Alagoas[INSTITUTE]University of Oxford

Peter LONG, University of Oxford ; Ana MALHADO, Universidade Federal de Alagoas ; Richard LADLE, Universidade Federal de Alagoas[INSTITUTE]University of Oxford ; Paul JEPSON, University of Oxford

The success of nature and biodiversity conservation efforts often depends on public support. Understanding and monitoring changes in conservation values over space and time and identifying the causes of these changes are therefore essential for a wide variety of conservation actions. The emerging field of 'culturomics' potentially provides new analytical techniques for studying social change and opens new possibilities to explore the interactions between social and natural sciences. Here, we briefly review the conceptual and methodological frameworks for mapping the saliency of biodiversity across space with a first example of its application to a case study using Brazilian birds. Specifically, we applied innovative 'culturomic' techniques to measure and map the digital saliency of Brazilian birds in national and international contexts. Our results clearly illustrate the potential of 'culturomics' for metricizing, measuring and mapping the digital saliency of conservation issues. In the example shown, bird assemblages of more populated and/or visited regions (where local people/international visitors see and engage with birds) tend to show a higher cultural saliency. Beyond their intrinsic interest, such results have the potential to inform macro-geographic conservation policy: for example, the choice of flagship species, PA designation or the focus of national and international awareness raising initiatives.

ASSESSING PUBLIC SALIENCY AND AWARENESS OF PROTECTED AREAS USING DIGITAL TOOLS

Ricardo Correia

Universidade Federal de Alagoas[INSTITUTE]University of Oxford

Ana MALHADO, Universidade Federal de Alagoas ; Paul JEPSON, University of Oxford ; Richard LADLE, Universidade Federal de Alagoas[INSTITUTE]University of Oxford

Protected areas (PAs) were originally created as strongholds for the conservation of iconic landscapes and endangered wildlife, but are nowadays expected to serve a much wider range of conservation and social goals. Despite their conservation importance, PAs are under increasing threat from development and economic interests due to competition for land and natural resources. While the increase in the extent of PAs (terrestrial and marine) over the last few decades has been remarkable, there is also evidence for an increasing number of degazettement, downgrading and downsizing events (usually referred to as PADDD). This is the case in Brazil, with its world-renowned PA network undergoing major PADDD events over the last decade. Under this scenario of increasing threats to PAs, public support is essential to avert further PADDD events. Here, we make a first attempt to assess the saliency and awareness of PAs within Brazilian society using an innovative set of digital tools. Our results demonstrate clear patterns of variation in public awareness for both different PA categories and individual protected areas. National Parks have the highest levels of saliency and, presumably, public support. However, other PA types garner comparatively less attention and may therefore be at increased risk of PADDD. Our results demonstrate the enormous potential of new digital tools to generate insights into public awareness of conservation issues. In the specific case of Brazilian PAs, measurements of digital saliency could be used to identify deficits in public awareness that can form the basis of future campaigns.

ENHANCING LEADERSHIP SKILLS FOR OUR NEXT GENERATION OF CONSERVATION LEADERS

Colleen Corrigan

University of Queensland

The skills required to be a successful conservation leader are underexplored and there is a significant role for the higher education sector to play in training and producing strong leaders (Dietz et al 2004). A review of conservation science leadership literature identified eight core principles associated with conservation leadership and recommendations for adhering to these principles (Manolis et al 2008). While self-development was found to be a critical mechanism for leadership enhancement, several of the recommendations suggested roles for education in delivering instruction in

leadership theory and skills development. These included actions such as facilitating networking opportunities between students and local conservation leaders and the provision of placements for first-hand engagement with professionals in the workplace (Manolis et al 2008). In a separate study, results using in-depth interviews of ten conservation leaders also indicated that education programs on the topics of economics and environmental policy, as well as exposure to a network of professional contacts, were important factors in success (Dietz et al 2004). While these studies provide some evidence for how to build environmental leadership, our collective understanding about skills that effective leaders require, as well as the approaches to acquire them, is limited, especially for professionals faced with current and future environmental issues. While conservation leadership programs are not new, their effectiveness has not been systematically evaluated and there is much to be learned from past experiences in these tailored programs as well as from other sectors that can provide innovation in resolving complex issues. This poster explores the development of a new leadership program in the Centre of Excellence for Environmental Decisions at the University of Queensland and insights gained on how institutions can collaborate through joint learning from past and current experiences.

SYMPOSIUM ID # 193. - FROM ABANDONED TO WILD LANDSCAPES: PRACTICES, CONSEQUENCES AND PERCEPTIONS OF REWILDING IN EUROPE.
TITLE : TOP SCAVENGERS IN A WILDER AND MORE UNPREDICTABLE EUROPE

Ainara Cortés Avizanda
CIBIO-InBIO

Avian scavengers are the target of restoration programs linked to the manipulation of food resources but we lack of a general approach to understanding how scavengers and the ecosystem services they provide will fit into a rewilded Europe. Carcasses play a key role in ecosystem functioning and energy-flux within food webs. Large ungulate carcass availability has through the course of evolution, given way to the appearance of true scavenger strategies displayed by vultures whose guilds are structured by complex interspecific relationships. Traditional agro-grazing systems have historically replaced wild ungulates as food source for vultures. In Europe this fact was exacerbated by modern farm intensification join to a stricter EU legislation that banned the abandonment of carcasses in parallel with arising human-vulture conflicts leading vulture populations to an unprecedented crisis. Consequently, supplementary feeding became a worldwide management recovery tool. Vulture restaurants, however, alter the spatial-temporal nature of food with strong consequences at individual, population,

community and ecosystem levels. The conservation of avian scavengers in rewilding European landscapes should rely on wild ungulate expansion, the recovery of large carnivore populations and, in humanized areas, the promotion of traditional extensive agro-grazing systems limiting artificial feeding activities. So, it may be possible to combine both the historically recognized ecosystem services provided by vultures (elimination of remains, nutrient cycling) with new recreational (aesthetical) while providing economic benefits to local societies. Vultures and other scavengers, because they exploit space at a huge scale, are singular actors within a rewilded Europe. Their conservation, and that of the ecological processes in which they are involved, requires large-scale approaches surpassing those limits imposed by administrations, habitats and even biomes.

LONG TERM MORTALITY PATTERNS IN THE ENDANGERED HUEMUL DEER (HIPPOCAMELUS BISULCUS) OF PATAGONIA

Paulo Corti

Instituto de Ciencia Animal & Programa de Investigacion Aplicada en Fauna Silvestre, Facultad de Ciencias Veterinarias, Universidad Austral de Chile
Achaz VON HARDENBERG, Alpine Wildlife Research Centre, Gran Paradiso National Park, Degioz 11

Conservation of endangered ungulates requires high quality data and long term monitoring of their populations. Most populations of threatened ungulates lack this information, which affects recovery and management plans. We conducted a 7-year study in Chilean Patagonia, from April 2005 to June 2012, to assess mortality patters in one huemul deer population. This endangered deer is endemic to the southern Andes of Chile and Argentina with a total population of less than 2,000 individuals. We identified 151 deer of all sex-age classes with ear tags, radiocollars, radio ear tags, or natural marks, recording a total of 62 mortality events. We recognized three main causes of mortality during the study period: predation from cougars (*Puma concolor*; 23% of all mortality), culpeo foxes (*Lycalopex culpaeus*; 29%), and domestic dogs (18%). In addition, we recorded isolated mortality events due to poaching, accidents, senescence, or undetermined causes of death (31%). On average, cougars preyed on 2 ± 1.91 huemul/year, culpeo foxes 2.57 ± 2.64 deer/year, and dogs killed 1.57 ± 1.27 huemul/year. Foxes only preyed on fawns, but cougars and dogs killed all age and sex classes. Here we model the implications of the predation by different predators on the dynamics of this huemul population. Management plans for the conservation of huemul should focus in monitoring populations in a long-term setting to account for predation variability and its real effects on population growth. In addition, a plan to control dogs, which are an anthropogenic cause of relevant loss in the huemul population, is urgently needed.

HOW WIDE SHOULD A CORRIDOR BE? USING RADIO-TRACKING DATA TO ESTIMATE WIDTH OF AMPHIBIAN MOVEMENT

Stephanie Coster

West Virginia University

Jessica VEYSEY POWELL, University of New Hampshire ;

Kimberly BABBITT, University of New Hampshire

A common question in the design of conservation corridors is: how wide should a corridor be? We used radio-tracking data from wood frogs (*Lithobates sylvaticus*) and spotted salamanders (*Ambystoma maculatum*) in a managed forest in Maine (U.S.A.) to characterize movement patterns of populations, and thus inform planning for the width of wildlife corridors. For each individual, we calculated the polar coordinates of all locations, estimated the vector sum of the polar coordinates, and measured the distance from each location to the vector sum. We created a population-level probability density function and estimated 95th percentiles to determine the width of lateral movement as individuals progressed from the pond to upland habitat. We found 95% of wood frog movements were ≤ 51 m wide and 95% of spotted salamander movements were ≤ 39 m wide. We have gathered movement data from other amphibian studies and are conducting a meta-analysis to explore how path width varies by location and species and to discuss the conservation implications.

INVASIVE PREDATORS DISRUPT A KEY ECOLOGICAL PROCESS ON CORAL REEFS

Isabelle Cote

Simon Fraser University

Jocelyn CURTIS-QUICK, Cape Eleuthera Institute ; Emily DARLING, University of North Carolina ; Fiona FRANCIS, Simon Fraser University ; Luis MALPICA-CRUZ, Simon Fraser University ; Nicola SMITH, Simon Fraser University

Predatory invaders can have substantial direct effects on the communities they invade. However, their impacts can extend far beyond reductions in prey abundance, particularly when the prey they remove play important roles in ecosystem processes and functions. Red lionfish (*Pterois volitans/miles*) were introduced from the Indo-Pacific region to Florida in the mid-1980s and have since spread throughout the Caribbean basin. They prey on many native reef fish species, including some responsible for providing the grazing pressure necessary to prevent algal proliferation and maintain coral health on coral reefs. We quantified the extent to which lionfish impair the key process of herbivory through a combination of fish population surveys, behavioural observations, and algal settlement experiments on Bahamian patch reefs, half of which have been regularly cleared of lionfish for 3+ years. The abundance

and biomass of herbivorous fishes was significantly higher on patches with few lionfish than on unmanipulated patches with more lionfish. As a result, herbivory rates were higher and algal biomass accumulation on settlement plates lower on reef patches without the invasive predators. This study provides the first empirical test of the indirect effects of lionfish on essential coral reef processes.

PASTORAL AND WOODCUTTING ACTIVITIES IN THE MOROCCAN MIDDLE ATLAS CEDRUS ATLANTICA FORESTS: IMPACTS ON ECOSYSTEM STRUCTURES AND MODES OF SOCIAL REGULATION

Marc Coudel

AgroParisTech

Pierre-Marie AUBERT, AgroParisTech ; Mohammed ADERGHAL, Faculté de lettres et sciences humaines ; Christelle HÉLY, Institut des sciences de l'évolution

Southern Mediterranean forests, their biodiversity and the livelihoods that rely on them are at risk from resource over-extraction. To produce the knowledge necessary for sustainable conservation, research faces methodological problems that must be overcome: gather information in contexts with many uncertainties about systems to understand their socio-ecological dynamics. This is true in the symbolical Moroccan Middle Atlas *Cedrus atlantica* forests. These ecosystems are critical ecologically and economically: they are North Africa's largest continuous forests and produce nationally important wood and sheep commodities. In the work to be presented, we sought to understand how the cedar forest socio-ecosystems behave and why resource extraction has so far been resistant to conservation efforts. We focused on pastoral and woodcutting activities as an interface between social and ecological dynamics. Ecologically, the patterns of activity intensities within the forests are linked to clear changes in ecosystem structures and dynamics. Cedar forests do not appear to be threatened regionally. However, cedar logging has reduced the standing forest capital. Locally, cedar populations may be vulnerable in one third of the forest due to pastoral activities and to unfavorable environmental conditions. Socially, the intensification of human activities is linked to low prospects for livelihoods that don't use forests and to the low cost resources they offer due to inadequate law enforcement. Reacting to ecosystem changes, users and managers regulate activities. Users individually try to lead less destructive methods. Community and extra-community based dynamics have also been successful to regulate resource extraction. Management has however not achieved its participative objectives. These results can direct future research and management needs for a better protection of Mediterranean forests and parklands and their biodiversity that also respects local population's livelihoods.

CORPORATE CITIZEN SCIENCE; A NOVEL TOOL FOR TACKLING ENVIRONMENTAL SUSTAINABILITY?

Jenny Cousins

Earthwatch Institute

Societies globally face unprecedented challenges, via climate change and unsustainable land use which degrade water quality and biological systems. The complex and contested nature of environmental sustainability requires collaboration between stakeholders and societal willingness to respond. As significant influencers of global environmental change, the private sector has a critical role in taking action towards sustainable solutions. Citizen science (CS) offers potential to engage employees in environmental data collection whilst empowering engagement in local and global sustainability issues. Corporate CS can foster new ways of thinking within businesses and connect scientists and business leaders towards informed decision-making and long-term solutions. This paper examines two different CS programmes, which engage employees of major multi-national companies. Freshwater Watch is a mass CS programme, connecting local scientists and corporate citizens in 32 cities worldwide, with research aimed at meeting local challenges in water management whilst developing a global database on water quality. The programme offers a limited training experience and uses mobile applications and online resources to support repeated data collection. In contrast, an intensive and immersive 5-day residential programme (the Sustainability Leadership Program) involves a global network of climate change-related experiments, with 100 senior business managers each year completing fieldwork alongside learning sessions. We explore the value of linking corporate engagement with CS to enhance environmental sustainability within business and personally. We consider the benefits and limitations of these programmes (each with a range of cultural and engagement challenges) via a unique dataset of corporate citizen scientists. The effectiveness of each programme is examined against data quality, enhanced awareness of environmental issues, behavioural change and changes in company culture.

MAXIMIZING MANGROVE FOREST CONSERVATION THROUGH MULTI-SCALE STAKEHOLDER ENGAGEMENT IN CITIZEN SCIENCE

Jenny Cousins

Earthwatch Institute

This poster takes a case-study approach to illustrate how effective engagement of stakeholders and communication of science at multiple scales has maximized the conservation and community outcomes of a mangrove research project in Kenya. For coastal communities, such as those living around Gazi Bay,

mangrove ecosystems provide firewood and building poles, nursery provision for fish, and coastal protection. They also play an important role in climate stabilization due to their ability to trap and sequester carbon. As one of the most severely threatened and undervalued ecosystems, their extractive use presents not only a threat to community livelihoods, but also an opportunity for stakeholder involvement in their conservation. Through partnership with Earthwatch this project is helping to sustain the supply of mangrove goods and services by engaging a range of participants in pioneering plantation experiments that measure a range of ecosystem functions in replanted mangrove stands. In particular, the project is pioneering the use of carbon credits as a new way to fund mangrove conservation and social development in the area. Participants include school children, the village committee, the local government, students, and international volunteers, whose learning around ecosystem services at different levels supports a range of impacts from individual, to project, to community - each level critical to long term project success and resilience of these ecological and social systems.

FROM ONE TO MANY: WHEN TO INCLUDE COMPLEX MANAGEMENT STRUCTURES IN CONSERVATION

Shaun R. Coutts

School of Biological Sciences, University of Queensland and School of Natural Sciences, Trinity College Dublin.

Jonathan RHODES, School of Geography, Planning and Environmental Management, University of Queensland ; David PANNELL, Centre for Environmental Economics and Policy, The University of Western Australia ; Sarah BEKESSY, Global, Urban and Social Studies, RMIT University ; Yvonne M. BUCKLEY, School of Natural Sciences, Trinity College Dublin.

It takes more than ecologically correct decisions to make good conservation decisions. Many populations of concern are embedded in landscapes with multiple decision makers and institutions, often with competing motivations or goals. How management is structured to deal with that complexity can be crucial to the success of a management program. To address this issue ecologists have often called for greater integration of ecological and social sciences. However, such integration can easily lead to more complex models and conceptual frameworks. This extra complexity will incur unavoidable and non-trivial costs. The relative benefits and costs of developing social or ecological components of population management models has received very little attention in the literature. Here we review the current conservation science and applied ecological literature to see how social complexity in decision making is included. We also examine when and why more complicated social scenarios are included. A simple single decision maker was the most commonly assumed management structure. Studies that assumed a single decision maker were often limited in scope and focused on cases where

a single organization undertakes the management at relatively small scales. Studies that assumed more complicated multi-decision maker management structures tended to heavily simplify the ecology and focus on problems at larger landscape scales. We assert that the blanket use of more complex models in population management is not necessarily the best solution, rather we need conceptual and mathematical models fitted to the problems at hand, not necessarily more complex ones. To aid in this we propose a framework to classify management structures and relate them to different conservation problem types.

STRUCTURE AND DYNAMICS OF AN UNEXPLOITED POPULATION OF THE REEF MANTA RAY *MANTA ALFREDI*

Lydie Couturier

School of Biomedical Sciences, The University of Queensland
Chirstine DUDGEON, School of Veterinary Science, The University of Queensland ; Kenneth POLLOCK, Department of Biology, North Carolina State University ; Fabrice JAINE, Marine Megafauna Foundation ; Michael BENNETT, School of Biomedical Sciences, The University of Queensland ; Kathy TOWNSEND, School of Biological Sciences, The University of Queensland ; Scarla WEEKS, Biophysical Oceanography Group, School of Geography, Planning and Environmental Management, The University of Queensland ; Anthony RICHARDSON, CSIRO Climate Adaptation Flagship, Marine and Atmospheric Research

Reliable abundance assessments are essential to the study of population dynamics and underpin conservation biology and management of a species. Although fishing pressure is a major threat to *Manta* spp., information on the trends and status of many of the species' subpopulations is lacking. Here we use photographic identification and mark-recapture methods to report on the site affinity, size and structure of an unexploited subpopulation of *Manta alfredi* in eastern Australian waters. A total of 716 individuals were identified between 2007 and 2012, including 636 at Lady Elliot Island (LEI), southern Great Barrier Reef. Over 60% of individuals were resighted at least once during the study period. Multiple resightings within and among years imply a high degree of site affinity to aggregation sites by individuals. One individual was sighted 11 times at LEI within a 27-year period. The sex ratio of this manta ray subpopulation was significantly biased toward females with an overall 1.3:1 female-to-male ratio. Overall, females were more likely to be resighted than males, however, site visitation at LEI varied between sexes. Robust design population models were used to estimate the population size of the winter aggregation at LEI over a 4-year period. The model estimated up to 532 individuals in the population within one winter season and that survivorship of *M. alfredi* between consecutive years

was exceptionally high ($\Phi \sim 1$). Our findings highlighted the importance of aggregation sites for *M. alfredi* subpopulations, and provide a valuable baseline to assist in the status assessment of exploited manta ray subpopulations.

99: GARDEN BIRD FEEDING: OUR DESIRE FOR CONNECTION

Daniel Cox

University of Exeter

Kevin GASTON, University of Exeter

Interacting with nature is now widely recognized as providing a range of health and well-being benefits to people living in urban areas. There is evidence that having more bird species, or at least the perception of more species, along with watching birds and listening to their songs has positive effects for our psychological well-being. As cities continue to grow and people live increasingly urbanized lifestyles the provision of food for garden birds may provide an important link by which people connect with nature. Indeed, garden bird feeding is a global phenomenon and one that continues to grow, with up to 75% of people in some urban areas regularly putting out food. Previous studies have examined the demographics of who is feeding garden birds and what they are feeding them, however there is no clear understanding behind why so many people put out food for birds. We quantitatively surveyed the bird feeding habits of urban households in the UK to investigate people's motivations behind garden bird feeding together with their perceptions and preferences of what they prefer to see at their feeders. Although these motivations are likely to be complex, we explore how they may stem from three core drivers; the pleasure benefits that people gain from watching avian behaviour at their feeders, a concern about bird welfare, and/or as a way for people to express their natural orientation towards interacting with nature. A person's desire to connect with their garden birds and the benefits that they receive from doing so may be motivated more through wanting to target specific bird species and communities, than just attracting birds per se. Understanding the role that species diversity and individual abundance play in these motivations has important implications both for harnessing the conservation potential of bird feeding and in urban planning for maximizing the ecosystem services that birds provide.

SYNTHESIZING THEORIES OF ENVIRONMENTAL GOVERNANCE

Michael Cox

Dartmouth College

There are several research communities that have dedicated themselves to the analysis of human-environment interactions and to similar themes (e.g. resilience, environmental

governance, common-pool resources, and conservation). Each of these communities has established the importance of a set of factors in affecting outcomes of social and ecological importance. To a slightly lesser extent, these communities have also established a set of theories that link these different factors up to each other and to important outcomes. For the most part, however, communities have not established a common protocol for consistently measuring theoretically important concepts. Moreover, no common method has been developed for consistently expressing the different theories that relate such concepts to each other. Without this common language for concepts and theories, the accumulation of scientific knowledge across study sites and related disciplines is stymied. In this presentation I will discuss one project that has attempted to address these challenges. This project is known as the Social-ecological Systems Meta-analysis Database (SESMAD) project. This project is a highly collaborative, interdisciplinary effort involving scholars from environmental social science, resilience science, and conservation science. Two primary goals of this project have been to develop an online relational database to store (1) an encyclopedia of variables of established importance across a range of disciplines, and (2) a companion encyclopedia of theories from multiple disciplines, each of which associates two or more variables together via a mechanistic account of their relationship to each other. In this presentation I will discuss these two encyclopedias, their relationship to the larger SESMAD project, and how they may help scholars focusing on different conservation contexts to determine what the most relevant concepts and theories are for their particular cases and research questions.

MARINE MAMMAL AND SEABIRD FORAGING AROUND A SHELF SEA FRONT AS REVEALED THROUGH A COMBINATION OF PASSIVE ACOUSTIC, SHIPBOARD SURVEY AND TRACKING DATA.

Samantha L Cox

Plymouth University

Clare EMBLING, Plymouth University ; Phil HOSEGOOD, Plymouth University ; Matt WITT, Exeter university ; Peter MILLER, Plymouth Marine Laboratory ; Brendan GODLEY, Exeter university ; Simon INGRAM, Exeter university ; Stephen VOTIER, Exeter university

Oceanic fronts have been linked to a diverse range of marine top predators. Increased productivity and biomass entrainment have been predicted to attract higher trophic level consumers but direct tests of this are lacking. Here, results are presented from three studies centred on understanding the small scale processes that underlie predator-prey interactions around a seasonally forming shelf sea front off the North Cornwall coast (UK). We first show, using passive acoustic data, that dolphin sp, associate with the presence of the

front during the summer months. Second we present results from two summer shipboard surveys where simultaneous measurements of oceanography and animal observations show both common dolphins, *Delphinus delphis*, and northern gannets, *Morus bassanus*, associate with patches of sub-surface chlorophyll present around the front. An in-depth analysis of the oceanographic data shows that these patches of productivity are mediated with the movement of the front with the spring-neap tidal cycle. Finally we suggest, using tracking data from gannets equipped with GPS and time-depth recorders (TDRs) at Grassholm Island (Wales), that fronts induce a behavioural shift in foraging strategy. Gannets were shown to make shorter shallower dives around fronts, suggesting prey availability is altered sufficiently to allow for a, presumably, more efficient dive strategy. As such, fronts appear to constitute enhanced foraging habitat and this should be considered in spatial management and the mitigation of the effects of anthropogenic activities including fisheries and marine renewable developments.

THE USE OF TIDALLY DRIVEN, HYDRODYNAMIC FEATURES BY FORAGING COASTAL BOTTLENOSE DOLPHINS

Samantha L Cox

Plymouth University

Phil HOSEGOOD, Plymouth University ; Anneli ENGLUND, University College Cork ; Stephen VOTIER, Exeter university ; Sophia BUTLER-COWDRY, National Oceanographic Centre ; Clare EMBLING, Plymouth University ; Emer ROGAN, University College Cork ; Simon INGRAM, Plymouth University

Understanding the distributions, movements and foraging behaviours of coastal top predators, such as the bottlenose dolphin *Tursiops truncatus*, is critical for effective marine planning and conservation management. Optimal foraging is likely a main driver of habitat use and whilst predator behaviours are often linked to the availability of their prey, gaining meaningful measurements of mobile prey distributions in complex marine habitats is often impracticable. Dolphin encounter locations, collected over 11 years (1997-2007 inclusive) during standardised surveys of the Shannon estuary SAC in western Ireland, were modelled using tidal temporal variables and benthic habitat descriptors. The Shannon estuary is a tidally dominated system with currents of up to 2.5ms⁻¹ at the estuary mouth and in the central channel. Dolphins were found to use different areas of the estuary dependent on the tide. This relationship was most prominent in a narrow channel in the centre of the estuary, where concentrated foraging activity occurred almost exclusively during the flood tide. In this study we use an acoustic current Doppler profiler (ADCP) to measure and characterise hydrodynamic features in the central channel, where we drove a repeat circuit mini-survey throughout a 12 hour tidal cycle. These surveys revealed high

levels of shear and strong down-welling between convergent fast flowing water during flood tides. We suggest the presence of these features aid animals in capturing their prey and so constitute important foraging habitat features within the estuary environment. Incorporating detailed measurements of the dynamic hydrography of a site such as the Shannon together with fine scale animal distribution provides an insight into drivers of habitat selection and the mechanisms of foraging behaviour which increases our understanding of the potential interactions of coastal dolphins with human activities in tidally dominant coastal systems.

CONSERVING GOD'S OWN COUNTRY: BIODIVERSITY IN AGROFORESTRY LANDSCAPES OF KERALA, INDIA

Theraesa Coyle

McGill University

Jeanine RHEMTULLA, The University of British Columbia ; Peter ARCESE, The University of British Columbia ; T K KUNHAMU, Kerala Agricultural University ; Navin RAMANKUTTY, The University of British Columbia ; Sarah TURNER, McGill University

The traditional home gardens of Kerala, India, may offer a sustainable balance between food production and ecosystem conservation. These complex agroforestry systems, situated within the Western Ghats biodiversity hotspot, may provide refuge for species threatened by habitat destruction, while still supplying food, fuel, medicines and income to local families. Despite their potential value, these ancient and diverse gardens are quickly disappearing with the rapid expansion of housing developments and monoculture plantations of non-edible cash crops, threatening both biodiversity and food security. This project explores the potential of home gardens to support wild biodiversity, and the attitudes of local home owners towards agriculture, wildlife and the environment. We used a combination of sociological and biological field surveys, as well as remote sensing and GIS, to examine 1) the diversity of birds, amphibians, insects and trees in home gardens; 2) the biotic and abiotic landscape features which influence this diversity; and 3) the correlations among home owner dependence upon agriculture, land management decisions, and attitudes towards environmental issues. We found substantial variation in the structure and composition of individual home gardens, as well as their landscape context, and significant correlations between these attributes and the richness and abundance of animal taxa residing within. We also found strong links between home owner perspectives and the management decisions which determine the structure of home gardens. Our results illustrate the importance of landscape and vegetation features when assessing wildlife habitat in human-dominated systems, as well as the need for interdisciplinary approaches to account for human management influences. This project highlights the value of maintaining traditional farming methods in rural landscapes, and aids our

understanding of land-use decisions and their importance for conserving biodiversity.

DETERMINANTS OF FOREST BIODIVERSITY VALUE IN A RAPIDLY URBANIZING AREA OF UPSTATE SOUTH CAROLINA

Melanie Cozad

Furman University

Jenny WARNKEN, Furman University ; John QUINN, Furman University

Rapid growth of communities in rural and peri-urban areas such as the southern Piedmont ecoregion of the United States is driving declining biodiversity and rapid forest loss; with the latter faster than any other region in the eastern United States. The subsequent decline in ecosystem services has given rise to concerns among stakeholders who express interest in restoring lost forest cover to reduce future loss of services. Yet, despite this interest, data on resource abundance and their value do not exist to help conservationists and planners in land management efforts. Using contingent valuation survey methodology, we value residents' willingness to pay (WTP) for forest preservation. WTP was assessed using a multiple-bounded discrete choice elicitation question that allows respondents to value forest preservation across a wide-range of monetary thresholds in addition to incorporating varying levels of uncertainty within responses. Tax and donation collection mechanisms were considered. For a 5% increase in forest cover over 10 years, we find WTP values of approximately 20 dollars per year across donation and tax bid vehicles. The WTP values increase as respondents' uncertainty across responses is allowed to vary demonstrating that the estimated value represents a lower bound. Perceptions regarding the reduction of society's current use of the environment for the benefit of future generations played a large role in determining WTP across both bid vehicles, while respondents' level of familiarization with biodiversity was significant in the donation vehicle where larger amounts of respondents' uncertainty was accounted for. Results suggest that it would possible to reach a conservation target of reversing forest cover loss from the last 40 years but that conservation efforts may need to focus on biodiversity education efforts.

EFFECTS OF HUMAN ACTIVITIES ON CARNIVORE BEHAVIOR AT THE INDIVIDUAL, POPULATION AND COMMUNITY LEVEL AND THEIR IMPLICATIONS FOR CONSERVATION

Gabriele Cozzi

Zurich University

Due to expanding human population into wildlife habitats, human wildlife interactions and subsequent conflicts have increased over the past decades. Understanding and predicting how wildlife species, particularly large mammals with cognitive and behavioral complexity, respond to human activities is needed to sustain coexistence. Here I present empirical evidence from three different systems and show how human activities and interventions influence the behavior of large carnivores at three different levels. 1) I discuss the effect of leftovers from elephant trophy hunting on the ranging behavior of spotted hyenas. While, on average, hyenas visit carcasses for 10-15 days, some individuals do so for > 50 days, indicating important impact of this surplus food source on their behavior and emphasizing individualities. 2) I illustrate how access to extra food from an open-sky garbage dump influences brown bear ranging and feeding behavior and is responsible for a behavioral dichotomy in life history strategies within the study population. Half of the monitored bears remain sedentary throughout the year and feed on garbage, whereas the other half migrates up to 100 km before hibernation to search for natural food sources. 3) Using African top predators, I show that, by differentially influencing competing species, human interventions can alter interactions and thus coexistence within an entire guild. The observed difficulty of lions to cross a veterinary fence results in a relatively lion-free zone, which in turn, provides refuge for those species competitively inferior, like the African wild dog. By showcasing these three different systems, I demonstrate how human activities can profoundly influence animal behavior and population dynamics. Quantifying the consequences of such activities on wildlife at different levels of organization is essential for implementing sound, evidence-based conservation action and promoting coexistence between humans and wildlife.

QUANTIFYING THE IMPACT OF BILLIONS OF DOLLARS OF GEF SUPPORT TO CONSERVATION IN PROTECTED AREAS

Ian Craigie

James Cook University

Megan BARNES, Australian Research Council Centre of Excellence for Environmental Decisions, the University of Queensland; Jonas GELDMANN, Center for Macroecology, Evolution and Climate, Natural History Museum of Denmark, University of Copenhagen; Stephen WOODLEY, IUCN World Commission on Protected Areas

Over the past 20 years the Global Environment Facility (GEF) of the World Bank has provided billions of dollars of support to protected areas and protected area systems in developing countries. However there is a poor understanding of what this

investment has achieved. We carried out a comprehensive impact assessment of GEF support to protected areas using three different conservation-relevant measures: management effectiveness scores, rates of forest loss and changes in abundance of wildlife populations. These outcomes were measured at each of the ~1800 protected areas the GEF is known to have supported in over 100 countries. Several different methods were used to assess GEF impact: before-after comparisons, difference in difference comparisons and propensity-score matched comparisons to protected areas without GEF support. Several of the methods used were unable to detect meaningful impact of GEF support. However it was found that management effectiveness scores increased more at GEF supported protected areas than those without support. A marginal decrease in the rate of forest loss was found in some regions. And increases in abundance of some threatened species in protected areas could be reasonably attributed to GEF projects. The difficulty in demonstrating significant impacts of GEF support to protected areas is concerning, especially given the levels of investment involved. This talk will highlight a number of improvements that could be made in GEF processes to allow future impact assessments to be more conclusive. This would allow improved targeting of funds to increase biodiversity benefits in future and create a body of evidence about what makes a project more likely to succeed. Given important role of the GEF and it's high public profile, it is imperative that projects are able to quantify their conservation-relevant outcomes in a more meaningful manner to provide lessons for future investments.

FORMALIZED CONSERVATION STRATEGIES TO ARREST AND REVERSE RAPID DECLINES AND RANGE CONTRACTIONS OF TWO ENDANGERED ENDEMIC PASSERINES ON KAUAI, HAWAII

Lisa H. Crampton

Hawaii Division of Forestry and Wildlife

Eben H. PAXTON, United States Geological Survey; Lucas BEHNKE, The Nature Conservancy; John VETTER, Hawaii Division of Forestry and Wildlife; Megan LAUT, US Fish and Wildlife Service; Liba PEJCHAR, Colorado State University; Steve MOREY, US Fish and Wildlife Service

Hawaii is one of the extinction capitals of the world, having lost at least half of its native avifauna in the 1000 years since colonization by humans, and with all but a few extant species listed as critically endangered. On Kauai Island, two critically endangered endemic honeycreepers, Akikiki (*Oreomystis bairdi*) and Akekee (*Loxops caeruleirostris*) are particularly imperiled. Largely restricted to the forests of the high elevation Alakai Plateau (>1000 m) these species face numerous threats: hurricanes; non-native, invasive plants and animals (both predators and ungulates), and deadly introduced

diseases. Bird density surveys carried out from 1981 to 2012 indicate rapidly declining numbers and contracting ranges for both species. Populations in 2012 were estimated at 468 birds for Akikiki (95% CI: 231 to 916) and 945 individuals for Akekee (95% CI: 460 to 1,547), down 71% and 48% respectively since 1981. Occupancy surveys in 2012 confirmed range contractions, with occupancy rates for both species increasing from west to east along the Plateau (Akikiki: $\psi = 0.02 \pm 0.07$ to 0.55 ± 0.21 Akekee: $\psi = 0.03 \pm 0.10$ to 0.53 ± 0.33), which reflects canopy height differences and a gradient of invasive species on the Plateau. In 2013, 14 experts used a Structured Decision Making format to analyze available information, and develop and rank alternatives to create a management plan to address these trends. Fifteen actions were evaluated on the likelihood that the action would prevent immediate extinction of each species; set the foundation for having a genetically-viable, reproducing, and stable population in 10 years; and allow for the long-term persistence of each species in the wild. Probability of success of each action was weighed against the constraints and costs of its implementation. The group recommended a combination of captive propagation and in situ threat management as the best strategy to save these species.

IN DEFENSE OF SMALL RESERVES: A CASE STUDY ON THE ROLE OF ENVIRONMENTAL EDUCATION PROGRAMS IN PROTECTED AREA DESIGN AND PLANNING

Matthew Crane

Suranaree University of Technology
Colin STRINE, Suranaree University of Technology ; Inês SILVA, Centre for Ecology, Evolution and Environmental Changes, University of Lisbon ; Taksin ARTCHAWAKOM, Sakaerat Environmental Research Station, Thailand Institute of Scientific and Technological Research

Small-scale reserves can provide real conservation benefits alongside large protected areas; however, they are often overlooked and underfunded, leaving them unprotected. We present a case study of a small reserve in Northeastern Thailand, as a model for incorporating environmental education into protected area planning as a means of supporting conservation, research activities, and local development in small protected areas. To compensate for limited government funding, Sakaerat Environmental Research Station (SERS) has developed a sustainable science camp for schools that incorporates conservation and local cultural knowledge. From its inception in 2002 until 2012, the Science Camp has generated 5,138,624 Thai Baht (138,593 €) in supplementary budget. The science camp profits have provided a constant source of income for the reserve while facilitating the main objectives for the Man and Biosphere

Reserve (MBR) Program: conservation, economic development, and logistical research support. The ranger corps has garnered a more substantial budget to deter poaching and illegal logging, increasing with the advent of the science camp program. Three major sustainable development projects have been supported through the Science Camps to provide alternative income to poaching for the local community. The SERS infrastructure developed for the Science Camp also provides logistical support for conservation research compared to the other small MBRs in Thailand. The SERS science camp is already fully booked through 2016, hosting roughly 17,000 students per annum providing sustainable long term income. The potential for small reserves to act as outdoor classrooms should be considered when assessing the costs in designing or reinventing small protected areas.

CONSERVATION PSYCHOLOGY IN ACTION: FOSTERING AND EVALUATING DURABLE MOTIVATION IN CAPACITY BUILDING PROGRAMS

Kayla A. Cranston

Antioch University New England

Conservation psychology is increasingly cited as offering essential insight to programs that aim to both conserve biodiversity and foster the wellbeing of humans involved in that conservation. This presentation contributes to this conversation by applying a psychological perspective to the field of capacity building for biodiversity conservation. I begin with an analysis of the conservation literature on capacity building at the institutional, community, and individual level. Through this analysis, I argue that conservation psychology is primed to offer a deeper investigation of the definition and development of individual capacity in this context. I review theoretical insight from the field of community and positive psychology to help supplement our current understanding of individual capacity for biodiversity conservation. Based on this investigation, I propose a psychological measurement for evaluating aspects of empowerment and long-term motivation for biodiversity conservation in people responsible for the continuation of these efforts within each region. I describe the results of research I've conducted with this instrument and discuss suggestions for its use in the field of capacity building for biodiversity conservation. Together, this presentation explores the development and use of a conservation psychology-based instrument that supports a novel approach to effectively sustaining human action toward the goal of biodiversity conservation.

USING CITIZEN SCIENCE TO MAP GEOSPATIAL AND TEMPORAL TRENDS IN HUMAN-ELEPHANT INTERACTIONS IN ASIA

Cheli Cresswell

University of Oxford

Paul JEPSON, University of Oxford

As elephant habitat becomes increasingly fragmented and human populations continue to rise, the frequency with which humans and elephants are coming into contact - and conflict - is on the rise. At the same time, the rapid spread of internet access and social media usage across Asia, combined with the rapid adoption of mobile devices with cameras and GIS means that people in these areas are sharing a wealth of information about their encounters online. Currently, however, that data is largely inaccessible to scientists who might be able to use it to help understand patterns and trends and to create more effective conservation strategies. The data is also too complex for the current state-of-the-art computer-automated processes alone. Our tool takes advantage of the affordances of the social machine - humans and computers working together to achieve more than can be done by either alone - and uses citizen scientists to process and extract relevant details about human-elephant interactions throughout the Asian elephant habitat range, which can then be visualized on a multi-layered map. The tool will promote a decentralized approach to conservation and can be used by contributors physically located anywhere in the world. It is also an exploration of the neogeographical space and the challenges - technological, ethical, and logistical - that come with a multi-stakeholder international citizen science project. As the project moves forward, we hope to explore how the interaction of VGI, big data, and non-traditional geographers interplay with the temporalities and the geographies of conservation.

USING UNMARKED COUNTS OF MIGRATING BIRDS TO ESTIMATE POPULATION CHANGE WHEN A LONG-TERM BIAS IN STOPOVER DURATION HAS OCCURRED

Tara Crewe

Western University

Philip TAYLOR, Acadia University; Denis LEPAGE, Bird Studies Canada

The use of unmarked counts of migrating animals to monitor long term population change assumes independence of daily counts and a constant rate of detection. However, migratory stopovers often last days or weeks, violating the assumption of count independence. Further, a temporal bias in stopover duration will result in a change in the probability of detecting individuals once, but also in the probability of detecting individuals on more than one occasion. We tested

how variation in stopover duration influenced accuracy and precision of population trends by simulating migration count data with known constant rate of population change and by allowing daily probability of survival (probability of remaining at the count site) to remain constant, or to vary randomly, cyclically, or increase linearly over time by various levels. Using simulated datasets with a linear bias in survival, we also tested whether any resulting bias in population trend could be reduced by modeling variation in survival, or by subsampling data to every three or five days to reduce the incidence of recounting. Mean bias in population trend did not differ significantly from zero when survival remained constant or varied randomly over time, but bias and the detection of false trends increased significantly with a linear increase in survival. Importantly, a linear bias in survival resulted in a compounding effect on counts due to the increased probability of detection and recounting. Under this scenario, bias in population trend could not be modeled using a covariate for survival alone. Rather, to improve inference drawn about long term population change using unmarked migration counts, analyses must include a covariate for the bias in detection, as well as incorporate sampling modifications (e.g., subsampling) to reduce the probability that individuals will be detected on more than one occasion.

DETERMINING THE PRIMARY DRIVERS OF NEST FAILURE IN OPEN-CUP NESTING SONGBIRDS

Merle Crombie

University of British Columbia

Peter ARCESE, University of British Columbia

Determining the factors that influence natality and mortality and their relative contribution to fitness is fundamental to understanding the dynamics of animal populations. In birds, nest fate is a key component of natality and is commonly used to quantify productivity, model population dynamics, and to develop habitat management plans. Prior research suggests that nest fate may be driven by (1) intrinsic qualities of the bird(s) caring for the nest, (2) nesting habitat characteristics, and/or (3) environmental factors related to weather events or predation. However, while individual drivers of nest fate have been identified, few are able to critically assess the combined influence of multiple drivers, leaving a substantial gap in our knowledge of their relative contribution to nest fate. Based on >3200 song sparrow (*Melospiza melodia*) nest monitoring records and detailed nest-site habitat characteristics, a 40-year social and genetic pedigree, and local climate data, I will take an information theoretic approach to ask how intrinsic qualities of the female (age¹, inbreeding coefficient², lifetime reproductive success³), nest-site habitat characteristics (percentage of thorny shrub cover surrounding nests⁴, nest micro-climate⁵), and environmental effects (cumulative inclement weather⁶, and predation risk as annual cowbird

parasitism rate) influence nest fate, as well as how they may interact and/or vary temporally. By using a dataset that includes marked variation in key drivers shown to affect nest fate in this and other bird populations, my work will be among the first to assess these drivers simultaneously, thus identifying key determinants of population fitness and growth that can be applied toward successful conservation efforts.

49-GLOBAL PATTERNS OF HABITAT LOSS AND FRAGMENTATION FOR THE WORLD'S MAMMALS

Kevin Crooks

Colorado State University

Christopher BURDETT, Colorado State University ; David THEOBALD, Conservation Science Partners ; Sarah KING, United States Geological Survey ; Moreno DI MARCO, Sapienza Università di Roma ; Carlo RONDININI, Sapienza Università di Roma ; Luigi BOITANI, Colorado State University

Habitat destruction is a primary threat to biological diversity and the world's mammals are particularly sensitive to habitat loss. Nevertheless, global assessments of degree of habitat loss and fragmentation for mammals are absent. We used high-resolution habitat-suitability models to conduct comparative analyses and to identify global hotspots of fragmentation and core habitat for the world's mammals. A database of 4148 mammal species from 26 taxonomic Orders was compiled from an extant mammalian phylogeny and the IUCN Red List of Threatened Species. We described the degree of fragmentation of high-quality habitat for each species with the GISfrag metric, which measures the average distance of all cells within a high-quality habitat patch to the nearest edge of the patch. Results demonstrate that species with less fragmentation (i.e., more interior high-quality habitat) had larger geographic ranges, a greater proportion of habitat within their range, and a lower risk of extinction. Body mass was not associated with degree of habitat fragmentation. On average, less than 50% of a species geographic range was comprised of high-quality habitat, and, more troubling, less than 4% of the range was comprised of such habitat within protected areas. Identification of hotspots of fragmentation and core habitat will help guide strategic priorities for global mammal conservation.

CORAL REEF CONNECTIVITY IN PALAU: A POPULATION GENETICS APPROACH TO CORAL REEF MANAGEMENT IN WARMING SEAS.

Annick Cros

Hawaii Institute of Marine Biology

Stephen A. KARL, Hawaii Institute of Marine Biology

Coral reefs are under increasing threats from climate change and human impacts. In response, scientists and managers are designing and implementing resilient marine protected area (MPA) networks to increase the chances of reef recovery

following disturbance. One of the key attributes in the design of a resilient MPA network is connectivity. Understanding patterns of population connectivity within a MPA network, however, remains a difficult task. In the marine environment, population genetics is becoming a promising tool to measure the relatedness of individuals and determine the connectivity of MPA networks. In this work, we use Palau's barrier reef as a case study to explore coral connectivity and provide advice for the design of their existing MPA network. Fifty colonies of *Acropora hyacinthus* were sampled at each of 25 sites around Palau's reef including in existing MPAs. We amplified 16 microsatellites with forward primers designed with an individual index for each colony (n=50). Samples were then pooled by site and given an additional site index using the Illumina TruSeq kit, creating a site ID. Once the colony and site indices were attached, all 25 sites were sequenced using Illumina MiSeq genome sequencer. A bioinformatics pipeline was created to assign each colony a genotype based on the 16 distinct microsatellites from which we could analyze nucleotide variants such as SNPs. The sequences will be analyzed and results presented providing an insight on the relatedness of the colonies of *Acropora hyacinthus* around Palau's reef and information on coral connectivity at an island scale. This will be useful at the management level providing guidelines on the design of resilient MPA networks.

73. DO THEORETICAL AND EMPIRICAL ESTIMATES OF CONNECTIVITY MATCH? A CASE STUDY IN THE SOUTH-WEST LAGOON OF NEW CALEDONIA.

Marion Cuif

Direction des pêches maritimes et de l'aquaculture

Christophe LETT, Institut de Recherche pour le Développement ; Laurent VIGLIOLA, Institut de Recherche pour le Développement ; David Mickaël KAPLAN, Virginia Institute of Marine Science ; Pascal DOUILLET, Institut de Recherche pour le Développement ; Cécile FAUVELOT, Institut de Recherche pour le Développement

Understanding marine populations' dynamics is critical to their effective management, and requires information on patterns of dispersal and connectivity that are still poorly known. Many marine organisms have a bipartite life history with a pelagic larval stage that often represents the only opportunity for dispersal. In the last decade, new empirical and simulation approaches to measuring larval dispersal have been developed, but results from these two different approaches have rarely been compared in the context of a single marine system, impeding the use of larval dispersal models in metapopulation models supporting decision making. We used both approaches to investigate larval connectivity for a coral reef fish, *Dascyllus aruanus*, in the South-West Lagoon of New Caledonia. Our biophysical dispersal model shows that larval retention exhibits considerable temporal variability at both lagoon and patch reef scales and periodically reaches large

values despite low average water residence time. Artificial transgenerational marking of embryonic otoliths in the wild also showed relatively low self-recruitment rates indicating high population openness at the reproductive season scale, with considerable monthly variability of self-recruitment. Large quantitative discrepancies between simulations and empirical results emphasize the need to better understand processes that facilitate local retention, such as homing behavior and very small scale circulation patterns.

NEW FRAMEWORKS FOR ASSESSING THE SPATIAL RESILIENCE OF PROTECTED AREAS

Graeme Cumming

James Cook University

Protected areas remain one of conservation biology's core approaches for conserving ecosystems and their associated functions and services. As the human population grows, protected areas are experiencing an unusual combination of increasing demand and increasing pressure. One outcome of these antagonistic forces is that protected areas in developing countries are increasingly expected to justify their own existence in competition with alternative land uses in a political and socioeconomic forum. In this presentation I consider protected areas as social-ecological elements in a multifunctional landscape. I present an extension of Ostrom's social-ecological systems framework that takes better account of issues of scale and function by explicit analysis of the hierarchical arrangement and alignment of ecological scales and socioeconomic/sociopolitical levels of organization relating to protected areas. A preliminary analysis of three case studies suggests that at broader scales, anthropogenic influences and socioeconomic decisions – such as climate change and governance – dominate ecological variables as influences on protected area sustainability and resilience. I then extend the framework further to consider scale mismatches in protected area management and present a new, semi-quantitative index that provides a potentially useful way of thinking about and diagnosing scale mismatches. If scale mismatches are hardest to resolve when ecological extent and organizational levels are furthest apart (maximally misaligned), then our analysis of a larger set of case studies suggests that there may exist a predictable relationship between ecological extent, sociopolitical level, and protected area resilience.

MAN VS CAT: THE CASE OF HUMAN-BIG CAT INTERACTIONS IN GUYANA

Anthony Cummings

University of Texas at Dallas

The status of big cats, in particular jaguars, within Latin America has gained much attention recently. Our understanding of these cats, and cat-human interactions have been shaped by studies within the context and spaces occupied by cattle ranchers, and other farmers. While such studies provide valuable knowledge on cats, the impacts of global processes such as economic collapse on human intrusion into cat habitats have been missed. As an agent of change, gold mining intensity is strongly linked to changes in global gold demand and offers a new perspective for viewing human-big cats interactions. In this study I postulated that the movement of gold miners into forested regions of Guyana will present a different dynamic for big cat-human interactions than those currently offered by cattle ranchers. Following a respondent driven sampling design, I examine the views of gold miners, cattle ranchers, indigenous peoples, resource managers, and loggers, towards jaguars and other big cats. Stakeholders were asked to relate whether they feared cats, whether they had heard of cats being killed or killed cats themselves. Overwhelmingly, respondents expressed fear towards cats, jaguars and pumas in particular, while most persons suggested they had heard of big cats being killed. The various groups of stakeholders offered different positions on how they responded to cats within their spaces of work. Gold miners are more likely to pursue strategies to eliminate cats from within their locale because of the perceived threat to their personal safety, while cattle ranchers are more concerned about the safety of their herd. While conventional methods for preventing human-cat conflicts are applicable to cattle ranchers and other farmers, the mobile nature of gold miners and cats alike, present multiple opportunities for conflicts to arise, demanding the development of more innovative conflict management solutions.

ETHNIC VARIATION IN THE VALUATION OF ECOSYSTEM SERVICES

Aida Cuni Sanchez

University of Copenhagen

Marion PFEIFER, Imperial College London ; Rob MARCHANT, University of York ; Nd BURGESS, University of Copenhagen

Forest islands in the desert provide key ecosystem services to surrounding communities, which completely depend on them for their livelihoods. With increasing human pressure and droughts, conserving these fragile ecosystems is not easy. We focused our work on three isolated forest mountains in northern Kenya, Mt Marsabit, Mt Kulal and Mt Nyiru. We aimed at determining if ethnic group and/or livelihood strategy affected the way local populations perceive and use these forests, so that better management strategies can be suggested. We used focus-groups (FG), semi-structured

interviews, observations on plant abundance and population structure in/outside the forests and observations on medicinal plant and fuelwood in local markets. Water was found to be the most important ecosystem service (ES) in all study sites and amongst all ethnic groups. However, the second most important ES differed: while the Boran (farmers) mentioned fuelwood, the Samburu (pastoralists) in Marsabit mentioned fodder and the Samburu in Kula mentioned medicine. Differences in other important ES and most important plant species were also observed, which were related to ethnic group and access to markets. Information from the FG was in agreement with field and market observations. Results highlight that local perceptions and use is affected by ethnic group (cultural aspects and livelihood strategy) and these should be considered not only when ES rating but also when finding alternative livelihood strategies for forest edge communities. Top-down approaches have often been justified in multi-cultural ecosystems providing a one size fits all solution to complex problems. However, our findings highlight the need to understand and address cultural diversity if targeted conservation actions at the local scale are to be successful.

TIME DISCOUNTING IN BIODIVERSITY OFFSETS AND ECOLOGICAL EQUIVALENCY ANALYSIS-APING ECONOMICS, OR ECONOMIZING BIODIVERSITY LOSS?

Michael Curran
ETH Zürich

Biodiversity offsets (and related compensation policies) are expanding globally. Offsets attempt to compensate the local, "residual" biodiversity impacts of development projects with a goal of "no net loss" of biodiversity. A common means of compensation is the restoration of degraded ecosystems, which leads to a mismatch between the instantaneous loss of biodiversity and the delayed gain of biodiversity (which is gradual and may require centuries or even millennia). To address this "time lag" in the delivery of biodiversity value, time discounting has been suggested as a means of bridging the gap. Time discounting penalizes distant gains in biodiversity by expressing them in "net present" terms to be directly compared to present losses. The justifications for this practice are drawn from "utility discounting" in neoclassical economics, which is the subject of considerable debate, particularly surrounding economic assessments of climate change. In offsets, recommendations for choosing a rate/function are scarce. In this talk, I clarify what discounting is and assumes. I recap the economics literature on discounting (functions, choice of rates, empirical evidence), and identify which justifications may be useful in ecology. I suggest possible ecological variables that could be used as a basis for the discount rate/function

and illustrate the influence of the discount rate with global, spatially differentiated models of habitat restoration based on a published meta-analysis of the restoration literature (expressing recovery of species similarity in degraded ecosystems). In a case study region, I use these predictions to calculate basic offset ratios and show that current ratios in existing policy are far from what is required to achieve a "no net loss" of biodiversity. Concluding, I consider the alternative "rights-based" (Kantian) view, which rejects temporal trades, as a potentially superior option for offsets.

DIVERSITY AND DISTRIBUTION OF THE LION (PANTHERA LEO) ACROSS ZAMBIA

Caitlin Curry

Texas A&M University

Paula WHITE, Center for Tropical Research, University of California ; James DERR, Texas A&M University

The true conservation status of the African lion (*Panthera leo*) is in question due to a lack of knowledge regarding genetic diversity and conflicting estimates of population size. For example, in Zambia, although the lion has a large distribution spanning over 167,000 km² of habitat in managed areas, there are limited estimates of both population size and genetic sub-structure. This lack of reliable information compromises conservation decisions, some of which, such as the banning of trophy hunting, could have a profound impact on both the long-term security of the species as well as Zambia's economy. Analysis of the 12S and 16S mitochondrial genes of 165 lions found in five main areas in Zambia shows gene diversity throughout the population is high (0.7319 +/- 0.0174) with eight haplotypes found; three haplotypes previously described and five previously unseen haplotypes. Bayesian analysis shows haplotypes present in the Zambian population which link the Southern Africa lineage with the Southern/East Africa lineage suggesting the Zambian population may act as a bridge connecting the lions in southern Africa to eastern Africa. AMOVA analysis, however, suggests there is little to no gene flow between the populations within Zambia ($F_{ST}=0.44$) when separated into regional populations. The determination of regional sub-populations, such as that of eastern and western Zambia, could be the first step to the creation of conservation programs and proper legislation to focus on saving specific, at risk populations.

BEHAVIOURAL RESPONSE OF TWO GRASSLAND SONGBIRDS TO NOISE POLLUTION FROM ENERGY DEVELOPMENT IN THE CANADIAN PRAIRIE

Claire Curry

University of Manitoba

Bridget ANTZE, University of Manitoba ; Paulson DES BRISAY, University of Manitoba ; Heather NENNINGER, University of

Manitoba ; Miya WARRINGTON, University of Manitoba ; Nicola KOPER, University of Manitoba

Anthropogenic noise, created by roads, urbanization, and energy development, may influence wildlife in both protected areas and multi-use landscapes. Some species alter amplitude, frequency, or structure of songs or calls to avoid masking by noise. Species that cannot alter their vocalizations may be at greater risk from anthropogenic noise. Baird's sparrows are a declining grassland songbird (a species of special concern in Canada, with 25% decline in the past decade) with few studies on their vocal behavior. Species with highly variable songs, such as the more common Savannah Sparrow may be able to adjust more easily to noise pollution. We demonstrated that Baird's sparrows avoid sites with noisy infrastructure, whereas the more common Savannah Sparrows do not avoid noisy infrastructure. We hypothesized that these differing abundance patterns around development are a result of differing ability to communicate in noisy habitats. To test this hypothesis, we recorded songs from 47 Baird's Sparrows and 142 Savannah Sparrows in 26 mixed-grass prairies with varying types and abundances of energy infrastructure in southeastern Alberta and from 3 sites before and during playbacks of well drilling noise. Preliminary analyses show Baird's Sparrows do not alter minimum frequency or amplitude during control silence versus noise playback. In contrast, Savannah Sparrow minimum frequency and amplitude positively correlate with louder ambient noise at infrastructure sites. Understanding effects of anthropogenic noise on at-risk and common species will help us develop appropriate habitat management strategies for conservation in areas with increasing energy development. If species of concern are only sensitive to noise and not to the infrastructure, noise mitigation could allow for both conservation and economic development in the same prairies.

INFERRING OPPORTUNITIES FOR SPECIES INTERACTION FROM CAMERA TRAP DATA

Jeremy Cusack

University of Oxford [INSTITUTE] Institute of Zoology ZSL
Amy DICKMAN, University of Oxford ; Marcus ROWCLIFFE, Institute of Zoology ZSL ; Chris CARBONE, Institute of Zoology ZSL ; David MACDONALD, University of Oxford ; Tim COULSON, University of Oxford

Remotely triggered camera traps are being used worldwide to gather information on species occurrence, density, activity patterns, habitat use and behaviour. Recently, the spatiotemporal information contained in camera trap images has been used to characterise species interactions, i.e. estimating whether two species avoid or attract each other more than expected by chance. We review, test and compare proposed methods to infer species interactions from camera traps (occupancy models, activity patterns, spatiotemporal

point processes), using simulations and empirical data on large mammals collected in southern Tanzania's Ruaha landscape. We find that the extent to which camera trap data can provide meaningful and robust insights into species interactions depends largely on the strength of the interaction, sampling effort and landscape heterogeneity. In most cases, however, camera trap data can reveal "opportunities for interaction" between pairs of species, and we discuss how these may be useful for conservation ecology.

DUALLY IMPROVING BIODIVERSITY AND POLLINATION SERVICES FOR ENHANCED COTTON YIELDS AND SUSTAINABILITY

Sarah Cusser

University of Texas, Austin
Shalene JHA, University of Texas, Austin

Cotton is an economically and culturally important crop worldwide. Although self-fertile, cotton benefits from pollination service, producing larger bolls with more seeds with outcross pollen. However, cotton growers do not manage domesticated pollinators or employ land management practices that promote the establishment or long-term stability of wild pollinator communities. To determine best management techniques for dually increasing cotton yield while promoting important biodiversity, we sought to investigate the relationship between pollen limitation, pollinator community composition, and aspects of land management in South Texas Cotton, one of the largest US cotton producing regions. Our study had three objectives: 1) determine the extent of pollen limitation, 2) establish the relationship between pollen limitation and aspects of the pollinator community, and 3) identify which aspects of land use promote diverse and abundant pollinator communities. To answer these questions, we used a combination pollen limitation experiments, pollinator community surveys, and GIS analysis in 12 large-scale cotton fields. Overall, we found that cotton is indeed pollen limited, producing significantly larger bolls with the addition of outcross pollen. Despite this general finding, we found enormous variation in the degree of pollen limitation between sites. The degree of pollen limitation was negatively related to aspects of pollinator community composition, including pollinator abundance and richness. Pollinator community composition, in turn, was closely related to aspects of land use. Surprisingly, no particular land use type was associated with rich, abundant communities, but rather land use heterogeneity at both local and regional scales had a strong positive influence. This relationship between land-use, pollination service, and crop yield in cotton, presents a unique opportunity to increase cotton yield while dually engaging in pollinator conservation on a large scale.

ENGAGING LOCAL COMMUNITIES IN CONSERVATION IN PAPUA NEW GUINEA: CASE STUDIES FROM THE ONE OF THE WORLD'S MOST BIOLOGICALLY AND CULTURALLY DIVERSE COUNTRIES

Richard Cuthbert

Wildlife Conservation Society

The interaction between biological and cultural diversity is nowhere more apparent than in Papua New Guinea (PNG), where the country's diversity of animals and plants – around 8% of the world's terrestrial biodiversity in 1% of global land area – is matched by the diversity of cultures with more than 840 recognized languages in the country. This diversity is facing a wide and growing range of threats; from large-scale extractive industries to climate change, along with a growing human population that is moving from a traditional subsistence lifestyle to the market economy. The challenge of implementing effective conservation measures in PNG is further complicated by the traditional ownership of land and coastal resources (around 97% of land and near-shore marine areas are under customary tenure) and because around 85% of the population gain a significant portion of their nutrition from terrestrial and marine wildlife. This complex situation poses challenges and also opportunities: as the communities with the biggest vested interest in the conservation of wildlife and their environment are the customary landowners who utilise, control and depend on their own natural resources. We discuss three varied conservation initiatives – forest protection in Manus Province, sustainable small-scale fisheries in New Ireland, and the use of fur and feathers in traditional outfits in the Highlands – as case studies for working in PNG. Experience gained from these projects demonstrates that the active engagement of local communities in the design, implementation and enforcement of conservation activities is essential for projects to be supported and that projects can also benefit if customary knowledge can be incorporated alongside modern techniques and conservation science. Strengthening community initiatives along with local and national policies is essential if PNG's diverse wildlife and cultures are to survive against the country's ever growing conservation threats.

A NEW IUCN STANDARD FOR THE IDENTIFICATION OF KEY BIODIVERSITY AREAS

Annabelle Cuttelod

Penny LANGHAMMER, Terraconsilium ; Fishpool LINCOLN, BirdLife International

Biodiversity loss is accelerating at genetic, species, and ecosystem levels with serious negative consequences for the

delivery of ecosystem services and human well-being. There is great demand from across society to know, with precision, where places that contribute significantly to the global persistence of biodiversity occur so that conservation efforts can be targeted effectively. The Convention for Biological Diversity, in its Aichi Target 11, recognized the necessity of ensuring that protected areas networks include, among other characteristics, "...areas of particular importance for biodiversity..." Addressing the challenge of how to identify such areas has been a primary objective of the IUCN WCPA/SSC Joint Taskforce on Biodiversity and Protected Areas. Over recent years, in response to a request from IUCN members, the Joint Taskforce has led a global consultation process involving conservation organizations, academics, national decision-makers, donors and the private sector to develop a globally-agreed standard for the identification of Key Biodiversity Areas (KBAs) as sites that contribute significantly to the global persistence of biodiversity. Building on existing approaches, such as Important Bird and Biodiversity Areas, the KBA Standard broadens the scope to address genetic and ecosystem levels of biodiversity in addition to species and is applicable across taxonomic groups in freshwater, terrestrial and marine systems. This presentation will introduce the criteria in the new KBA Standard, including efforts to test and calibrate the thresholds using data on various taxa and techniques from systematic conservation planning; guidelines for site delineation; and the process to propose a site as a Key Biodiversity Area.

MISSION TREE KANGAROO: A COMMUNITY-BASED APPROACH TO CONSERVATION IN PAPUA NEW GUINEA

Lisa Dabek

Woodland Park Zoo

Matschie's tree kangaroos are listed as endangered (IUCN Red List 2014). They are important to the indigenous landowners of the cloud forest of Yopno-Uruwa-Som (YUS), Morobe Province, Papua New Guinea (PNG) for food and cultural purposes. This species is only found on the Huon Peninsula in Morobe Province. There is a customary land tenure system in PNG and local villagers own over 90% of the land. Since 1996 the Tree Kangaroo Conservation Program (TKCP) has utilized a community-based interdisciplinary approach for both protecting this endangered species and for integrating support for the local communities in the areas of health, education, land-use planning, and sustainable livelihoods. The work of TKCP in partnership with the local landowners resulted in the first and only Conservation Area in Papua New Guinea, which is managed on a local level. This presentation will share TKCP's innovative and groundbreaking approaches to conservation in Papua New Guinea that has resulted in TKCP being a model for

the PNG government for protected areas policy and a model for community conservation in remote areas of Papua New Guinea. Our work adds to the body of knowledge and practice of community driven conservation that can be shared globally. The discussion will specifically include our YUS Landscape Plan; Healthy Village, Healthy Forest project; YUS Conservation Ranger program for monitoring the YUS Conservation Area; tree kangaroo ecological research; Conservation Coffee project with Caffè Vita; and capacity building of staff in the local NGO, Tree Kangaroo Conservation Program - PNG.

POPULATION GROWTH RATE OF TARGET BIRD SPECIES SHOWS POSITIVE ASSOCIATIONS WITH A HIGHER-LEVEL AGRI-ENVIRONMENT SCHEME IN WALES.

Daria Dadam

British Trust for Ornithology

Gavin SIRIWARDENA, British Trust for Ornithology

Declines in farmland biodiversity have been extensively reported across Europe and agri-environment schemes (AES) have been the main geographically-widespread mechanism utilised to address this decline. Their deployment has involved the extensive investment of taxpayers' money, so testing their efficacy is of paramount importance. Previous studies have successfully tested the impacts of English AESs on birds using national-scale survey data. Here we present a similar approach to test the effect of the recently-ceased Welsh higher-level AES, Tir Gofal, on birds. We were able to utilise data from the entire implementation of Tir Gofal, from 1999 to 2013, and use bird data from 300 1km-squares of the long-term BTO/JNCC/RSPB Breeding Bird Survey (BBS). Tir Gofal options were grouped between those providing woodland creation and stock exclusion, scrub management, grassland habitat, arable winter seed, arable invertebrates, heathland, and hedgerow management. Population growth rate of target species in areas with AES was compared to that in the wider countryside outside AES by modelling bird population growth rates with respect to spatio-temporal covariates, namely AES option quantities and appropriate control variables. Grassland and heathland options did not show a clear pattern but woodland and scrub management options were associated with positive population growth rate of several species, including red-listed habitat specialists, a novel pattern that had not emerged from previous work on AES in the UK. Other key results included positive associations of arable winter seed and hedgerow management on a number of target species. In this study we showed a strong association between a number of AES higher-level options and population growth rate of target species, reinforcing the evidence for the need of targeted mechanisms to tackle species decline at habitat level.

POSITIVE AND UNFORESEEN NEGATIVE EFFECTS OF AGRI-ENVIRONMENT MANAGEMENT ON BIRDS

Daria Dadam

British Trust for Ornithology

Gavin Siriwardena, British Trust for Ornithology ; Phil GRICE, Natural England

Environmental Stewardship (ES) was the major agri-environment scheme in England between 2005 and 2014 and included a range of management options designed wholly or partly to help to reverse long-term declines in farmland bird populations. National bird monitoring data were used to test the effects of eight years of ES management on bird population growth rates to inform scheme revisions under the new European Union Common Agricultural Policy (CAP). Analyses were conducted by management option type on all individual species that the management might plausibly benefit. There were broad, positive effects of crop stubble management on granivorous species, reflecting population-limiting factors, but the patterns were less clear for other option types. Considering the results by each of a number of key, farmland-dependent species (as opposed to looking for general patterns by option), there were also net positive associations between population growth rates and ES management for several species. This provides good evidence that ES management has contributed to an ongoing reversal of the population declines of several key species, sometimes operating via the effects of multiple option types. However, there were mixed or negative effects of sacrificial seed crops, suggesting that new ecological relationships involving predation, competition or disease transmission may be developing and overriding positive effects of the management option. Further monitoring and management option development is needed if modified agri-environment management is to succeed in reversing bird declines under the new CAP. This is particularly challenging both because funding is being reduced and because this study shows that responses to management in practice may be modified from those found during developmental or initial monitoring studies.

MARINE PROTECTED AREAS LAG BEHIND WILDERNESS IN THE CONSERVATION OF FUNCTIONAL ROLES

Stéphanie D'agata

University Montpellier

David MOUILLOT, University Montpellier ; Laurent WANTIEZ, Université de Nouvelle-Calédonie ; Alan FRIEDLANDER, University Hawaii Manoa ; Michel KULBICKI, Institut de

Recherche pour le Développement ; Laurent VIGLIOLA, Institut de Recherche pour le Développement

Marine Protected Areas (MPAs) represent one of the most effective management responses to the pervasive human impacts on the world's oceans. However, due to their limited age, size and regulation or their location in regions with deep and long-lasting human footprints, MPAs may fail to provide their full potential benefits and thus appropriate ecological targets for measuring conservation effectiveness. A fair comparison with areas isolated from human activities but located in the same region, while controlling for environmental factors, would reveal the real ecological performance of MPAs with different key conservation features. Here we show that the biomass of apex predators and the breadth of functional roles are significantly higher in fish communities of coral reefs far from the market (>20 hours of travel time) than even in the oldest (38 years old), largest (17,500 ha) and most restricting (no-entry) MPA of New Caledonia (South-Pacific). The release from fish market pressure is dependent of the community aspect, and begins at 7.5 and 12 hours travel for the biomass of herbivores and apex predators, respectively, and at 16.5 hours for the recovery of functional roles. Overall our results suggest that beyond a threshold of 20 hours travel, considered as a delimitation for wilderness, ecological values saturate at levels that are neither reached in MPAs nor in traditionally managed areas. More specifically, apex predators have 3.5 more biomass in wilderness areas than in the most efficient MPA, while some key functional roles (mobile predators) are critically missing in MPAs. We thus demonstrate that wilderness areas support unique ecological values with no equivalency as one gets closer to human activities even in MPAs cumulating key conservation features. Wilderness areas may serve as benchmarks for management efficiency and act as the last sanctuaries for the most vulnerable functional roles, potentially mitigating their decline.

SURVEYS MAKE ME FEEL GOOD: A MULTI-NATIONAL EVALUATION OF SOCIAL DESIRABILITY BIAS WHEN VALUING ENVIRONMENTAL PUBLIC GOODS

Martin Dallimer

University of Leeds

Jette BREHDAHL JACOBSEN, University of Copenhagen ; Thomas HEDEMARK LUNDHEDE, University of Copenhagen ; Bo JELLESMARK THORSEN, University of Copenhagen

Conservation biologists generally accept that the general public value biodiversity and other non-market goods associated with the natural world. This is illustrated by the

large number of survey-based estimates of willingness to pay (WTP) for environmental goods. However, evidence from psychology suggests that a component of any stated value is associated with a social desirability bias (SDB) as respondents seek to feel better about themselves through over-stating their good intentions. This could lead to inflated estimates of WTP. Here we test for the presence of a SDB by comparing personal WTP with the amounts respondents say their peers would pay. We do this within a stated preference survey to elicit WTP for the conservation of semi-natural grassland in 3 European countries (Denmark, Poland, Estonia). Respondents (2122 out of 2900) were personally willing to pay for conservation to enhance environmental goods. They also reported a positive WTP for their peers. An SDB was present, with mean personal WTP of €24.38, some €12.84 (95% CI: 11.21-14.46) higher than that for their peers. Using a hurdle model we investigated socio-demographic drivers of the SDB. The propensity to state different individual and peer WTP amounts was positively related to income and involvement with environmental organisations, while respondents from Poland and Estonia were significantly less likely to report a SDB than people in Denmark. The magnitude of the SDB was not related to any socio-demographic variables, apart from nationality. Here, the presence of an SDB has led to an over-estimate of the values that the general public attribute to the conservation of the natural world. If widespread, such an overestimation could alter what conservationists have come to accept as the strength of the relationship between people and environmental goods. We must therefore develop appropriate methods that control and correct for SDB when valuing the natural world.

INTEGRATING BIODIVERSITY RESEARCH FOR IMPACT MITIGATION ON A TRANS-ANDEAN MEGAPROJECT: CASE STUDY FROM PERU

Francisco Dallmeier

Smithsonian Conservation Biology Institute

Catherine SAHLEY, Smithsonian Conservation Biology Institute ; Bruno VILDOSO, PERU LNG ; Reynaldo LINARES, Smithsonian Conservation Biology Institute ; Pablo TABORGA, PERU LNG ; Karim LEDESMA, Smithsonian Conservation Biology Institute ; Carolina CASARETTO, PERU LNG ; Alfonso ALONSO, Smithsonian Conservation Biology Institute

The PERU LNG Project consists of a 408 km natural gas pipeline that transverses 14 ecological landscape units (ELUs) through the eastern Andes, inter-Andean valleys and Pacific coastline desert. Because of the region's diversity, the Project developed a Biodiversity Action Plan to conserve biodiversity during construction and operation of the pipeline and marine terminal. The Project implemented a Biodiversity Monitoring and Assessment Program (BMAP) to understand the status and trends of species and habitats in the area of influence (Aoi), to assess the effectiveness of mitigation, and to contribute to the

knowledge, management and conservation of biodiversity. The Project used the Mitigation Hierarchy (MH) framework to quantify impacts, assess the effectiveness of mitigation and restoration strategies and align management objectives with best practices for conservation. High-resolution satellite images and field analysis of habitats and vegetation cover of the Aol were used to estimate hectares of habitat avoided during pipeline micro-rerouting and impact minimization efforts. Potential impacts were quantified as quality hectares impacted with and without micro-routing, minimization, or biorecovery for all ELUs. Minimization was quantified by the reduction of right-of-way width in the ELUs and habitats. Biorecovery was also quantified and ground truthed by the BMAP. Residual impacts were calculated by subtracting avoidance, minimization and restoration values from the estimated potential impact, allowing for the design of conservation initiatives aimed at achieving no net loss of biodiversity. A positive restoration trajectory for some ELUs has been reached, indicating that no net loss objectives may be reached. Implementing a BMAP and a MH quantification process contributed to best practices to document, quantify and implement impact mitigation while contributing to innovative approaches to integrate development needs with conservation priorities.

73-LARGE SCALE CONNECTIVITY: ADVANCING OUR KNOWLEDGE IN THE MEDITERRANEAN SEA

Alicia Dalongeville

CEFE, CNRS

Marco ANDRELLO, CEFE, CNRS ; Stéphanie MANEL, CEFE, EPHE

Marine ecosystems are threatened by multiple stressors such as fishing, pollution and climate change, which affect the functioning of ecosystems and their capacity to provide services to society. In particular, commercial fish species suffer important decreases of density and biomass. In that context, Marine Protected Areas (MPAs) have been promoted as a powerful tool to mitigate threats to oceans, but also benefit fisheries by increasing stock levels in fishing areas through adult spillover and larval supply. Up to now, MPAs have been generally set up according to independent local decisions instead of regional management plans. Hence, the spatial design of the actual MPA network is mainly the results of socio-economic factors rather than ecological considerations. Thus, a macroecological perspective on the connectivity of MPA network and its ability to sustain populations is surprisingly lacking. Arguably, this gap of knowledge may be largely due to the lack of detailed and spatially explicit datasets needed for such analyses, the improvement of genetic technologies can provide such datasets by estimating the level of gene flow between populations. We will present here an integrated view of genetic connectivity at the scale of Mediterranean Sea combining results obtained from biophysical modelling

(Andrello et al., 2013, 2015), a quantitative review of fish genetic diversity (Dalongeville et al. submitted) and we will illustrate the project SEACONNECT, which aims to estimate genetic connectivity of fishes from a large spatial sampling at the scale of the Mediterranean Sea using 'Next Generation Sequencing' technology.

MANAGEMENT RESPONSES TO HYBRIDISATION: THE SOUTH AFRICAN PERSPECTIVE

Desire Dalton

National Zoological Gardens of South Africa

Anri VAN WYK, National Zoological Gardens of South Africa ; J. Paul GROBLER, University of the Free State ; Coral BIRSS, Cape Nature ; Antoinette KOTZE, National Zoological Gardens of South Africa

Hybridisation between introduced and endemic ungulates in South Africa resulting from anthropogenic actions has been reported for several species. Hybridization resulting in fertile offspring has been reported in the blue and black wildebeest, black-faced impala (and common impala, grevy's zebra and plains zebra and bontebok and blesbok. Conservation authorities and game farmers supported the development of a set of markers for the routine identification of pure and hybrid individuals in herds. Diagnostic markers for bontebok and blesbok have been developed. Genetic analysis of hybridisation is conducted routinely on bontebok samples collected under chain of custody and these markers have sufficient power to identify fixed genetic differences. In an attempt to acknowledge ancestral polymorphisms and to address concerns related to the low genetic diversity present in bontebok populations, the methods for defining hybrid bontebok incorporates the implementation of a threshold of 90% based on acceptable limits of variability aimed at ensuring the maintenance of the majority of pure bontebok and associated allelic diversity to counter the loss of heterozygosity within bontebok populations. Due to the development of the marker set, national policy and provincial legislation on biodiversity conservation has been adapted and permits for translocation can only be obtained if a genetic certificate is issued. The developed test is of benefit to the private game farmer and nature conservation. Presently there is a huge economic incentive for game farmers to have pure certified animals. In addition, the test supports nature conservation as their current policy states that they do not support the crossbreeding of species, subspecies or ecotypes. Thus, the genetic integrity of the bontebok will be maintained due to a combination of genetic research and the implementation of management responses.

IMPACT OF SOIL PROPERTIES ON THE DISTRIBUTION AND ABUNDANCE OF ISOBERLINIA DOKA IN NIGERIA

Olayinka Daodu

A.P. Leventis Ornithological Research Institute, University of Jos, Nigeria.

Distribution ranges of plant species are related to physical variables of ecosystems that limit plant growth. This study examined the impact of soil properties on the distribution and abundance of *Isoperlinia doka* Craib & Stapf, a hardwood West African tropical timber tree in Kamuku National Park, Birnin Gwari, Kaduna State. A total of 60 sample plots measuring 1000 m² with twenty quadrats of 10 m × 5 m in each of the sampling plots was used to measure and record the floristic and structural vegetation data such as density, species composition, diameter at breast height (dbh), vegetation/crown cover, species richness and diversity index of woody species (≥ 3m high). Frequencies and tree basal areas were also measured, while the percentage litter cover, grass cover as well as bare ground were estimated by sight. Soil samples were also collected from three 10 m x 5 m quadrats in each of the major plots using a cylindrical core and samples were taken to the laboratory for further analysis. Woody species abundance was higher in the mixed species woodlands than inside the *Isoperlinia doka* woodlands (1,542 and 905 respectively) but species richness was higher in the *Isoperlinia doka* woodland than in the mixed species woodlands (65 and 53 respectively). Woody plant species belonging to the family Combretaceae, Euphorbiaceae and Rubiaceae were dominant in the mixed species woodlands while woody plant species belonging to Fabaceae, Annonaceae and Combretaceae dominated the *Isoperlinia doka* woodlands. Woodlands dominated by *Isoperlinia doka* differ markedly in soil features from those in the mixed species: pH, organic Carbon, total Nitrogen, available Phosphorus, exchangeable Calcium, exchangeable Potassium, exchangeable Sodium and Cation Exchange Capacity all showed significant differences. However, the soils of both woodland types were similar in exchangeable Acidity (H+Al) and exchangeable Magnesium.

124 GERMAN IMPACT MITIGATION REGULATION - AN EXAMPLE TOWARDS NO NET LOSS OF BIODIVERSITY?

Marianne Darbi

Leibniz Institute of Ecological Urban and Regional Development

Wolfgang WENDE, Leibniz Institute of Ecological Urban and Regional Development

Germany has an impact mitigation regulation (IMR) procedure since 1976 legally based in the Federal Nature Conservation

Act. The planning and assessment instrument accompanies the environmental impact assessment, and results in legally binding no net loss (NNL) and biodiversity offset requirements. We present real-world experiences with IMR and with the establishment and use of habitat banks, as demonstrated through the Burgberg Zschaitz Habitat Bank in Saxony. Both key factors to success and obstacles under the German IMR are identified, providing valuable lessons learned: 1. Successful offsets are backed by clear regulation and policy guidance, while unclear and uncertain administrative action and sometimes lacking engagement of government agencies may be an obstacle. 2. Cooperation with stakeholders at regional level, including land owners and farmers, is crucial, ensuring public acceptance through clear conservation goals (including socioecological aspects, e.g. environmental education, aesthetic and recreational values). 3. The implementation of larger, complex and high quality measures not only adds to reaching state-wide nature conservation goals and strengthen biotope networks and connectivity, but is also more cost-efficient to plan and implement. 4. To ensure this delivers best outcomes, compensation services providers (i.e. habitat banks) need trained personnel and a sound methodology. 5. Problems of uncertainty and advance financing as well as the negative effects of competition (i.e. price dumping) are best addressed by a stable, independent and not profit-oriented compensation services provider who should also guarantee the maintenance and safeguarding of the measures in perpetuity. In addition, we share experiences on metrics as applied in Saxony and illustrate how biodiversity offset measures around an EU Natura 2000 site provide an actual 'add-on' of measures beyond the currently required Habitats Directive management measures.

181 - DATA-DRIVEN PORTFOLIOS OF CLIMATE ADAPTATION STRATEGIES FOR INDO-PACIFIC CORAL REEFS

Emily Darling

Wildlife Conservation Society

Joseph MAINA, University of Queensland; David MOUILLOT, Université Montpellier; Tim MCCLANAHAN, Wildlife Conservation Society

Climate change is an unprecedented threat to global coral reefs. There is mounting evidence that conventional marine conservation cannot prevent wholesale losses in the face of climate change. Urgently, innovative regional approaches to are needed to tackle climate change through portfolios of local conservation and management actions, such as strategically establishing marine reserves within natural climate refuges or promoting climate-tolerant fisheries. I will present a multi-stakeholder project that involves 90+ international researchers, NGOs and government agencies to identify climate adaptation options for 2200+ coral reefs throughout the Indo-Pacific. This data-driven approach combines coral reef surveys with climate

models to identify portfolios of adaptation actions across gradients of climate exposure and functional diversity. I will also address the practical realities of coordinating multiple, complementary conservation actions for coral reefs and the communities that depend on these valuable ecosystems across the Indo-Pacific.

CROPS, COMMUNITY AND CONFLICT

Jyoti Das

AARANYAK

Bibhuti LAHKAR, AARANYAK ; Bibhab TALUKDAR, AARANYAK

Human elephant conflict is a major issue in Golaghat district of Assam and it is one of the most affected areas in entire India. The district has witnessed loss of enormous forest cover owing to deforestation, encroachment, tea cultivation and construction of an oil refinery in last two decades. Keeping this in view, we initiated this study to mitigate human elephant conflict by using multi dimensional approach for driving away elephants. The ultimate aim was to create an environment for co-existence of elephants and people in harmony. We selected a village named Sundarpur (found to be the most affected by elephants) and decided to work with the communities. We recorded a total of 245 conflict incidents (n=245) during the study period (2012-13). This included 53 incidents of house damage, 8 incidents of physical injury or death and 184 incidents of crop-raiding. We implemented community based crop protection measures in the model village of Sundarpur. Initially, three groups of local youths were formed and trained. Trial plots were established to investigate the potential of different methods like trip wire and chilli fencing to drive the elephants. Further, chilli cultivation was carried out to look at the potential as cash crop for the locals. Both the methods were tried separately and showed a 60 - 70 % success rates in driving away the elephants. Out of 18 occasions when the elephants visited the trial plots, the trip wire and chilli fencing method successfully driven away the elephants for 13 and 14 times respectively. We recommend chilli fencing method to be implemented in this locality which is cost effective and also income generating for the local farmers. Human and elephant can co-exist in harmony with this initiative in this area.

SECURING THE CONSERVATION OF BENGAL SLOW LORIS; APPROACHING INTERDISCIPLINARY CONSERVATION ACTION PLAN (ICAP)

Nabajit Das

Primate Research Centre NE India

K. A. I. NEKARIS, Oxford Brookes University ; Jihosuo BISWAS, Primate Research Centre NE India ; P. C. BHATTACHARJEE, Gauhati University

Endemic to Southeast Asia, including Northeast India, the Bengal slow loris *Nycticebus bengalensis*, a nocturnal primate, draws less attention from conservationists. The combination of being strictly nocturnal makes the species sensitive to any changes in their habitat. Hunting for medicinal beliefs, combined with habitat loss and fragmentation are the major threats. Status of Bengal slow loris is currently listed as Vulnerable on the IUCN Red List, basis of habitat loss alone. From 2009 to 2013, we carried out a detailed survey to estimate the population status in protected areas of Assam and Arunachal Pradesh, Northeast India. Line transect methods were used to estimate loris encounter rates. A team of 3-4 individuals conducted surveys at night (1800 – 0300h) on foot, detecting lorises visually. During first phase of survey we covered 370 km and in second phase of survey covered 71 km only in Namdapha National Park, Arunachal Pradesh. The abundance estimate of this species was calculated at 0.06 to 0.42 loris / km, which is relatively low when compared to estimates of slow lorises throughout their distribution range in Southeast Asia. Combined with ongoing anthropogenic threats and very likely listing of the Indo-Burmese form as a distinct taxon, the species should be regarded in a crisis situation in Northeast India. An action plan should be implemented including planned management, habitat protection, management of people and their activities, legislation and its enforcement and training of manpower to implement key actions. A more comprehensive, interdisciplinary approach to action planning will result a plans that effectively assisting decision makers responsible for allocating resources and authorizing action, as well as implementers of species conservation.

ID 7 : CAN ZONOTIC DISEASE RISK HELP CURB THE WILDLIFE TRADE IN CHINA?

Peter Daszak

EcoHealth Alliance

Maureen MILLER, EcoHealth Alliance ; Aleksei CHMURA, EcoHealth Alliance ; James DESMOND, EcoHealth Alliance ; Parviez HOSSEINI, EcoHealth Alliance ; Jon EPSTEIN, EcoHealth Alliance ; Kevin OLIVAL, EcoHealth Alliance ; Zhengli SHI, Wuhan Institute of Virology ; Guangjian ZHU, EcoHealth Alliance

The unsustainable consumption of wildlife for food in China is a significant conservation concern. Despite international pressure, and interventions from the Chinese government, the trade in wildlife within southern China, and neighboring countries appears to be expanding. The consumption of wildlife for food has been linked to the emergence of a range

of highly lethal emerging diseases, including Ebola virus disease, SARS and others. In this talk, we describe a strategy to quantify the risk of the wildlife trade in southeast Asia to human health. This involves a combination of human behavioral risk surveillance, characterization of market 'value chains', economic analysis of emerging disease costs, and identification of novel and known viruses in animals traded within markets. In addition, we are sampling captive raised wildlife to examine whether farming wildlife reduces the risk of disease emergence. Demonstrating that this is a more healthy alternative to consumption of wild-caught animals, reduces conservation impact, and remains economically viable, could lead to this becoming an acceptable alternative to an unsustainable and risky trade.

ID#151 : HOW BIODIVERSITY CONSERVATION CAN PREVENT PANDEMICS

Peter Daszak

EcoHealth Alliance

Carlos ZAMBRANA-TORRELIO, EcoHealth Alliance ; Kevin J. OLIVAL, EcoHealth Alliance ; Kris A. MURRAY, Imperial College ; Toph ALLEN, EcoHealth Alliance ; Tom HUGHES, EcoHealth Alliance ; Dan SCHAR, USAID RDMA ; Katherine D. LEE, University of Wyoming ; Elizabeth H. LOH, EcoHealth Alliance ; David C. FINNOFF, University of Wyoming ; Parvies Rana HOSSEINI, EcoHealth Alliance ; Jamie PIKE, EcoHealth Alliance ; Catherine MACHALABA, EcoHealth Alliance ; Jon H. EPSTEIN, EcoHealth Alliance ; William B. KARESH, EcoHealth Alliance

Policy efforts to conserve biodiversity are often given short shrift when balanced against the realities of lives lost due to pandemic zoonotic disease emergence (e.g. H1N1, SARS, Ebola), or the high profits of land conversion, agricultural intensification and trade. However, we propose that there are hidden and highly valuable health benefits in protecting biodiverse landscapes from exploitation, specifically linked to disease emergence. In this talk, we lay out a framework to leverage health impacts and economic costs of emerging diseases to help promote biodiversity conservation. First, we present a new analysis of Emerging Infectious Disease (EID) hotspots using new underlying data and a new modeling framework. Our results confirm that, while human population density (and population change) and mammalian species richness are correlated with zoonotic EID risk, so also are measures of land use change. Secondly, we present data from economic modeling of disease risk in the Amazon and in Borneo that demonstrate if the economic costs of disease emergence from these highly biodiverse regions are taken into account, the rate of deforestation is demonstrably unsustainable from an ecosystem services perspective. Finally, we show that strategies to prevent pandemic emergence by dealing with the underlying drivers of emergence (e.g. land use change, wildlife trade) are more cost effective in the

long term than business-as-usual. Our work demonstrates the health benefits of conserving wildlife biodiversity, and specifically promotes biodiversity conservation as a strategy to prevent the most high-profile health threats: emerging zoonoses. We propose that highlighting these specific health benefits of conservation will be a useful tool in efforts to reduce deforestation and the global wildlife trade in the age of pandemics.

FALLOW HUNTERS: SPATIO-TEMPORAL DYNAMICS OF LARGE MAMMAL HUNTING IN A SHIFTING CULTIVATION LANDSCAPE IN ARUNACHAL PRADESH, INDIA

Anirban Datta-Roy

Ashoka Trust for Research in Ecology and the Environment (ATREE)

Nitin Rai, Ashoka Trust for Research in Ecology and the Environment (ATREE)

Subsistence hunting and shifting cultivation have been traditional practices of indigenous people of upland areas across parts of the world including the Himalayan biodiversity hotspot areas. In northeast India, although these practices are discouraged through policies and laws, they continue to play an important role in the cultural and socio-economic lives of indigenous people. An understanding of such systems has been hampered by the lack of detailed studies. We used participatory methods to document subsistence hunting based on a self reporting offtake monitoring system. We present spatial and temporal dynamics of large mammal hunting over 22 months in an eastern Himalayan village inhabited by the Adi tribe, who practice traditional shifting cultivation and subsistence hunting. Preliminary analysis of the spatio-temporal patterns of hunting indicate that 45% of the hunts occur in the shifting cultivation fallows around the village while temporal intensity of hunting appears to be influenced by the timing of the agricultural calendar. 47% of wild meat biomass is procured from hunts that occur in a matrix of cultivation and differently aged fallows. Hunting in the fallows is characterised by short hunting trips. Results are consistent with observations by previous authors of 'garden hunting' among indigenous shifting cultivators in central and south America. This study provides first documentation of actual hunting yields for the region. While the results indicate the importance of these mixed-use landscapes as an important source of food and sustenance for the villagers, these landscapes are currently under threat. Government policies have been largely intolerant of shifting cultivation and are attempting to replace them with permanent cultivation in the form of terraces and horticultural orchards. Our study suggests there is much merit in maintaining these landscapes for subsistence practices and simultaneously reducing hunting pressure on the adjoining forests

CONSERVATION OF AFRICAN RAIN FORESTS: A RAPID ASSESSMENT OF THREAT USING A META-DATASET OF PLANT OCCURRENCES RECORDS

Gilles Dauby

Institut de Recherche pour le Développement
Anne BLACH-OVERGAARD, Aarhus university; Vincent DEBLAUWE, Institut de Recherche pour le Développement ; Vincent DROISSART, Institut de Recherche pour le Développement ; Olivier J. HARDY, Université Libre de Bruxelles ; David HARRIS, Royal Botanic Garden Edinburgh ; Alexandra LEY, University Halle-Wittenberg ; Barbara MACKINDER, Royal Botanic Garden Edinburgh ; Marc SOSEF, Botanic Garden Meise ; Tariq STÉVART, Missouri Botanical Garden ; Bonaventure SONKÉ, Université de Yaoundé 1 ; Jens-Christian SVENNING, Aarhus university ; Pierre SEPULCHRE, CNRS ; Jan WIERINGA, Naturalis Biodiversity Center ; Rainer ZAISS, Institut de Recherche pour le Développement ; Thomas L. COUVREUR, Institut de Recherche pour le Développement

Africa hosts the second largest extent of tropical rain forest (TRF) in the world. Even though they represent one of the most species-rich places on Earth, African TRFs are being depleted of their biodiversity resulting mainly from global changes. Species with small ranges are particularly vulnerable to extinction. Identifying areas with high concentration of such microendemic and threatened species is therefore of crucial importance for conservation planning. Despite considerable efforts to improve our knowledge on biodiversity patterns across African TRF, estimates of levels of threat are largely lacking. Indeed, published IUCN assessments are only available for ca. 1,500 plant species whereas the total number of species in African TRF probably exceeds 15,000. This is explained mainly by the time-consuming species by species process of properly assessing and publishing conservation status using IUCN Red List criteria and categories, but also by the poor knowledge of plant distributions. Here, we undertake a rapid risk of extinction assessment of more than 5,000 African TRF plant species based on the unique RAINBIO database representing over half a million occurrences of sub-Saharan vascular plant species. Using an R routine that calculates the EOO, AOO and number of localities, we used the criteria B to identify threatened species and provide their conservation status following the Red List categories. We use these results to generate various maps of risk for the region's flora using the different Red List categories. To assess the robustness of our approach, results are compared to available IUCN assessment for Cameroon and Gabon. Even though this approach might seem rudimentary, it provides a quick but necessary approach of exploring current threats for a large number of species and identifying potentially high-priority areas for future conservation efforts while providing preliminary data for assessments of Red List index in the region.

POPULATION DYNAMICS FOR THE VULNERABLE POPULATION OF SOUTHERN RIGHT WHALES (EUBALAENA AUSTRALIS) IN NEW ZEALAND WATERS

Anthony Raphael Davidson

University of Otago

Liz SLOOTEN, University of Otago ; William RAYMENT, University of Otago

The analysis of population dynamics is key in the conservation for endangered and vulnerable species. Southern right whales (*Eubalaena australis*) were nearly extirpated from New Zealand (NZ) waters by commercial whaling in the 19th century but are now thought to be recovering. Here we present the first matrix model for right whales in NZ to assess population dynamics. Parameters used in the matrix model incorporated new estimates of life history traits from data collected in Port Ross, Auckland Islands (2006-2012), and conspecific parameters. A three-stage, female only, matrix population model was used to estimate growth rate, stage distribution and sensitivity/elasticity. The estimated growth rate is $\lambda=1.056$ (95% bootstrapped CI: 1.019-1.130). Sensitivity analysis suggests the survival rate of the mature female stage had the highest proportional effect on population growth rate. This population growth, coupled with recent re-colonization of former habitats around mainland, and evidence from congeneric populations, suggest that southern right whales in New Zealand may become exposed to impacts in the future, e.g. from fishing and shipping. Conservation management aimed at maximizing mature female survival (e.g. MPAs, shipping restrictions) will be important for continued population recovery.

AN ECOSYSTEMS APPROACH TO MANAGING VEGETATION ALONG BRITAIN'S TRANSPORT CORRIDORS

Helen Davies

ADAS UK Ltd

Marion FRANDSEN, ADAS UK Ltd ; Mike IMAGE, ADAS UK Ltd ; Clare WARBURTON, Natural England ; Nick WHITE, Natural England

The study set out to investigate how vegetation adjacent to railway lines and motorways (the 'soft estate') could be managed to maximise biodiversity gain, ecological connectivity, ecosystem services provision, and resilience of transport infrastructure to climate change. This involved a review of literature to identify existing good practice in the UK and beyond; engagement with stakeholders within the two Nature Improvement Areas (NIAs) of Morecambe Bay and the Humberhead Levels; interviews with regional Network Rail and Highways Agency staff covering these two areas; and the development of a GIS-based multi-criteria decision aid to

identify vegetation management options for those sections of the transport network with the greatest opportunity or need. The options identified vary according to the existing habitat within the transport corridor (based on 100m segments), the surrounding land use (e.g. agricultural) and land cover (woodland, grassland or wetland), and the nearby presence of hazards (such as flood risk or leaf fall) and biodiversity designations. The project has shown that management strategies for transport soft estate can deliver multiple ecosystem services, for example pollination, water regulation and provision of biomass. This novel study brought together a wealth of previously disparate literature, providing a scientific basis to discussions between land managers/owners and wider environmental stakeholders who jointly attended meetings in order to better understand the opportunities and constraints. Over the next three years, Network Rail, the Highways Agency, Natural England and the Wildlife Trusts of Cumbria and Yorkshire will invest millions of pounds implementing these management options in up to six opportunity areas identified in each of the two NIAs. If successful, this innovative yet simple approach could be rolled out on a wider scale, potentially covering transport and other linear corridors across the UK.

NURSING STUDENTS WALKING IN URBAN AREAS TO DEVELOP AN UNDERSTANDING OF OPEN SPACES AS A RESOURCE FOR HEALTH

Jacqueline Davies

City University London

Student nurses walk in urban streets and parks to observe ecological concerns such as energy pollution and human-wildlife conflicts; and reflect on how they will communicate the benefits of outdoor activities for a range of individuals. While the socially advantaged may readily embrace outdoor activities, those from less advantaged backgrounds often view public spaces as high risk environments. On their walk students meet and talk to the people they will care for when they are in practice. They learn about the space where they will later encourage people to walk. And they get to walk and meet each other. Some reports from these urban walks view nature as dirty and dangerous. The teaching innovation that which requires students to step out into the real three dimensional world and use all five senses to observe has won a prestigious quality award from the local health education board and been evaluated positively by students. The method draws on the health worker's long established practice of 'walking the patch' and their need to observe and write a report of what was noticed in a given time and area. The walk provides an opportunity to observe both old and new public health challenges and initiatives, from drainage systems upwards. The instructions given to the student to walk about in a group, observing, notice and conversing have been

developed from the psychogeography 'dérive' developed by Guy Debord in Paris in the 1950s, which we first used successfully with business studies students to disrupt traditional transmissive learning. The educational initiative is valuable for healthcare professionals to learning about their area of practice and reflecting on how to develop strategies and manage challenges of using the natural environment as a space for developing healthy living.

DIAGNOSING LARGE-SCALE MARINE PROTECTED AREAS: A COMPARATIVE ANALYSIS OF THE SOCIAL, ECOLOGICAL AND INSTITUTIONAL DRIVERS OF SUCCESSFUL CONSERVATION

Tammy Davies

University of Victoria

Natalie BAN, University of Victoria ; Michael COX, Dartmouth College ; Louisa EVANS, University of Exeter ; Graham EPSTEIN, Indiana University ; Mateja NENADOVIC, Duke University ; Sara MAXWELL, Old Dominion University ; Cassandra BROOKS, Stanford University ; Stacy AGUILERA, University of Miami

To meet global conservation targets and secure sustainable resource use, governments and NGOs are increasingly establishing large marine protected areas (MPAs). Large MPAs face unique management challenges, yet we know little about what affects their performance. To identify pathways to effective management, we systematically investigated the ecological, social and governance characteristics that contribute to effective management of large MPAs. We used the MPA global database (www.mpaglobal.org) to identify large MPAs (marine portion larger than 10,000km²) with governance arrangements in place for at least five years. There were 15 MPAs globally that fulfilled these criteria and that had sufficient secondary data to enable reliable and accurate coding. Cases were entered in the Social-Ecological Systems Meta-analysis Database (<http://sesmad.dartmouth.edu/>), which enables consistent measurement of key variables related to the ecological and social components of social-ecological systems, as well as the governance system that influence the ways in which people interact with the environment and each other. Our comparative analysis combines the quantitative rigor of formal statistical meta-analysis with some of the flexibility of qualitative and primary data collection to address critical research areas concerning: 1) the applicability of knowledge developed in small-scale systems to large scale systems, and 2) the extent to which success factors proposed in conservation biology and MPA design apply across cases. By drawing upon multiple perspectives, our analysis highlights key lessons for MPA success at large scales, while also suggesting important future research priorities for this field.

101 SPRINGS: CONSERVING PERENNIAL WATER CRITICAL IN ARID LANDSCAPES

Jenny Davis

University of Canberra

Sam NICOL, CSIRO; Rafael DE GRENADE, University of Arizona;

Charles FOLEY, Wildlife Conservation Society

Arid landscapes are highly water-limited environments and all water (surface and groundwater) is environmentally, culturally and economically important. Springs, sites where groundwater discharges at the Earth's surface, are often the only long lasting, or perennial aquatic habitats in arid regions. Accordingly, they provide habitats for aquatic biota, as well being an essential water resource for terrestrial species and human settlements. Small spring-fed aquatic habitats often contain the greatest concentration of endemic species of plants, fishes and invertebrates within a region. They are increasingly being recognized as globally important biodiversity hotspots and evolutionary and ecological refugia. However, water resource development represents a major threat to spring ecosystems. Increasing groundwater withdrawal for direct human consumption and the production of food, fibre and energy, all driven by global population growth, is a major management issue for many spring habitats. Predictions from global climate models that suggest that drier regions will become drier and extreme events (extended droughts) more common. This will increase the pressure to extract groundwater for human use and result in the loss of spring habitats and the endemic and dispersal-limited species they support. Additional management challenges include impacts of exotic and invasive species and unmanaged recreational activities. The isolation and small size of spring habitats makes them extremely vulnerable to anthropogenic impacts. However, it also means that important conservation actions may be more feasible and cost effective for springs than for larger aquatic ecosystems. Conservation measures include fencing to exclude feral herbivores, removal of alien aquatic species and assisted re-colonisation of dispersal-limited, endemic species. However, the protection of the groundwater resource on which desert springs depend must be a fundamental protection priority.

ACCOUNTING FOR ENFORCEMENT COSTS IN THE SPATIAL ALLOCATION OF MARINE ZONES

Katrina Davis

University of Western Australia

Marit KRAGT, University of Western Australia; Stefan GELCICH,

Pontificia Universidad Catolica de Chile; Steven SCHILLIZI,

University of Western Australia; David PANNELL, University of Western Australia

Marine fish stocks are in many cases extracted above sustainable levels, but they may be protected through restricted-use zoning systems. The effectiveness of these

systems typically depends on support from coastal fishing communities. High management costs including those of enforcement may, however, deter fishers from supporting marine management. We incorporated enforcement costs into a spatial optimization model that identified how conservation targets can be met while maximizing fishers' revenue. Our model identified the optimal allocation of the study area among different zones: no-take, territorial user rights for fisheries (TURFs), or open access. The analysis demonstrated that enforcing no-take and TURF zones incurs a cost, but results in higher species abundance by preventing poaching and overfishing. We analyzed how different enforcement scenarios affected fishers' revenue. Fisher revenue was approximately 50% higher when territorial user rights were enforced than when they were not. The model preferentially allocated area to the enforced-TURF zone over other zones, demonstrating that the financial benefits of enforcement (derived from higher species abundance) exceeded the costs. These findings were robust to increases in enforcement costs but sensitive to changes in species' market price. We also found that revenue under the existing zoning regime in the study area was 13-30% lower than under an optimal solution. Our results highlight the importance of accounting for both the benefits and costs of enforcement in marine conservation, particularly when incurred by fishers.

ELASTICITY IN ECOSYSTEM SERVICES: ANALYSING VARIABLE RELATIONSHIPS BETWEEN ECOSYSTEMS AND HUMAN WELLBEING

Tim Daw

Centre; Katrina BROWN, University of Exeter

The Millennium Ecosystem Assessment highlighted the role of ecosystem services for human wellbeing, suggesting a positive relationship between ecosystem health and human wellbeing. Yet improvements in human wellbeing have coincided with ecosystem degradation, suggesting a more complex relationship. To investigate this relationship, the NERC/

ESPA funded Sustainable Poverty Alleviation from Coastal Ecosystem Services (SPACES) project has applied an extensive ecological and social dataset from rapidly transforming coastal areas of Kenya and Mozambique to a heuristic framework to conceptualise and assess the processes linking ecosystems to human wellbeing. The SPACES framework uses multiple interlinked chains of ecosystem services that encompass multiple provisioning, regulating and cultural services. For each service we assess the elements of the ecosystem underpinning the services and goods obtained, how these are given value through access and markets, and the distribution of wellbeing benefits among groups of people. Here, we show how fishery catch data, Ecopath modelling, reef carbonate budget censuses, household and community surveys can be used to populate this framework. The framework describes the “elasticity” of each service, (how human wellbeing responds to incremental changes in ecosystem quality), and the linkages, conflicts and inequalities within and between ecosystem services. Further, this framework will allow us to investigate which links in the chains are most sensitive to changes in the levels, access or value of goods and services provided by the ecosystem and how human needs and wellbeing can drive feedbacks within chains. By exploring “elasticities” under different future scenarios the framework can be used to identify where policy and management tools for promoting both human wellbeing and ecosystem health are likely to have the greatest impact.

118 POVERTY, WELLBEING AND EQUITABLE CONSERVATION - EMPIRICAL INSIGHTS FROM RWANDA AND LAOS

Neil Dawson

University of East Anglia

This talk presents social studies from forest-adjacent villages in Rwanda and Laos, funded through the Ecosystem Services for Poverty Alleviation programme. In summary, tradeoffs and synergies between the wellbeing of local populations and conservation goals were extremely context specific and variable, suggesting prescriptive one-size-fits-all conservation and development initiatives are unlikely to result in win-wins. Fine-scale studies discussed here sought to interpret perspectives of those living alongside the world’s biodiversity hotspots, their own priorities and values, as well as evaluate their standard of living. In line with more comprehensive definitions of equity, concerns of local populations rest not only on distribution of material resources but also procedures through which decisions are made plus recognition of context-specific needs and socio-cultural values. This has important implications: For example attempts to restrict traditional, ‘unproductive’ modes of farming in both countries were viewed quite differently based on how alternatives were introduced,

choices afforded to smallholders and compatibility with local culture and aspirations (not simply profitability). While equity research reveals perceptions of governance, wellbeing enhances understanding of local values and behaviour. Poverty research can then complement this, but here mainstream poverty indicators are shown to be of limited value, for example taking no account of land tenure, so often a major factor in perceptions of conservation initiatives. The common assumption that poverty leads to resource exploitation was, currently, unfounded in these case studies. Moreover the importance placed on different habitats in the wider landscape (not only forests) revealed opportunities for meeting joint social and ecological goals through integrated landscape management, opportunities so far unrealised due to lack of community engagement.

ENVIRONMENTAL FLOWS AT WORK; RESTORING FLOODPLAIN WETLANDS THROUGH RETURN OF HISTORICAL CONDITIONS

Samantha K. Dawson

Centre for Ecosystem Sciences, University of New South Wales

Richard T. KINGSFORD, Centre for Ecosystem Sciences, University of New South Wales ; Jane A. CATFORD, School of BioSciences, The University of Melbourne [INSTITUTE] Fenner School of Environment and Society, The Australian National University [INSTITUTE] Department of Ecology, Evolution and Behavior, University of Minnesota ; Peter BERNEY, National Parks and Wildlife Services, Office of Environment and Heritage ; David KEITH, Centre for Ecosystem Sciences, University of New South Wales [INSTITUTE] New South Wales Office of Environment and Heritage

Wetlands are among the most degraded ecosystems worldwide, demanding effective restoration. In an effort to ameliorate ecological degradation from upstream water diversions, environmental and managed flows (E-flows) are increasingly used to help restore vegetation communities. Understanding of factors affecting the success and efficacy, however, remains limited. We investigated the capacity of flooding, including E-flows, to restore wetland flora across areas varying in disturbance intensity from historic land-use (land-use intensity). We predicted that increasing land-use intensity would decrease restoration effectiveness, while more frequent and increased duration flooding should improve restoration outcomes. A case study was used to assess vegetation restoration: a floodplain wetland with a land-use intensity chronosequence, flooded through E-flows, in the Macquarie Marshes in the Murray-Darling Basin of south-eastern Australia. We examined extant vegetation, soil seedbanks, plant trait distributions and historical vegetation change through surveys of plant community composition, greenhouse seedbank

germination, trait modelling approaches and Landsat imagery analysis. Composition of extant herbaceous vegetation correlated with land-use intensity and flooding, while extant shrub and woody species were more strongly correlated with land-use. Within seedbanks, exotic and disturbance-adapted species were associated with higher land-use intensity and native wetland species were associated with lower land-use intensity and increased frequency and duration of flooding. Trait analyses showed similar results to the seedbank with respect to disturbance and wetland traits. Imagery analysis showed regular flooding coincided with restoration success. In conclusion, flooding was critical to achieving restoration objectives, with higher frequencies increasing efficacy, but increased land-use intensity compromises restoration rates.

CONSIDERATIONS OF SCALE IN JAGUAR AND PUMA RESOURCE SELECTION MODELS BASED ON SCAT LOCATIONS IN SOUTHERN MEXICO

Jennifer Day

University of Washington

Jurgi CRISTOBAL-AZKARATE, University of Cambridge ; Brenda SOLORZANO, National Autonomous University of Mexico ; Samuel WASSER, University of Washington

Mexico's Isthmus of Tehuantepec is a critical bridge between Central and North American populations of jaguar (*Panthera onca*) and puma (*Puma concolor*). The goal of our study is to develop species-specific landscape connectivity models of southern Mexico as tools for conservation. We collected 126 putative felid scat samples in the Uxpanapa valley of Veracruz, Mexico with the aid of wildlife detection dogs. Of those, 56 samples contained sufficient quality DNA for species confirmation based on mtDNA sequences (28 jaguar locations, 8 puma, 20 small felid). Resource selection probability functions (RSPFs) were fit using scat locations as used sites and generated points within the surveyed track zone as available sites. Here, we focus on the consideration of geographic scale when evaluating covariates, such as terrain ruggedness or road density, for building RSPF models along with the consequences of scale-selection on downstream construction of connectivity models of the Uxpanapa valley.

USING ECO-EVOLUTIONARY INDIVIDUAL-BASED MODELS TO INVESTIGATE SPATIALLY-DEPENDENT PROCESSES IN CONSERVATION GENETICS

Jennifer Day

University of Washington

Nathan SCHUMAKER, US Environmental Protection Agency

Eco-evolutionary individual-based models (IBMs) are powerful new forecasting tools for exploring management strategies for climate change and other dynamic disturbance regimes. Additionally, eco-evo IBMs are useful for investigating

theoretical feedbacks between evolutionary dynamics and wildlife population dynamics. We designed a series of theoretical simulation models within the software platform HexSim, to investigate how spatial landscape pattern influence eco-evo processes relevant to conservation. Our simulation uses a changing landscape to drive changes in isolation by distance (IBD), drift, migration, and selection, incorporating both demographic and genetic metrics to track eco-evolutionary responses. Our series of simulations addresses the following questions: 1. In well-connected landscapes exhibiting little genetic drift, how does isolation by distance (IBD) affect inferences of genetic structure? 2. In disconnected landscapes, how does drift interact with IBD, and thus affect inferences of genetic structure? 3. In poorly-connected landscapes, how effective is dispersal at homogenizing population structure resulting from both IBD and drift? 4. In poorly-connected landscapes, how does dispersal ability influence genetic structure when populations are subjected to IBD, drift, and selective pressure? We demonstrate how the results of our simulations lay the groundwork for applying eco-evo spatial IBMs to specific conservation applications with a simulation investigating jaguar habitat connectivity and landscape genetics in southern Mexico.

LIGHT POLLUTION AND BATS: IS IT TIME TO SWITCH OFF THE LIGHTS?

Julie Day

University of Exeter

James BAKER, The Vincent Wildlife Trust [INSTITUTE] University of Exeter ; Henry SCHOFIELD, The Vincent Wildlife Trust ; Kevin GASTON, University of Exeter ; Fiona MATHEWS, University of Exeter

Artificial nighttime lighting is a growing conservation concern, affecting many groups of organisms. Most bats are nocturnal and so particularly vulnerable to light pollution. A proposed mitigation option to reduce negative environmental impacts of street lighting is to reduce exposures by switching off streetlights for part of the night. These schemes often retain lighting during the hours of most human activity. We assessed the potential benefits of part-night lighting on a photophobic bat species, *Rhinolophus ferrumequinum* and explored the extent to which periods of peak bat activity in roadside environments close to roosts coincided with the proposed switch-off times for streetlights. Following this we then monitored the activity of multiple bat species activity at seventeen sites before and after the implementation of part-night lighting. For *R. ferrumequinum*, a large primary peak in activity was observed one hour after sunset with a smaller secondary peak before sunrise. Due to the large proportion of activity early in the night, we conclude that the potential for part-night lighting schemes to benefit this species is very limited. In our observational study of part-night lighting,

switching off the lights after 2am affected species composition and abundance to varying degrees, depending on habitat. Sites with poor habitat showed little increase in bat activity when streetlights were switched off, whilst sites with better quality habitat saw increases in bat activity and species diversity. Part-night lighting may therefore provide some benefits for bats in certain environments.

NEW PROSPECTS FOR STANDARDIZED MICROSATELLITE GENOTYPING USING HIGH THROUGHPUT SEQUENCING

Marta De Barba

Univ. Joseph Fourier

Christian MIQUEL, Univ. Joseph Fourier ; Stephan LOBREAUX, Univ. Joseph Fourier ; Frederic BOYER, Univ. Joseph Fourier ; Jon SWENSON, Norwegian University of Life Sciences ; Pierre TABERLET, Univ. Joseph Fourier

Individual identification based on microsatellite genotyping using DNA extracted from biological samples has played a major role in wildlife research during the past 20 years. Molecular individual identification has been the basis for demographic, genetic, and ecological studies of wild animals, including applications for population estimation and monitoring, movement tracking, pedigree reconstruction, assessing genetic diversity, structure and gene flow, and forensics. This information contributed to increase knowledge of species biology and has been key for conservation. Currently, microsatellites are genotyped by scoring alleles on electropherograms resulting from running PCR products on a capillary sequencer. However, this method poses limitations on the number of samples that can be run in parallel and for complete automation and standardization of the genotyping process. We present a new genotyping approach based on the use of high throughput sequencing (HTS). With this method, multilocus genotypes are scored by analyzing directly the sequence of the alleles. This feature provides greater accuracy of allele determination because alleles are unambiguously identified by their sequences. This will also permit to easily share genotype data generated in different labs without need of calibrating allele sizes, which will represent an important advantage for effective monitoring of populations across countries and the creation of transboundary databases. In addition, due to the ability of HTS to produce huge amount of sequence data, large sample sizes could be processed for many markers in parallel, allowing to reduce time and costs of large scale projects and analyses requiring a greater number of loci than just for individual identification. We will present the technical basis of the method and discuss aspects of its implementation in comparison to the traditional method. In addition, we will provide results of its application for genotyping wild carnivore samples.

“HOTSPOTS” TO “REDDSPOTS”: OPTIMISING CARBON, JAGUARS AND BIODIVERSITY CONSERVATION

Alan Eduardo De Barros

University of Oxford/ University of Sao Paulo

Ewan A. MACDONALD, School of Geography and Environment, University of Oxford ; Marcelo Hiromiti MATSUMOTO, The Nature Conservancy of Brazil ; Rogerio C. PAULA, CENAP, National Research Center for Carnivore Conservation ; Sahil NIJHAWAN, Panthera ; Y. MALHI, School of Geography and Environment, University of Oxford ; David W. MACDONALD, Wildlife Conservation Research Unit, Department of Zoology, University of Oxford, The Recanati-Kaplan Centre, Tubney

A major question in global environmental policy is whether schemes to reduce carbon pollution through forest management, such as Reducing Emissions from Deforestation and Degradation (REDD+), can deliver co-benefits for biodiversity conservation in tropical countries. Here, we identify municipalities in Brazil that are priorities for reducing rates of deforestation and thus preserving carbon stocks, while simultaneously being conservation targets for the endangered jaguar, *Panthera onca*, and wider biodiversity. We used a multi-criteria decision analysis to identify municipalities that offered the best opportunities for co-benefits under a range of scenarios for varying rates of deforestation and carbon values. These areas were then further refined on the basis of their representativeness of the country as a whole (on measures such as percent forest cover), and an indirect measure of cost (number of municipalities). The areas that are identified as offering optimal co-benefits are termed “REDDspots” and their spatial distribution is compared with that of current and proposed REDD projects. We conclude that REDD+ strategies could be an efficient tool for biodiversity conservation in key locations, especially in Amazonian and Atlantic Forest biomes.

CONSTRUCTING BAT HOUSES MATCHING THE THERMAL CHARACTERISTICS OF NATURAL ROOSTS IN TREE CAVITIES

Luc De Bruyn

Research Institute for Nature and Forest (INBO)

Ben VAN DER WIJDEN, University of Antwerp

The availability of suitable roost sites is essential for the survival of bats. Roosts are used for mating, hibernation, and rearing the young; they offer protection from adverse weather and predators. Selection of specific roost sites by breeding female bats has consequences for survival and reproductive success. Tree cavities are scarce in most intensively managed Western European forests. In the past, several attempts were made to provide forest dwelling bats with alternative roosts with variable results. In general, these experiments failed to

attract reproduction colonies of typical tree cavity-dwelling bats, which seriously limits the potential of bat houses as a mitigation measure. Previous research yielded that the internal temperature regime of tree cavities, previously used by bats, are seriously buffered compared to external temperature and temperature peaks inside the cavity show a 6 to 8 hours delay compared to the external peaks. Slight differences in wall thickness had significant influence on the internal temperatures. Therefore, the influence of wall thickness, external color and material (wood or woodcrete) used on the thermal characteristics of bat houses was further investigated. The objective of this project was to investigate the relationships between wall thickness, material used and internal temperature regimes of artificial bat roosts. Based on those relationships, a type of bat house is suggested that approaches the thermal characteristics of natural tree cavities, but combines ease of manufacture, ease of control and relatively low cost.

JAGUARS IN THE GREATER LACANDONA ECOSYSTEM, MEXICO: CONSERVATION STRATEGY AND LONG TERM MONITORING.

Antonio De La Torre

National Autonomous University of Mexico
*Valeria TOWNS, National Autonomous University of Mexico ;
Rodrigo MEDELLIN, National Autonomous University of Mexico*

The Greater Lacandona Ecosystem is the last remnant of tropical rainforest in Mexico. This region, together with Calakmul in Campeche and the Peten in Guatemala and Belize, represents the greatest portion of tropical forest in Central America (The Mayan Forest). In this region inhabits the second biggest population of jaguars (*Panthera onca*) in the continent. Jaguar conservation in Mexico faces great difficulties because natural resources in the country are rapidly deteriorating. This is why a great effort in monitoring wildlife populations along with maintaining connectivity inside the country and between borders must be done. We have been studying the jaguar population in the Grater Lacandona Ecosystem, since 2007. By using camera traps and telemetry techniques, we have estimated jaguar population densities, home ranges sizes and occurrence patterns. Besides, after seven years of monitoring, we have been able to understand behavioural aspects and life history traits that give us a deeper insight into jaguar ecology. By now, we have identified that the northern portion of the Greater Lacandona Ecosystem, is a critical area to maintain the population connectivity between Mexico and Guatemala. Therefore, we are strengthening together with local authorities, academic institutions, government agencies and national and international NGO's; a collaborative strategy for the conservation and management of jaguars and its habitat. As part of this initiative, local inhabitants and students are becoming part of the monitoring program of the species and

will take advantages of this results by using the information for the management and environmental services payment, eco-tourism and environmental education activities. Our main goal is to generate information enough to improve jaguar conservation initiatives and to minimise the human causes that are threatening their survival.

ASSESSING THE SUSTAINABILITY OF WILDLIFE HARVESTING: COMMERCIAL AND SUBSISTENCE HUNTING OF ENDEMIC PIGEONS IN THE TROPICAL ISLAND OF SÃO TOMÉ

Ricardo De Lima

Lisbon University
Mariana CARVALHO, Lisbon University ; Gabriel OQUIONGO, Associação Monte Pico ; Aristides MONTEIRO, Associação Monte Pico ; Nelson SOLÉ, Associação Monte Pico ; Francisco REGO, Lisbon University ; John FA, Imperial College London ; Jorge PALMEIRIM, Lisbon University

The harvest of wildlife for human consumption threatens species and may disrupt ecosystem functioning. Determining the sustainability of wildlife harvest is therefore paramount to defining conservation strategies, but it is also notoriously difficult to achieve because sustainability models require data that is hard to obtain. Here, we assess the sustainability of hunting of four endemic pigeon species in the tropical island of São Tomé (Democratic Republic of São Tomé and Príncipe, central Africa). For each species, we estimated population size using distance sampling along transects, and obtained extraction data from interviews to commercial hunters, who supply urban areas, and to rural inhabitants, who practice subsistence hunting. To assess the sustainability of hunting, we applied these data to three commonly used sustainability models. Our results indicated that the endangered Maroon pigeon *Columba thomensis*, and the vulnerable São Tomé green pigeon *Treron sanctithomae* are harvested unsustainably, while the São Tomé lemon dove *Columba simplex* and bronze-naped pigeon *Columba malherbii* are within safe hunting boundaries. The relative contribution made by subsistence and commercial hunting to total extraction varies markedly between species. This study is an important contribution to guide the conservation of São Tomé's endemic pigeons, which are key species to ensure the long-term functioning of the island's forest ecosystems. Because the endemic pigeons of São Tomé differ in their ecological requirements and are subject to varying hunting pressure, they offer an interesting system to test the performance of different sustainability models. Therefore, we also hope to revive the debate around the need for testing and creating better sustainability models.

RECOMMENDATIONS FOR PROMOTING BIODIVERSITY IN EXTENSIVELY MANAGED MEADOWS: EVALUATING MOWING REGIMES IN A FIELD SCALE EXPERIMENT

Davide De Masi

University of Bern

Jean-Yves HUMBERT, University of Bern ; Raphaël ARLETTAZ, University of Bern

In the latter half of the 20th century, mixed-used farming gave way to highly intensive forms of agricultural production in the developed world in order to increase production efficiency and yield. Semi-natural grasslands are becoming less and less common in agricultural regions in Europe and North America. Consequently, many species that were able to tolerate more traditional farming practices have become endangered or extinct. Mowing is an agricultural practice to collect grass and hay and is thought to affect biodiversity by altering habitat heterogeneity and temporal resource availability. To understand the effects of mowing on biodiversity, we investigated the effects of four different mowing regimes on plant and insect biodiversity: (1) control meadow with first cut not before 15 June; (2) delayed meadow (first cut not before 15 July); (3) eight weeks, (first cut not before 15 June and second cut not earlier than 8 weeks from the first cut); (4) refuge meadow, first cut not before 15 June but 10-20% of the meadow area is left uncut. Data on orthopterans, plants, wild bees and butterflies were collected 1-4 years after the implementation of the mowing regime. Positive effects on orthopterans were found in delayed (species density) and refuge (species density and richness) meadows and on pollinators as well as butterflies in refuge treatments. Preliminary results after four years suggest an altered plant community biodiversity as well as an increase in parasitoid wasps in delayed meadows. These results suggest that modified mowing regimes can drastically alter overall biodiversity on a timescale of just a few years and can have important implications for grassland restoration efforts and conservation. We therefore develop a precise set of recommendations based on our experimental evidence to promote grassland biodiversity in specific case study in mid-elevation prairies of the Western United States.

ARTIFICIAL SALINES AS ALTERNATIVE HABITATS FOR SHOREBIRD CONSERVATION IN THE NORTHEASTERN BRAZIL

Vitor De Oliveira Lunardi

Federal Rural University of Semiarid - UFERSA

Anyelle PAIVA ROCHA ELIAS, Federal Rural University of Semiarid - UFERSA ; Maria Luiza ANDRADE MENDONÇA, Federal Rural University of Semiarid - UFERSA ; Diana

GONÇALVES LUNARDI, Federal Rural University of Semiarid - UFERSA

Shorebird populations have declined around the world primarily due to the loss and conversion of natural habitats. The identification of anthropic alternative habitats that ensures essential resources is currently a key conservation strategy for this animal group. This study presents for the first time data on the use of alternative habitats for shorebirds in one of the largest saline wetland complex in the northeastern Brazil: the Apodi-Mossoró estuary. This estuary was originally characterized by mangrove associated with natural hypersaline supratidal flats and today it is completely fragmented and converted primarily to artificial salt ponds by the salt industry. We have performed bird counts fortnightly from August 2012 to December 2014 on a ~35ha area, covering approximately 10% of the estuary. For each bird registered, we identified the species, the behavioral state and the microhabitat where it was registered. A total of approximately 17,400 birds of 18 species of Charadriiformes were registered, with 68.1% of those records belonging to Nearctic migratory species. In relation to habitat use, 87.3% of the records were in salt evaporation ponds, 8.6% in pumping ponds and 4.1% in salt crystallization ponds. The behavioral state more frequently were foraging (75.1% of the registers) and resting (20.6%). In addition to these results, we registered during the censuses a colony of reproduction of *Himantopus mexicanus* (Recurvirostridae) in salt evaporation ponds between May and August of 2013 and 2014. We registered a total of 35 nests in 2013 and 41 nests in 2014. The nest predation rate in 2013 was 74% and in 2014 was 41%. Domestic dogs footprints were found near the predated nests. The results of this study show that salines represent alternative habitats for shorebirds in Apodi-Mossoró estuary. Salines of the northeastern Brazil should prioritize the conservation and management of evaporation ponds to ensure food, resting and breeding opportunities to shorebirds.

INVESTIGATING THE FLORAL PREFERENCES OF POLLINATING INSECTS USING POLLEN DNA METABARCODING

Natasha De Vere

National Botanic Garden of Wales

Andrew LUCAS, Swansea University ; Jenny HAWKINS, Cardiff University ; Dan FORMAN, Swansea University ; Col FORD, National Botanic Garden of Wales ; Matt HEGARTY, Aberystwyth University ; Tegan GILMORE, National Botanic Garden of Wales ; Abi LOWE, National Botanic Garden of Wales ; Jake MOSCROP, National Botanic Garden of Wales

Insect pollination is a key regulating ecosystem service so there is considerable concern worldwide about declines in both wild pollinators and honeybees due to habitat loss, agricultural intensification, pests and disease and climate

change. Understanding the reasons for declines and providing conservation guidance requires detailed information on the habitat requirements and foraging preferences of pollinating insects. DNA metabarcoding of pollen collected by insects provides a powerful method for tracking floral visitation. Pollen can be retrieved from the bodies of insects, or from pollen loads or honey from honeybees. DNA is extracted and amplified using the *rbcL* and *ITS2* DNA barcode markers. Resulting amplicons are sequenced using the Illumina MiSeq platform and identified by matching them to GenBank. Key to ability to identify unknown DNA samples is a comprehensive DNA barcode reference library. We have DNA barcoded all of the native flowering plants of the UK (1479 species) along with non-native, horticultural and agricultural plants likely to be important for pollinators. Here we present three case studies that illustrate the use of pollen DNA metabarcoding.

1: Pollen loads and honey samples have been collected from six hives situated within the National Botanic Garden of Wales and Waun Las National Nature Reserve. The vegetation of the botanic garden and nature reserve has been mapped so that honeybee foraging can be shown in a spatially explicit way. The importance of different plant taxonomic groups and relative use of native versus non-native flora is being investigated.

2: Honey samples have been collected from beekeepers throughout the UK to investigate the floral range of honeybees in different geographic areas.

3: Hoverflies of the genera *Eristalis*, *Sericomyia*, *Rhingia*, and *Cheilosia* have been sampled from four *Cirsio-Molinietum* grasslands of varying plant species diversity. Floral constancy will be compared across individuals, species and sites.

GENETIC AND ECOLOGICAL STUDIES ON THE COASTAL PLANT *MALCOLMIA LITTOREA* (L.) R. BR. (BRASSICACEAE) ACROSS EUROPE: IDENTIFICATION OF PRIORITIES FOR ITS CONSERVATION

Marcello De Vitis

Tuscia University
 Hugh PRITCHARD, Royal Botanic Gardens of Kew; Tiziana ULIAN, Royal Botanic Gardens of Kew; Claudia MATTIONI, Institute of Agro-environmental and Forest Biology - National Research Council; Charlotte SEAL, Royal Botanic Gardens of Kew; Efisio MATTANA, Royal Botanic Gardens of Kew; Francesca CHIOCCINI, Institute of Agro-environmental and Forest Biology - National Research Council; Sara MAGRINI, Tuscia University

Malcolmia littorea is a plant which occurs on the coasts of Portugal, Spain, France, Italy, Algeria and Morocco. The continuous fragmentation and degradation of the coastal dunes are threatening the persistence of this species, reducing the abundance of its populations together with their genetic variability. In the present study, results of both genetic and

ecophysiological analysis, conducted on a set of European populations, are discussed. In particular, five chloroplast and four nuclear microsatellite loci were analysed and the genetic parameters were estimated and compared. The genetic structure of the species was also investigated, and a spatial analysis was performed. An ecophysiological study on seed germination was conducted, incubating the seeds of the several populations at eight constant temperatures (0-27°C). Then, germination data were compared among populations and tested for correlation with independent variables like population's area of occupancy, latitude and climatic variables, to understand which are the driving forces of differences in germination responses. From the genetic standpoint, it was not detected any significant difference among populations in the within-population genetic diversity, even if they showed significant ($P < 0.05$) differentiation values of Φ_{PT} (chloroplast) and *FST* (nuclear), forming two main gene pools. Based on the allelic composition and richness, three populations were identified as priority conservation spots. Two of them occur in very small areas ($AOO < 0.1$ ha) and showed the lowest germination percentages. The study on seed ecology revealed that the AOO was highly correlated to the germination percentage, indicating a reduced vigour in small populations. The results of this study provide useful information for the development of a conservation strategy for *M. littorea* in Europe, identifying specific populations with high conservation priority.

CULTURAL MONUMENTS AND NATURE CONSERVATION: THE ROLE OF KURGANS IN MAINTAINING STEPPE VEGETATION

Balázs Deák

MTA-DE Biodiversity and Ecosystem Services Research Group
 Béla TÓTHMÉRÉSZ, MTA-DE Biodiversity and Ecosystem Services Research Group; Orsolya VALKÓ, University of Debrecen, Department of Ecology; Barbara SUDNIK-WÓJCIKOWSKA, Department of Plant Ecology and Environment Conservation, Faculty of Biology, University of Warsaw; Tatyana BRAGINA, Kostanay State Pedagogical Institute, Kazakhstan & Southern Federal University; Ivan MOYSIYENKO, Department of Botany, Kherson State University; Iva APOSTOLOVA, Institute of Biodiversity and Ecosystem Research, Bulgarian Academy of Sciences; Péter TÖRÖK, University of Debrecen, Department of Ecology

Steppe is among the most endangered biome in the world. Steppes have been destroyed in the last centuries due to agricultural intensification and afforestation. Nowadays steppe vegetation is often restricted to small fragments generally inadequate for arable farming like ancient soil monuments of the steppe region called 'kurgans'. We collected existing

knowledge on kurgans, focusing on their distribution, vegetation and threatening factors, and to highlight the necessity of their effective protection. Despite their small size (generally up to a few hectares) kurgans are characterised by a high microhabitat diversity and play a crucial role in preserving steppe vegetation, especially in intensively managed agricultural landscapes. Kurgans hold endangered desert-, grass-, herb-grass- and forest steppe habitats. They harbour red listed species such as *Adonis vernalis*, *Amygdalus nana*, *Echium russicum* and *Tulipa schrenkii* which are extinct in the surrounding areas. Kurgans represent a unique nature conservation and historical value, but their protection is not guaranteed in most regions. According to our estimations 250,000 kurgans remained in the whole steppe and forest steppe zone, which is only 20% of their original number. Kurgans are essential for maintaining landscape-scale habitat- and species diversity, and can act as stepping stones and potential core areas for habitat restoration projects.

185- BIODIVERSITY AND ECOSYSTEM SERVICES: HOW DOES BETTER INFORMATION AFFECT MANAGEMENT DECISIONS AND VALUE?

Laura Dee

University of California, Santa Barbara
ladine CHADÈS, CSIRO ; Steve MILLER, University of California, Santa Barbara ; Eve MCDONALD-MADDEN, University of Queensland ; Steven GAINES, University of California, Santa Barbara

The 'new conservation' focuses increasingly on managing nature explicitly for ecosystem services that provide benefits to humans, rather than for its intrinsic value. Though often debated, the consequences of conserving ecosystems for their services rather than for the explicit goal of biodiversity protection are not clear. Biodiversity is thought to be essential to ecosystem services at some level, but the number and identity of species that must be protected to secure services remain unresolved. Further, this uncertainty is only compounded by global change and market dynamics. These sources of uncertainty are crucial both to managers optimizing service value and the resulting consequences for biodiversity protection. Recent theory (Dee et al) and the precautionary principle suggest that uncertainty over how biodiversity produces services can provide an economic incentive to protect more species than are presumed directly critical to a service. However, resolving such uncertainty, such as via investments in scientific research, can improve knowledge about which species are critical or which species will be lost given a particular management choice. We ask: how valuable would such reduced uncertainty be to ecosystem service objectives? How could reducing uncertainty alter biodiversity outcomes that result from managing solely for services? We use dynamic programming techniques to compute the value

of several types of information and to understand the impact that the reduction of uncertainty has on optimal management choices. The results shed light on potential tensions between managing for ecosystem services and conserving biodiversity and may help inform and prioritize monitoring efforts and management of ecosystems.

(ID 64 CONSERVATION 3.0) ACCELERATING THE SPEED, SCALE & IMPACT OF CONSERVATION SOLUTIONS THROUGH INNOVATION

Alex Dehgan

Conservation X Labs & Duke University

The current extinction crisis, which will become worse as emerging middle classes around the world put exponential new demands on natural systems. This requires us to dramatically increase the speed, scale, efficacy of our understanding of the rate and scale of the environmental changes under way and our ability to engineer new solutions to address these threats. The existing research infrastructure and set of conservation tools we are increasingly insufficient to match the speed at which these pathogens emerge, and the risks they pose. However, the democratization of science and technology, exponential increases in global connectivity, new low cost technologies like arduino sensors, nanosatellites, and drones, and greater availability of data has provided us a new set of tools and approaches that reveal the state of the world in unprecedented detail to improve the knowledge about species status and prognosis, and, second, operationalize that data to improve global conservation efforts, including generating new solutions. The most critical innovation however, has been through the ability of harnessing the power of the crowd through open source approaches for collection, analysis, and funding of data and research. This movement towards open source or networked includes approaches such as prizes and challenges, hackathons, citizen science and gamification of science, and crowdfunding and crowdsourcing. This approach is useful where the distribution of the species or the scale of the change is large (continental scale sensing) or changing, such as for studies of macro-ecology, biogeography or climate change, or where there is a need for rapid assessment or collection of data, such as a response to an environmental emergency, could not be financially feasible otherwise. Finally, open source conservation serves to not only revolutionize conservation, but to bring the public into science.

(ID 64 CONSERVATION 3.0) CONSERVATION FINANCE: RETHINKING HOW WE FUND CONSERVATION

Alex Dehgan

Conservation X Labs & Duke University

John TOBIN-DE LA PUENTE, *Credit Suisse*

To preserve the health of natural ecosystems, a significantly larger amount of capital investment is required than the sums currently being allocated to conservation. Private sector investment is needed, not to replace but to supplement traditional sources of conservation capital such as public funding or philanthropy, which have been impacted by the global economic downturn. Against this backdrop, Credit Suisse, WWF and McKinsey joined forces in the area of conservation finance to identify the conditions needed to attract and redirect private capital toward conservation. Our research has shown that there are many unexploited private sector investment opportunities to increase conservation finance and deliver maximum conservation impacts while, at the same time, generating returns for investors.

(ID 64: CONSERVATION 3.0) THE ART OF THE WILD: THINKING ABOUT MESSAGING IN CONSERVATION

Alex Dehgan

Conservation X Labs & Duke University

Asher JAY, *National Geographic*

The consumer demand for wildlife products, exotic meats and pets to produce snake oil cures for human ailments and assert status, and individuality for the elite have created profit markets that bank on extinctions in the Anthropocene. This has resulted in a global market place that illegally capitalizes on the exploitation of our planet's finite natural resources to cater the myopic vested interests of a few at the cost of many. More recently, this demand has trebled with a rise in the purchasing power of a burgeoning middle class, which has implied the inevitable demise of various species, unless public education seeds shifts in cultural consciousness. In the digital age, where public engagement in global concerns that affect collective welfare is incited by pithy sound-bytes that are 140 characters or less, it is vital not only to condense and collate data sets but translate them into a vernacular that is familiar to the masses. Unless academic research is made accessible to the layperson in simple, mainstream vocabulary, the long-term conservation of wildlife and wilderness areas will remain a marginalized interest of an exclusive community. The work I produce bridges the hiatus between science and storytelling, it utilizes advertising and marketing tactics to galvanize community involvement.

MATRIX INTENSIFICATION AFFECTS BODY AND PHYSIOLOGICAL CONDITION OF TROPICAL FOREST-DEPENDENT PASSERINES

Justus Deikumah

University of Cape Coast

Matrix land-use intensification is a relatively recent and novel landscape change that can have important influences on the biota within adjacent remnant habitats. Anthropogenically-mediated chronic stress from the effects of high-intensity land use could affect individuals in nearby remnants, leading ultimately to population declines. We investigated how physiological indicators and body condition measures of tropical forest-dependent birds differ between native remnants adjacent to surface mining sites and those near farmlands at two distances from remnant edge in southwest Ghana. We used mixed effects models of several condition indices including residual body mass and heterophil to lymphocyte (H/L) ratios (an indicator of elevated chronic stress) to explore the effect of landscape change and matrix intensification on two contrasting categories of tropical forest-dependent passerines (sedentary area-sensitive habitat specialists vs. nomadic highly mobile generalists). Individual birds occupying tropical forest remnants near surface mining sites were in poorer condition, as indicated by lower residual body mass and elevated chronic stress, compared to those in remnants near agricultural lands. The condition of the sedentary forest habitat specialists *Alethe diademata* and *Cyanomitra obscura* was most negatively affected by high-intensity surface mining land-use adjacent to remnants, whereas generalist species were not affected. The carrying capacity of a landscape is likely to be affected not only by habitat extent, but also by the hospitability of the matrix, which is in turn influenced by intensity of land use. Land use intensification may set in train a new trajectory of faunal relaxation beyond that expected based on habitat loss alone. Patterns of individual condition may be useful in identifying habitats where species population declines may occur before faunal relaxation has concluded.

MAPPING ECOSYSTEM GOODS AND SERVICES TO INFORM CORAL REEF ECOSYSTEM-BASED MANAGEMENT IN MAUI NUI, HAWAII

Jade Delevaux

University of Hawai'i at Manoa

Kostantinos STAMOULIS, University of Hawai'i at Manoa ; Mary DONOVAN, University of Hawai'i at Manoa ; Alan FRIEDLANDER, Pristine Seas Project-National Geographic Society ; Susan YEE, US EPA Gulf Ecology Division, 1 Sabine Island Drive ; Robert TOONEN, University of Hawai'i at Manoa ; Susan CROW, University of Hawai'i at Manoa ; Jack KITTINGER, Conservation International Hawaii ; Anders KNUDBY, Department of Geography, Simon Fraser University ; Kirsten OLESON, University of Hawai'i at Manoa

Coral reefs provide diverse goods and services critical to human wellbeing. In Hawaii, direct human activities and climate change threaten coral reefs. Observed declines in

reef state jeopardize the delivery of these critical goods and services. To support policy-making, we are constructing a decision support tool linking coral reef ecological properties to ecosystem service provisioning. We used remote sensing and spatial predictive modeling techniques to map the current ecological properties of Maui Nui (Maui, Molokai, Lanai) coral reefs. We adapted ecological production functions to convert ecological properties into ecosystem services metrics. More specifically, those functions quantify the potential supply of three types of reef services: reef health (supporting), seafood supply (provisioning), and biocultural resource abundance (cultural). We linked those functions to a spatially explicit dynamic ecological coral reef model (Coral Reef Scenario Evaluation Tool – CORSET) to create a scenario-based decision support tool. The tool can model the impact of alternative land and marine management scenarios on reef services delivery, enabling trade-offs and opportunities assessment in service delivery. Preliminary results include identifying key ecological attributes that make up important reef services and then spatially characterizing and estimating potential supply of those services. Our results can inform the shift towards spatial planning and ecosystem-based management of coral reefs by identifying areas to optimize management, and/or identify locations where potential conflicts may arise. By employing an ecosystem services approach, our results express management targets in ecological terms, while being grounded in the local socio-cultural context relevant to the policy realm. This place-based approach can promote adaptive management by accounting for critical linkages and feedbacks connecting people and reefs.

210-NEVER A ROAD HAS GONE: NORTH AMERICA ROADLESS AREAS AS “NO GO” ZONES

Dominick Dellasala
Geos Institute

Roadless areas play a pivotal role in preparing large landscapes for climate change. In the USA, the Roadless Conservation Rule protected >23 million ha of inventoried roadless areas (IRAs >2,000 ha) that may provide refugia for climate-forced wildlife migrations, are a buffer against weed invasions, and contain carbon-dense ecosystems important to climate stabilization. IRAs also are source areas for municipalities that treat and distribute drinking water; the cost-savings to water treatment plants and highway departments from avoiding sedimentation caused by logging and road building is estimated at ~ \$18 billion annually. IRAs also provide \$490 million annually in waste treatment, services that will only increase in value as climate change triggers regional droughts. Although there is no national roadless policy in Canada, an inventory of intact areas by Global Forest Watch-Canada shows them concentrated in boreal and coastal rainforests. Canada's boreal region, in

particular, contains one-quarter of the world's wetlands, more surface water than any other continental-scale landscape, and stores an estimated 147 billion tonnes of carbon, equivalent to >25 years of current emissions. Road building and development compound stressors to ecosystems already dealing with accelerated climate change and degradation of critical ecosystem services. Climate change policies need to treat roadless areas as “no go” zones for industrial activities, especially new roads.

NON-TARGET MORTALITY OF ENDEMIC LESSER SHORT-TAILED BATS FROM TOXIC BAITING TO CONTROL EXOTIC MAMMALS IN A NEW ZEALAND CONSERVATION RESERVE

Gillian Dennis

Massey University

Brett GARTRELL, Massey University; Doug ARMSTRONG, Massey University; Colin O'DONNELL, Department of Conservation; Alastair ROBERTSON, Massey University

The use of toxic baits to control introduced mammals is essential for wildlife conservation in New Zealand, but also involves risks to non-target species, including the lesser short-tailed bat (*Mystacina tuberculata*). Due to its terrestrial foraging behaviour and broad diet this species has been considered at risk of primary or secondary poisoning. In 2009, 115 lesser short-tailed bats were found dead during a rodent control operation in Pureora Forest Park. Post-mortem examination of bats confirmed poisoning with the anticoagulant rodenticide diphacinone. This was the first recorded non-target mass mortality of this species. To determine the route of exposure of the bats to diphacinone, we used infra-red cameras to record whether bats consumed similar non-toxic bait in captive and wild settings, and to record whether bait was consumed in the wild by arthropods known to be prey items for the bats. Our results suggest that the bats are more at risk through secondary ingestion of toxicants via arthropod consumption than through direct ingestion of bait. Adjustments to bait presentation and delivery in bat habitat did not completely prevent exposure of wild bats, as revealed by detection of diphacinone in guano, but there were no obvious mortalities. To determine the effect of this level of exposure on wild bats we assessed population survival and physiological measures of fitness in individuals before, during and after a rodent control operation using the modified baiting practices. Our results suggest that exposure of bats to diphacinone was sub-clinical. However, while the pathway of secondary poisoning remains intact we propose that the risk of adverse affects on bats could vary annually depending on the abundance of certain arthropod populations and prey switching by the bats. We recommend further review of toxicant choice and bait delivery methods in lesser short-tailed bat habitat.

**DISENTANGLING THE RATIONALE OF
DEFORESTATION TO UNDERSTAND BETTER THE
PARTIAL EFFECTIVENESS OF PROTECTED AREAS.
A CASE STUDY FOR MADAGASCAR'S EASTERN
RAINFOREST CORRIDOR (2001-12)**

Sébastien Desbureaux

Sigrid AUBERT, CIRAD ; Laura BRIMONT, CIRAD ; Alain KARSENTY, CIRAD ; Alexio Clovis LOHANIVO, CIRAD ; Manohisoa RAKOTONDRAIBE, CIRAD ; Andrianjakarivo Henintsoa RAZAFINDRAIBE, CIRAD ; Jules RAZAFIARIJOANA, ESSA

Madagascar's notoriously high level of biodiversity is currently threatened by deforestation. Protected Areas (hereafter "PAs") remain until now the central instrument to protect it whilst little is known about their environmental effectiveness in the country. With a matching approach in a quasi-natural experiment setting, we demonstrate for the entire island's rainforest that PAs' additionality has been limited from 2001 to 2012. PAs have made it possible for deforestation to be stabilized in a trend and has restricted the upsurge of deforestation resulting from the country's late political instability. Nonetheless, post-matching analyzes reveal that PAs have only contained some of the causes of deforestation. Effectively stopping the latter will require further ambitious policies to trigger the necessary agricultural transition for the country.

**THE GENETIC DIVERSITY AND SPATIAL GENETIC
STRUCTURE OF THE FERULA COMMUNIS COMPLEX
(APIACEAE) IN THE TYRRHENIAN AREA.**

Caterina Angela Dettori

Centro Conservazione Biodiversità - Università degli Studi di Cagliari

Maria Cecilia LOI, Centro Conservazione Biodiversità - Università degli Studi di Cagliari ; Gianluigi BACCHETTA, Centro Conservazione Biodiversità - Università degli Studi di Cagliari

The giant fennel is a circum-Mediterranean complex characterized by a great morphological variability and comprising several species and subspecies. The focus of our work is on the taxa inhabiting the Tyrrhenian islands and coasts, namely *Ferula arrigonii* Bocchieri, a Corso-Sardinian endemic located in a few coastal sites and on small islands, *F. tunetana* Pomel ex Batt., endemic to Tunisia, and the widespread *F. communis* s.l. AFLP markers and a population genetic approach were used to investigate these taxa, with the following main aims: i) gaining insight into the patterns of molecular variation of the *F. communis* complex in the Tyrrhenian area and verifying how they are related with geographic boundaries and the current taxonomic treatments; ii) assessing the species-wide spatial genetic

structure and diversity of the previously unstudied endemic *F. arrigonii* and provide suggestions for its conservation; and iii) comparing levels of genetic diversity between *F. arrigonii* and its widespread congener *F. communis*. Results indicate that the *F. communis* complex constitutes a relatively heterogeneous group whose genetic structure is organized in multiple hierarchical levels and is only partially coherent with the geographic provenance of the populations, previous findings and current taxonomic treatments. All the investigated populations are characterized by high levels of genetic diversity, with no significant differences between *F. communis* and *F. arrigonii*. Three genetically distinct groups were detected within this latter taxon, although with considerable overlap between populations. Our data therefore suggests that in situ actions are not urgently needed for this species, and that a geographic criterion aimed at conserving it in its whole distributional range should be adopted when planning germplasm collections for long-term ex situ conservation.

**CONSERVATION OF GENTIANA LUTEA L.
(GENTIANACEAE) IN SARDINIA THROUGH A
MULTIDISCIPLINARY APPROACH.**

Caterina Angela Dettori

Centro Conservazione Biodiversità - Università degli Studi di Cagliari

Donatella COGONI, Centro Conservazione Biodiversità - Università degli Studi di Cagliari ; Alba CUENA LOMBRAÑA, Centro Conservazione Biodiversità - Università degli Studi di Cagliari ; Giuseppe FENU, Dipartimento di Biologia Ambientale - Sapienza Università di Roma ; Mauro FOIS, Centro Conservazione Biodiversità - Università degli Studi di Cagliari ; Marco PORCEDDU, Centro Conservazione Biodiversità - Università degli Studi di Cagliari ; Laura SERRELLI, Dipartimento di Fisica - Università degli Studi di Cagliari ; Gianluigi BACCHETTA, Centro Conservazione Biodiversità - Università degli Studi di Cagliari

Gentiana lutea L. s.l. (Gentianaceae) is an orophyte plant which occurs in Southern European mountains. It has a long-standing history of human exploitation, mainly for liqueurs preparation and in the pharmaceutical industry and it is currently listed in the EU Habitat Directive 92/43/EEC Annex V. Its distribution range in Sardinia consists of only a few groups of individuals limited to small areas of the Gennargentu massif (Central-Eastern part of the island). A conservation project is being carried out at the CCB (Centre for the Conservation of Biodiversity) with the aims of assessing the conservation status of this taxon and actively plan and carry out subsequent ex situ and in situ conservation measures, with a particular focus on its possible reintroduction in areas where it has gone extinct. A multidisciplinary approach is being undertaken, which involves the following activities: i) assessment of the

actual distribution range of the taxon in Sardinia through the analysis of the available historical data, environmental modelling and extensive field surveys; ii) in situ studies, including the investigation of the species' phenology and reproductive biology, the analysis of the demographic trends and the identification of the main threatening factors; iii) implementation of the existing ex situ conservation measures, investigation of the requirements for seed germination by testing different protocols and environmental factors, and comparison with the optimal germination conditions in the field; and iv) population genetic analyses using AFLP markers to investigate the genetic diversity at both the intra- and inter-population levels and the spatial genetic structure. We hereby present the preliminary results of the project and the utility of our integrative approach for the conservation of this plant. This research is supported by the Regione Autonoma della Sardegna (Rep. 27512-91 del 9-XII-2013 RAS).

MITOCHONDRIAL DNA-BASED IDENTIFICATION OF FRESHWATER EELS OF NORTHEAST INDIA

Papari Devi

DEPARTMENT OF ZOOLOGY, GAUHATI UNIVERSITY
*Chittaranjan BARUAH, DEPARTMENT OF ZOOLOGY,
DARRANG COLLEGE, ; Dharendra K SHARMA, DEPARTMENT OF
ZOOLOGY, GAUHATI UNIVERSITY*

Freshwater habitats provide the occurrence of various species of freshwater eels – a fish with an elongated snake like structure. Populations of these eel species are declining due to loss of habitat, overfishing, barriers to migration, pollution and changes to water currents. A Mitochondrial DNA-based system for the identification of eel species found in Northeast India has been established in the present study based on the following criteria: adequate molecular variation, comprehensive specimen sampling, explicit morphological species identification and phylogenetic analysis. Nucleotide sequence analysis of mitochondrial COI gene and D-loop region of seven eel shaped fishes belonging to three families Synbranchidae (*Monopterusuchia* and *Monopterus albus*), Anguillidae (*Anguilla bengalensis*) and Mastacembelidae (*Mastacembelus armatus*, *Macrogathus pancalus*, *Macrogathus aral*, *Macrogathus aculeatus*) have been performed in the present study. The study provides a comparative account of the taxonomic differences among the eel like species of freshwater habitats in Northeast India. Several interesting differences between *M. albus* and *M. cuchia* at molecular level have been established, which clarifies their genetic distinctness rather than species complex as suggested by earlier conventional morphometric studies. **Key words:** eels, molecular, morphology, phylogeny

116. WHERE ARE WE? 15 YEARS OF BAD AND GOOD NEWS IN CONSERVATION SCIENCE

Vincent Devictor

ISEM, CNRS

Conservation science is a mission discipline meant to produce knowledge on the fate of biodiversity and relevant guidelines for action to halt the biodiversity crisis. But what kind of knowledge and what kind of actions is actually produced? To what extent conservationists document warnings and hopes? Do we read any signs of improvement or degradation in the fate of nature from conservationists themselves? Here, we explored all papers (~13,000) published in conservation journals during the last 15 years to assess the distribution of studies documenting effective and potential improvement or degradation in the status of species and habitats. We show that, surprisingly, only few papers propose concrete assessments and conservation implications. Among those papers with concrete results on the fate of biodiversity, we identify a majority of bad or potential bad news. However many papers also reflect that many conservation actions have actually worked and that a considerable useful knowledge is available to improve many situations. We further reveal how the distribution of bad and good news has changed through time, among countries and taxonomic groups. Overall, this study suggests that before choosing new paths for conservation we should better understand what has already been accomplished in this discipline.

APPLYING AN INTEGRATIVE MODEL OF BEHAVIOR CHANGE TO IMPROVE GLOBAL CONSERVATION OUTCOMES

Amielle Dewan

IFAW

Kevin GREEN, RARE ; Brian CRAWFORD, UNIVERSITY OF GEORGIA

Recent studies predict that current species extinction rates are 100 to 1,000 times pre-human background rates, and some species have lost over 50 percent of their historic range. This rapidly increasing rate of biodiversity and habitat loss is largely the result of human behavior. Scientists and practitioners increasingly agree that achieving conservation outcomes is fundamentally about changing behaviors. Although many initiatives have addressed human behavior-driven threats, particularly through education, little evidence supports their success. The field of public health has recognized the need to move beyond traditional awareness-raising, applying targeted campaigns grounded in theory from the behavioral sciences. The conservation field has made less progress in this direction, but some advances have been made in applying models of human behavior to conservation problems. We evaluated the

impact of 84 such projects that target destructive behaviors such as illegal hunting and overfishing using the same integrative model of behavior change. Across interventions, all behavior change model variables demonstrated significant increases ($p < 0.001$) ranging from 16.1 - 25.0 percentage points. Most importantly, our results demonstrate large overall changes in behavior across interventions (95% confidence interval: 12.1 – 24.0 pp), providing new evidence that interventions that apply this model can be effective for addressing challenging and widespread conservation problems. Based on an unprecedented sample of systematic interventions, our results highlight the importance of integrating behavioral theory into traditional conservation programs. Our study offers hope that applying such a model can be a powerful tool for improving global conservation outcomes.

SYMPOSIA 129 - AN OVERVIEW OF THE OPEN STANDARDS FOR THE PRACTICE OF CONSERVATION

Amielle Dewan

IFAW

Nick SALAFSKY, Foundations of Success

The Open Standards for the Practice of Conservation (OS) synthesizes common concepts of and approaches to good project design, management, and monitoring, to provide a common framework for project cycle management/adaptive management for conservation. Numerous conservation organizations have come together in a collaborative partnership to develop, operationalize, and improve the OS since its development and first release in 2004. In 2014, the community commissioned an evaluation of the extent to which the OS, and the associated partnerships, have strengthened Results Based Management (RBM) in the conservation sector from 2002 - 2013. Results demonstrated widespread adoption of the OS, with 71% of web survey respondents using the OS for program management ($n=231$) with an additional 11.3% using a different RBM approach. The study also suggests that adoption of the OS has led to increased conservation funding, stakeholder participation, effective project management, and investment in learning. Here we provide an overview of Open Standards for the Practice of Conservation, as well as key results and lessons learned from the comprehensive evaluation

WECARE: A LOCAL HUMAN NETWORKING APPROACH TOWARDS BIODIVERSITY CONSERVATION & SUSTAINABLE DEVELOPMENT POST UTTARAKHAND DISASTER

Saurabh Dewan

HNB GARHWAL UNIVERSITY

Manisha SARSWAT, HNB GARHWAL UNIVERSITY; Yashpal SINGH, HNB GARHWAL UNIVERSITY; Jitendra Singh RANA,

HNB GARHWAL UNIVERSITY; Anand KUMAR, HNB GARHWAL UNIVERSITY; Shurveer SINGH, HNB GARHWAL UNIVERSITY; Upendra SINGH, HNB GARHWAL UNIVERSITY; Gaurav BHATT, HNB GARHWAL UNIVERSITY; Pranav SINGH, HNB GARHWAL UNIVERSITY; Navneet SWAMI, HNB GARHWAL UNIVERSITY; Gaurishankar GOSWAMI, HNB GARHWAL UNIVERSITY

WeCare-a local approach to global concern, is a platform aimed to conglomerate people from all strata of society towards biodiversity conservation and sustainable development. Still in its preliminary stage, it is an initiative of research scholars of the department conceptualised aftermath tragic Uttarakhand disaster in June 2013. It is foreseen as a vibrant tool to address the issue of conservation by active participation of local mass. In less than a year, we have entwined a network of more than 1500 local people comprising school kids, house wives, farmers, shopkeepers in around 20 villages, who wilfully dedicate whatever little time they can to issues of biodiversity threat & conservation. Their efforts include contributing to biodiversity data-basing of this region through their collected species photos or verbal descriptions, assessment of local population of a species using basic tutorials prepared by our scholars, reporting local threats to us, creating forums & discussion panels at village level, where every one has an equal say and can come up with their own idea of conservation. To our surprise, locals now feel free to unravel the atrocities being committed to nature by catching the real site images, they identify the lacunae in local policies and even suggest ways to rectify them. With time more people are volunteering to form physical groups & coming up with concrete recommendations which could be forwarded to policy makers. This platform is running without any capital investment or government funds, yet it has helped us in strengthening the unexplored species database of the region, in identifying the local threats as well as species population decline due to unplanned anthropogenic activities and was followed up by actual field visits by the scholars and subsequent scientific investigations; however the full credit goes to that reporting commoners.

PLACE VULNERABILITY OF HUMAN ELEPHANT CONFLICT: A CASE OF EASTERN NEPAL

Bhuwan Dhakal

University of Florida

Nepal's elephant is largely represented by the migrating population that traverses frequently between India and Nepal. Jhapa district of Eastern Nepal borders with the West Bengal of India and lies on the historical route for migrating elephants from Assam, West Bengal to Chitwan, Central Nepal. With the increased human population and decreased habitat, the migratory route has been blocked, and now about 200 elephants are confined within and around the forests of

Mahananda Wildlife Sanctuary in West Bengal. In the crop harvesting season (May-July, and Oct-Dec), these elephants migrate to Eastern Nepal, through Bahundangi village of Jhapa district, every night looking for corn and paddy. In Bahundangi village only, they destroy hundreds of hectares of farmland and harvest ready products worth USD 150 per family. Further, there are human and elephant casualties. Given the problem, the government has failed to develop and implement an effective policy for the region. The complexity of the problem has escalated as there is no protected area in Nepal side, and hence no mechanism for dealing the problem. This study accounts the degree of vulnerability faced by the people in Bahundangi because of elephant attacks. By taking into the account of the place vulnerability, this study identifies the high, medium and least vulnerable areas. Both geographic and social vulnerabilities are taken into account. This is a noble approach of understanding human-wildlife conflict, as there is the lack of studies carried out from the hazard perspectives in the context of Human Wildlife Conflict. We believe such kind of approaches will help the management and policy makers find innovative ways of solving the problem.

BIODIVERSITY LOSS ASSOCIATED WITH OIL PALM PLANTATIONS IN MALAYSIA: SERVING THE NEED VERSUS SAVING THE NATURE

Selvakumar Dhandapani
The University of Nottingham

Oil palm is considered as one of the most important crops for the future in serving the global food and biodiesel needs. Oil palm also serves as the important source for rural employment and plays a major role in poverty alleviation in Malaysia. The increasing need for palm oil has resulted in the rapid expansion of oil palm plantations in the last few decades, which has become the biggest cause for deforestation in Malaysia. The google deforestation map for the year 2000-2012 shows that Malaysia has the highest deforestation rate of all the countries in the world. This research assessed the biodiversity value of oil palm in comparison with primary forests and secondary forests. The biodiversity value of secondary forests are overly underestimated and are readily converted into plantations. Using species richness data of vertebrates and invertebrates from previous publications, this research argues that conversion of either primary or secondary forest to oil palm plantation would adversely affect biodiversity. The oil palm plantations are filled with non-native invasive species or generalist species of low conservation interest. The review results compiling numerous species richness surveys in Malaysia show that there is a 34.9% net reduction in species richness in oil palm compared to forest habitats, and 79.6% of the species found in forest habitats were not found

in oil palm habitats. The primary causes for the reduction of species richness is found to be poor ground vegetation, lack of structural complexity and poor microclimate in oil palm plantations. In order to sustain the biodiversity in Malaysia, It is recommended that future expansion of plantations in primary or secondary forests should be strictly prohibited. It is also recommended that the oil palm management regime should focus on improving the structural complexity and ground vegetation of oil palm plantations.

SETTING CONSERVATION PRIORITIES IN DYNAMIC MIGRATORY NETWORKS

Kiran Dhanjal-Adams
University of Queensland

Marcel KLAASSEN, Deakin University ; Hugh POSSINGHAM, University of Queensland ; Sam NICOL, CSIRO ; Iadine CHADES, CSIRO ; Richard FULLER, University of Queensland

Many migratory species have been found to alter their migratory pathways as a result of threats at stopover sites. However current conservation plans assume that migratory networks are static and that if stopover sites are lost, migrants will be unable to adapt and will therefore go locally extinct. Here we use a measure of irreplaceability to identify conservation priorities within a migratory network. We create an individual-based model which uses potential connectivity between stopover sites to model population flow through the migratory network. We parameterise this model using satellite tracking data. We show that the portfolio of sites needed to conserve migrants differs markedly if the underlying pattern of migratory connectivity is assumed to be static versus dynamic. We also find that for migratory species usually traveling short distances, the best strategy is to conserve many inter-connected sites. For species making a small number of long distance journeys, the best approach is to conserve a handful of strategically placed stopover sites. Setting priorities for multi-species migratory systems must therefore explore the trade-offs between priority sites for different species, and explicitly decide whether to assume a dynamics migratory network or not.

OPTIMIZING DISTURBANCE MANAGEMENT FOR WILDLIFE PROTECTION

Kiran Dhanjal-Adams
University of Queensland

Karen MUSTIN, University of Queensland ; Hugh POSSINGHAM, University of Queensland ; Richard FULLER, University of Queensland

To ensure public compliance with regulations designed to protect wildlife, many protected areas need to be patrolled. However, there have been few attempts to determine how to deploy enforcement effort to get the best return

on investment. This is particularly complex where species experience spatially heterogeneous threats. Furthermore, repeated enforcement visits may result in diminishing returns on investment and simple quantitative methods to solve such problems are not available to conservation practitioners. We use a decision science approach to find the most cost-effective allocation of patrol effort among sites with a limited budget. We use the case study of declining migratory shorebirds threatened by disturbance in Moreton Bay, Australia, to determine where and when Marine Park personnel could manage for disturbance using two different scenarios: (i) where a fixed subset of sites is chosen for management each year, and (ii) where different sites are visited during each patrol. We show that by prioritizing enforcement based on cost-effectiveness, it is possible to avoid inefficient allocation of resources. Indeed, 90% of the maximum possible benefit can be achieved with only 25% of the total available budget. In addition, visiting a range of enforcement sites at varying rates yields a greater return on investment than visiting only a fixed number of sites. The choice of patrol location and frequency is therefore not a trivial problem, and prudent investment can substantially improve conservation outcomes. Our research demonstrates a simple and objective method of allocating enforcement effort while accounting for diminishing returns on investment over multiple visits to the same sites. Our method is transferable to many other enforcement problems, and provides solutions that are cost-effective and easily communicable to managers.

BIODIVERSITY CONSERVATION OF WILD, ENDEMIC AND MEDICINAL PLANTS OF HIGH ALTITUDE REGION AT MT. EVEREST NATIONAL PARK IN NEPAL

Deepa Dhital

Nepal Academy of Science and Technology (NAST)
Graziano Rossi, Department of Earth and Environmental Sciences, University of Pavia, Pavia, Italy; Sangeeta Shrestha, Nepal Academy of Science and Technology (NAST)

Nepal harbors many globally significant wild, endemic, medicinal and aromatic plant species; hence it is rich in floral biodiversity in the world. The high Himalayan regions of Nepal remain one of the most important storehouses for them, although valuable plants are distributed from low land Terai to high mountains. These plants are at great risk due to various anthropogenic activities, overexploitation for national and international trade, and consequences of prevailing climate change, causing massive loss of biodiversity. The plant biodiversity from Himalayan region are conserved through the seeds in seed bank for their ex-situ conservation. The seeds are being researched not only to understand their future reactions to climate change but also to preserve them from extinction in the long run, hoping that these seeds and their embryos can survive outside their natural environment in high tech structures like seed bank. The seeds of most plant species can

be dried and stored from year-to-year and they remain viable for tens/hundreds of years. The need of conservation of these plant biodiversity is very important; hence Himalayan Seed Bank (HSB) and seed research facility has been established at Nepal Academy of Science and Technology (NAST). This is a joint initiative of NAST and EvK2CNR-University of Pavia, Italy. Initiation of activities of seed conservation, characterization and seed biological research have been started from the Sagarmatha National Park (SNP) region, and 325 accessions have already been conserved at HSB. Key words: Plant biodiversity Ę Himalayan Seed Bank (HSB) Ę Seed biology Ę Climate change

EFFECT OF CLIMATE CHANGE ON RICHNESS AND DIVERSITY OF BIRD COMMUNITIES IN MEDITERRANEAN BASIN: AN IMPLEMENTATION OF THE SESAM FRAMEWORK

Mirko Di Febbraro

University of Molise, Dep. Biosciences and Territory - DiBT
Manuela D'Amen, University of Lausanne; Davide DE ROSA, University of Molise, Dep. Biosciences and Territory - DiBT; Anna LOY, University of Molise, Dep. Biosciences and Territory - DiBT; Antoine GUISSAN, University of Lausanne

Climate change is expected to threaten biodiversity in plenty of ways. The impacts are predicted to be particularly relevant in the Mediterranean region, considered as one of the major biodiversity hotspot. Although birds have been the topic of many investigations, few studies investigated the potential impacts of climate change on bird community and diversity patterns in this highly sensitive area. Here, we use bird community data to predict the current and future patterns of species richness and composition in a heterogeneous area of Southern Italy. We apply two modelling strategies: the classic sum of binary predictions from species distribution models (bS-SDM) and other more advanced options of the recently developed "SESAM" modelling framework. In particular, we implemented the following steps: i) we used species distribution models (SDMs) to model the suitability to the abiotic habitat for single species, under current and future climate; ii) we predicted the distribution of species richness through macroecological models (MEMs) to control the number of species expected to co-occur within each site, in current and future conditions; iii) we used a biotic rule to select which species could coexist in each site, conditional to the richness value defined in Step iii. SDMs showed good to excellent predictive performance, whereas MEM proved less accurate. SESAM accurately predicted the current spatial patterns of the analysed communities and allowed highlighting a potential loss of species in the area, a reduction of γ -diversity and alterations in community composition under future conditions. In the simplest implementation, bS-SDM

only predicted a reduction of species richness at site-level. Applying bs-SDM or the full SESAM framework predicted different degrees of climate change impacts, rising interesting questions about the use of simple versus more complex modelling approaches for conservation applications under climate change.

122 ARE “ONE-SIZE-FITS-ALL” TARGETS FOR POPULATION SIZE SENSIBLE UNDER LIMITED CONSERVATION RESOURCES?

Martina Di Fonzo

The University of Queensland
Lochran TRAILL, University of the Witwatersrand ; Eve MCDONALD-MADDEN, The University of Queensland ; Philip STEVENS, Durham University ; Howard WILSON, The University of Queensland ; Jonathan RHODES, The University of Queensland

“One-size-fits-all” targets have great appeal in conservation biology, acting as short-cuts for management decisions where suitable data are lacking. The concept of a universal minimum viable population (MVP) size is an example of a population target advocated to ensure species persistence. As with most rules-of-thumb, the underlying theory and empirical accuracy of a universal MVP size has provoked extensive debate, with the decision to apply a general MVP rule commonly traded-off against a manager’s uncertainty in its effectiveness. Although already widely discussed, this debate has yet to acknowledge the importance of constraints such as time, resources and competing values in the decision of whether to recover a population. Here, we examine this issue using a formal decision theoretic framework for setting population size targets that is explicit about budget constraints, costs of management, and uncertainty in MVP estimates. We illustrate our framework with a case-study based on the setting of targets across several charismatic mammals, each with a range of MVP size estimates and corresponding level of uncertainty. We demonstrate that even when we are highly uncertain about MVP sizes for each species, setting a universal target is always sub-optimal when we have constraints on conservation resources. This has broad reaching implications for the debate about how to set population targets based on MVP sizes.

130-HISTORICAL DRIVERS OF EXTINCTION RISK: USING PAST EVIDENCE TO DIRECT FUTURE MONITORING

Moreno Di Marco

Sapienza University

Ben COLLEN, University College London ; Carlo RONDININI, Sapienza University ; Georgina M MACE, University College London

Global commitments to halt biodiversity decline mean that it is essential to monitor species’ extinction risk. However, the work involved in extinction risk assessment is currently intensive, and it may be unsustainable without substantial increase in funding. We demonstrate an alternative approach to monitor changes in extinction risk, based on the response of species to external conditions, and validated using historical information. We defined transitions in the extinction risk of ca. 500 species of mammalian carnivores and ungulates, and modelled the probability that these transitions occurred between 1975-today. A set of 24 predictor variables was used, including intrinsic traits (i.e. species biology) and external conditions (human pressure, distribution state, conservation interventions). The models correctly classified up to 90% of all observed extinction risk transitions and revealed complex interactions between variables, e.g. protected areas and human impact. We found that a small number of predictors can successfully explain transitions in species’ extinction risk. The most important predictors were: initial extinction risk, protected areas extent, geographical range size, body size, taxonomic family, human impact. Including more than a handful of variables increased the model complexity but not its performance in terms of classification ability. Monitoring a targeted set of metrics, such as those included in our analyses, would allow to anticipate future escalations in species’ extinction risk. There is great potential for the application of our approach to other taxa, especially considering the increasing availability of retrospective extinction risk assessments for groups such as birds, amphibians and corals. Our approach can also guide efficient allocation of resources between monitoring of species’ extinction risk and monitoring of external pressures.

HUMAN PRESSURES PREDICT SPECIES’ GEOGRAPHIC RANGE SIZE BETTER THAN BIOLOGICAL TRAITS

Moreno Di Marco

Sapienza University

Luca SANTINI, Sapienza University

Geographic range size is the manifestation of complex interactions between intrinsic species’ traits and extrinsic environmental conditions. It is a fundamental ecological attribute of species and a key extinction risk correlate. Past research has primarily focused on the role of biological and environmental predictors of range size, but macroecological patterns can be distorted by human activities. Here we analyse the role of extrinsic (biogeography, habitat state, climate, human pressure) and intrinsic (biology) variables in predicting range size of the world’s terrestrial mammals. Our

aim is to compare the predictive ability of human pressure vs species biology. We evaluated the ability of 19 intrinsic and extrinsic variables in predicting range size for 4,867 terrestrial mammals. We repeated the analyses after excluding restricted-range species and performed separate analyses for species in different biogeographic realms and taxonomic groups. Our model had high predictive ability, and showed that climatic variables and human pressures are the most influential predictors of range size. Interestingly, human pressures predict current geographic range size better than biological traits. These findings were confirmed when repeating the analyses on large-ranged species, individual biogeographic regions and individual taxonomic groups. Climatic and human impacts have determined the extinction of mammal species in the past, and are the main factors shaping their present distribution. These factors also affect other vertebrate groups globally, and their influence on range size may be similar as well. Measuring climatic and human variables can allow to obtain approximate range size estimations for data deficient and newly discovered species (e.g. hundreds of mammal species worldwide). Our results support the need for a more careful consideration of the role of climate change and human impact - as opposed to species biological traits - in shaping species ranges.

A LEGAL TRADE IN HORN FOR IMPROVED RHINO PROTECTION AND SUSTAINABLE DEVELOPMENT

Enrico Di Minin

University of Helsinki

Jussi LAITILA, University of Helsinki ; Federico MONTESINO-POUZOLS, University of Helsinki ; Nigel LEADER-WILLIAMS, University of Cambridge ; Rob SLOTOW, University of KwaZulu-Natal ; Peter GOODMAN, Ezemvelo KZN Wildlife ; Anthony CONWAY, Ezemvelo KZN Wildlife ; Atte MOILANEN, University of Helsinki

Illegal killing of both southern white (*Ceratotherium simum simum*) and black (*Diceros bicornis*) rhinoceros for their horn has escalated in South Africa since 2007, even though international trade in rhino products has been banned since 1977. Consequently, we provide an ecological-economic analysis to understand whether a legal trade in horn could be useful to address the emerging rhino 'crisis'. Our results suggest that the southern white rhino population will be at high risk of extinction in the wild unless law enforcement is enhanced. Legalizing the trade without enhancing law enforcement will not change the status quo. Without legalizing the trade, enhancing the protection of the rhino population would require raising many millions of dollars year after year to protect rhinos from poaching. However, the funding generated by selling an effective quota every year could be used to enhance the protection of the rhino population to levels that will undermine illegal poaching activities and allow the rhino population to increase in size. Hence, an important contribution

that the legal trade could make is to cover such costs, at least in the short term, until other measures over some longer period lead to a reduction in demand from users in the Far East. We suggest the recent escalation in illegal killing within South Africa, the country most effective at conserving its rhinos, makes it timely to consider alternative options.

SPATIAL PRIORITIES FOR CARNIVORE CONSERVATION UNDER LAND USE CHANGE

Enrico Di Minin

University of Helsinki

Rob SLOTOW, University of KwaZulu-Natal ; Luke HUNTER, Panthera ; Federico MONTESINO-POUZOLS, University of Helsinki ; Tuuli TOIVONEN, University of Helsinki [INSTITUTE] University of Helsinki ; Peter VERBURG, University of Amsterdam ; Nigel LEADER-WILLIAMS, University of Cambridge ; Lianne PETRACCA, Panthera ; Atte MOILANEN, University of Helsinki

Carnivores are among the most iconic and charismatic species that help generate millions of dollars of funding for biodiversity conservation every year. Yet, they have suffered the biggest range contraction among all biodiversity and include some of the most persecuted species by humans. We used newly developed spatial conservation prioritization tools in combination with global high-resolution distribution maps and global land use change scenarios to identify global spatial priorities for the conservation of placental and marsupial carnivores. Our results suggest that the current global biodiversity target to protect 17% of terrestrial land area is insufficient to adequately protect carnivores. In addition, the risk of human-carnivore conflict is high in countries where spatial priorities for carnivore conservation were identified. We discuss how innovative interventions will be needed to mitigate human-carnivore conflict outside protected areas.

HUMAN IMPACT AND THE SUSTAINABLE CONSERVATION OF LARGE MAMMALS IN THE DENG DENG NATIONAL PARK

Mercy Nambu Diangha

Brandenburg Technical University, Cottbus -Senftenberg

Gerhard WIEGLEB, Brandenburg Technical University, Cottbus -Senftenberg ; Udo BRÖRING, Brandenburg Technical University, Cottbus -Senftenberg ; Roger FOTSO, Wildlife Conservation Society/Cameroon Biodiversity Programme

In view of the roles played by humans in structuring biological resources, research was conducted in the Deng Deng National Park with the aim to assess the effects of human influences on large mammals. Specifically, the study aimed at identifying human factors threatening the park, determine where threats are occurring, their corresponding intensity, and analyse the relationship and variation between identified threats and the

encounter rates and distribution of large mammals in the park's landscape. Historical topographic and land use maps, and satellite images detailing land use such as settlement and presence of infrastructural features within the park were important secondary sources used for the determination of human factors threatening the park. Field surveys along transects and reconnaissance walks were also elucidated to complement and update the types of human threats occurring in the park. Kilometric index analyses approach was applied to determine threats frequency and encounter rates in the study area. More than 300 observations of eight categories of threats were recorded. Using a spatial analysis approach in geographic information system, distribution of threat categories was analysed. Results revealed that the park is experiencing threats that are changing the physical environment in simple and reversible manner but also threats that have changed the park's environment in permanent ways; all from impacts of adjacent human settlements and development activities. Generally species abundance was significantly high ($p = 0.03$) in habitats where threats encounter rates were low and vice versa. This is a clear indication that human activities have created depressing effects on the habitats of large mammal species in the park. Efforts to limit human activities around the park, to sustain the large mammals and their habitats especially within threat hotspots identified in this study are proposed, to ensure a sustainable future for large mammals in the park.

EFFECT OF TOURISM ON THE MANATEE PRESENCE, IN THE NORTH OF QUINTANA ROO, MEXICO, AFTER 15TH YEARS

Mireya Diaz Ortiz

Universidad Autónoma de Guadalajara

Nataly CASTELBLANCO-MARTÍNEZ, Oceanic Society; Coralie NOURISSON, CIBIO-InBIO

The manatee is an endangered species protected throughout its range. In Mexico, manatees are present in the Gulf coast and Caribbean Sea. Annually five millions of tourists visit beaches and inlets of the Mexican Caribbean, but the effects of this high influx of tourism on manatee are still unknown. Forty-eight interviews were conducted to local people to assess areas with manatee presence and knowledge about the species. The main areas reported of presence were the inlets of Xel-Ha and Xpu-Ha, on the north of the Yucatan Peninsula, in the tourist corridor Cancun-Tulum. All interviewees know what a manatee is and can describe it sometimes in great detail. 45.4% believe that the population is declining. From June to December 2013, 227.27 hours of observation ad libitum were conducted, to detect the presence of manatees in Xel-Ha and Xpu-Ha. Four different manatees in the estuary of Xpu-Ha (Relative Abundance Index = 0.82 manatees/hr) were detected. Manatees were present in 96.6% of the survey days and, during 66.6 % of the time a cow-calf pair was observed. Behaviors

such as feeding, playing and breathing were recorded, among others. In Xel-Ha no manatee was observed. These results differ from those obtained by a study 15 years ago, in which eight manatees were observed in Xel-Ha and two in Xpu-Ha. They suggest that the change in presence and use of inlets by manatees is related to the number of tourists using the area. Xel-Ha receives on average 2184 visitors per day, while Xpu-Ha only 22. In Mexico, manatees still used areas heavily impacted by tourism, such as north of Playa del Carmen and Holbox, probably moving from protected areas. The tourist corridor Cancun-Tulum is especially important for manatees as it is the contact area of the two manatee populations in Mexico and could be essential to ensure connectivity between them. It is necessary to implement management strategies and environmental education to mitigate the effect of tourism in these areas.

124 MONEY TALKS: THE DRIVERS OF CORPORATE BIODIVERSITY COMMITMENTS

Steven Dickinson

TOTAL/Cross-sector Biodiversity Initiative

John PILGRIM, The Biodiversity Consultancy

Companies that manage biodiversity risks and impacts effectively often benefit from a competitive advantage in accessing resources, capital or markets, and suffer fewer project and permitting delays. Greater understanding of the costs to business of poor biodiversity management - and opportunities from good management - has driven increasingly quantified commitments at both the project and corporate level. This new world of No Net Loss and Net Gain commitments has been particularly driven and shaped by Multilateral Financial Institution lending standards. Many companies obtain project finance from these institutions, or from commercial banks that follow their standards (such as the 80 Equator Principles Financial Institutions). Even when companies do not seek external finance, many large projects are part-owned by host country governments, which often borrow their project equity from these financial institutions. Such is the cumulative momentum behind these financial institution standards that they are rapidly becoming best practice globally. They are being voluntarily incorporated into corporate or project strategies, and even into national government legislation. Conservation biologists who understand financial lending standards are finding huge new opportunities to achieve conservation goals that align with emerging corporate best practice.

91-GETTING SCIENTIFIC EVIDENCE USED IN PRACTICE: PROGRESS, BARRIERS AND SOLUTIONS. ORGANISING EVIDENCE FOR ENVIRONMENTAL MANAGEMENT DECISIONS: A '4S' HIERARCHY

Lynn Dicks

University of Cambridge

Jessica WALSH, University of Cambridge ; William SUTHERLAND, University of Cambridge

Making decisions informed by the best-available science is an objective for many organisations managing the environment or natural resources. Yet, available science is still not widely used in environmental policy and practice. We describe a '4S' hierarchy for organising relevant science to inform decisions. Primary Studies are collated into Systematic Reviews, both Studies and Systematic Reviews are presented in Summaries, and Decision Support Systems place the evidence into a decision-making context. At each stage of ascent, the original scientific information is condensed, summarised, and becomes more accessible to decision-makers. This hierarchy has already revolutionised clinical practice. It is beginning to emerge for environmental management, although all four levels need substantial development before environmental decision-makers can reliably and efficiently find the evidence they need. We expose common bypass routes that currently lead to poor or biased representation of scientific knowledge. We argue that the least developed level of the hierarchy is that closest to decision-makers, placing synthesised scientific knowledge into environmental decision support systems.

NEW APPROACHES TO INFORM THE CONNECTION AND PROTECTION OF THE LAST VAST PLACES IN THE UNITED STATES.

Brett Dickson

Conservation Science Partners, Inc.

Luke ZACHMANN, Conservation Science Partners, Inc. ; Christine ALBANO, Conservation Science Partners, Inc.

In the face of global change, there is a pressing need to strategically design, connect, and conserve new landscapes that more effectively capture biodiversity and ecological processes at relevant spatial scales. In the United States, extensive areas of public land, including those administered by the Bureau of Land Management (BLM), present substantial opportunities to protect well-connected areas of conservation concern. For 12 western states, we used a novel multiple-criteria analysis to map contiguous areas of roadless BLM land that possessed important ecological indicators of high biodiversity, resilience to climate change, and connectivity. We leveraged new and existing spatial datasets to implement a systematic and statistically robust analysis of eight key indicators at several spatial scales, and to identify areas

with high conservation value across 41-million hectares of roadless BLM land. We identified 13-million hectares of land with relatively high conservation value mostly located in Alaska, Utah, Colorado, Arizona, Oregon, and Nevada. Highest value lands exhibited greater species richness, vegetation community diversity, topographic complexity, and surface water availability than existing BLM protected areas. These lands also encompass vast areas of ecological importance relative to other federal lands, and serve as critical linkages between already protected public lands in the West. Analyses based on circuit theory indicated high likelihood of ecological connectivity from southern Nevada through Utah and into western Colorado. Connectivity was facilitated by a network of existing protected areas, and across multiple jurisdictions. Our results provide a timely decision-making tool as the BLM and other federal agencies engage in large landscape analyses and planning efforts. Our methodological framework can integrate among variables at multiple spatial scales and is readily applicable to other jurisdictions and regions within the U.S. and beyond.

218 EU CONSERVATION DIRECTIVES - A SCIENCE PERSPECTIVE

Martin Dieterich

University of Hohenheim/ILN Singen

Willem LAERMANS, ILN Singen ; Stefan KREFT, Hochschule für Nachhaltige Entwicklung Eberswalde (HNEE)

The EU Habitats Directive can be considered one of the most advanced legal foundations for nature conservation worldwide. In article 18 (Research), the Habitats Directive attributes a particular role to science in identifying effective species and habitat specific measures, integration of regional stakeholders, and devising sound monitoring programs. Not surprisingly, criticism and suggestions for improvements of the Habitats Directive have been raised. Criticism includes ineffective choice of protected target species and habitats, insufficient protection of ecosystem processes, lack of a truly coherent network of protected sites, lack of sufficient flexibility in light of climate change. The EU Habitats and Birds Directives have not prevented the EU's failure to meet the 2010 targets. However, there is scientific evidence to conclude that the EU conservation directives and the Natura 2000 network established under the directives have at least slowed biodiversity loss in the EU. The EU conservation directives have increased the engagement of civil society. Both the EU Habitats and Birds Directives have provided conservationists with new legal opportunities requiring industry and the agriculture sector to adapt relevant projects and management to conservation needs. Numerous court decisions have upheld conservation as an overriding public interest against development or unsustainable resource exploitation. This seems to yield some delicate balances

between conservationists, industry and land-users, albeit with many remaining conflicts. Currently, the Habitats and Birds Directives are undergoing an audit (refit) that may yield considerable change and weakening. The EU conservation directives maintain much potential for further subsidiarity in allowing regional adjustments and optimisations. Apart from some adaptations, from a scientific perspective we can mostly suggest strengthening of the EU conservation directives and their implementation across policy sectors.

SCALING THE DIVIDE: SOCIAL VALUES AND BIODIVERSITY CONSERVATION IN A DYNAMIC WORLD

Alia Dietsch

Ohio State University

Mike MANFREDO, Colorado State University ; Tara TEEL, Colorado State University

Humans are increasingly represented in social-ecological systems as active agents that influence and are affected by their surroundings in complex relationships of adaptation and change. These relationships (i.e., feedback loops) necessitate an increased understanding of the social, biological, and ecological components of systems. Less understood is exactly how to address these phenomena when they operate across different levels and scales. Our work supports the notion that studies explicitly testing for cross-scale and cross-level dynamics can improve the efficacy of conservation solutions and allow for better explanation of factors that influence social values. In response to this desire to understand system dynamics and inform conservation decision-making, we explicate the relationship between indicators of social change and values at different levels within spatial (county and individual levels) and cognitive (values-attitudes-behaviors) scales. Using multilevel modeling, we show that individuals' fundamental values are influenced by characteristics, including demographics (e.g., education, income and urbanization), of the place in which they live independent of their own sociodemographics. We then show how these values influence individual-level support for various conservation actions. Finally, we provide a case study examination of human responses to wolf (*Canis lupis*) recovery in Washington state (U.S.) to illustrate how our findings apply in a particular social-ecological system. Results suggest that linkages between spatial and cognitive scales have important implications for the success of conservation actions and, specifically, for the social-ecological benefits anticipated as resulting from endangered species recovery.

MARINE ECOSYSTEMS FUNCTION FOR DEVELOPMENT OF SUSTAINABLE ANCIENT SHIPWRECK SITES IN NATUNA SEA, INDONESIA

Ira Dillenia

University of Indonesia

Natuna is a group of small islands in Indonesia located in South China Sea. It's directly adjacent with Singapore and Malaysia Country. Based on historical records, Natuna Sea had being passed by many ships from Asian and European Country for trading to spices archipelago in Indonesia. Their destination were Banten and Sunda Kelapa (Java), Celebes (Sulawesi), Borneo (Kalimantan), Moluccas (Maluku). Some of them never arrived at their destination and lost in Natuna Sea. Then, as the second world war happened, the battles between Japan and allied forces took place at South China Sea in Natuna and This was the caused many of warplane and warship crashed on Natuna Sea. Nowadays, these phenomenon are a reason for existence the ancient shipwreck sites buried in Natuna Sea. The distribution of sites are located in 8 areas of Natuna Sea with different depths. Integration between the historical values of the ancient shipwrecks and marine ecosystems living on the sites give fascinating for the people visiting them. Furthermore, marine ecosystems give influence of the sites physical stability. They protect the sites from diving activities impact and unstable water condition. On the contrary, excessive sites exploitation for archaeological research will destroy of the ancient shipwreck sites and their marine ecosystems. This paper will first discuss about the ancient shipwreck sites problem related by marine ecosystems function for their sustainability in Natuna sea. Then this paper also describe about the kind of marine ecosystems giving impact for the sites sustainability. Finally, this paper will give a marine conservation model for the ancient shipwreck sites based on ecosystems of Natuna Sea, with using marine ecological approach and marine archaeological research method.

KEYWORDS: ancient shipwreck, ecosystems, Natuna Sea

CLIMATIC DRIVERS OF BIODIVERSITY IN THE TIME OF THE GREEN SAHARA

Brendan Dillon

University of Queensland [INSTITUTE] University of Oxford
Marc MACIAS-FAURIA, University of Oxford ; Andrew MARTIN, University of Oxford

Scattered across the Sahara is a rich collection of rock art that depicts thriving fauna, fossils of savannah and water dependent species, and animal populations that are restricted to mountain tops and oases. These are relicts of the most recent period of high humidity in the Sahara which persisted throughout the first half of the Holocene. Periods of high humidity in the Sahara are the result of orbitally induced

enhancement of summer rainfall and positive feedbacks between vegetation and precipitation. I used paleoclimate snapshots and palynological data held in the African Pollen Database in order to model the effect of paleoclimate and soil properties on the beta diversity of fossil pollen using Generalised Dissimilarity Modelling (GDM). I found that paleoclimate and soil properties explain a modest proportion of compositional dissimilarity during the African Humid Period and that this is strongest when species of modern Saharan affinity are examined in isolation of those now found at tropical latitudes. This result is consistent with studies showing a strong affinity of tropical trees to water bodies even as they may have been expected to exist across the landscape at large. Climate change is expected to bring increased rainfall in the Sahara and may see a renewed expansion of savannah ecosystems and northward migration of tropical plant species along reactivated lakes and water bodies.

SYMPOSIUM 91: THE ART OF CONSERVATION SCIENCE IN THE FIELD: BARRIERS TO THE USE OF EVIDENCE

Alex Diment
WCS

Conservation science is a complex and multi-disciplinary field, which aims to address pressing issues of extinction and biodiversity loss. In many cases 'field' conservation can often be more art than science, working with governments, civil society, and local communities to negotiate trade-offs and collaborative solutions to achieve positive outcomes. This can be especially true when working in developing countries undergoing rapid transitions and with weak governance. However, despite the inherent challenges of researching complex and dynamic socio-political situations, there remains a crucial role for collecting and disseminating of evidence for the impacts of conservation interventions. Assumptions are commonplace in field projects, and substantial resources are regularly expended with seemingly no learning from the experience of others, and no monitoring of project impacts. Numerous barriers remain for the uptake and application of science in conservation projects, including education and language, cultural and political, logistical and financial, and plain old 'human nature'. Here I describe some of the key barriers to the use of evidence to guide field conservation projects, and to the collection of evidence for adaptive management. I highlight several case studies and discuss a range of potential solutions, including the evidence for their effectiveness.

PHYSIOLOGICAL AND BIOCHEMICAL RESPONSES OF CILIATE MODEL PARAMECIUM SP. TO DITHIOCARBAMATES AND TRIAZOLES FUNGICIDES

Meriem Djekoun

Laboratory of Cell Toxicology

Houria BERRABEH, Laboratory of Cell Toxicology ; Med Reda DJEBAR, Laboratory of Cell Toxicology

The last decade witnessed a dramatic increase in the use of fungicides. Such compounds affect the aquatic populations and may disturb their metabolism. In this study, we investigated the physiological and biochemical effects of two fungicides, thiram and tebuconazole, to a freshwater ciliate *Paramecium* sp. After exposing the cultures of the ciliates to the fungicides at several selected concentrations, the growth kinetics was followed for 96h. The results showed a significant decrease in the growth rate and a disruption in the motion of the protist. The monitoring of respiratory metabolism showed a significant decrease in oxygen consumption in the cultures treated by thiram. On another level, biochemical assays revealed the existence of oxidative stress generated by the xenobiotics tested, resulting in a disruption of the enzymatic activity of Catalase and Glutathione S-transferase in treated cells. Keywords: *Paramecium* sp., thiram, tebuconazole, CAT, GST.

HABITAT AMOUNT DETERMINES SPECIES' EXTINCTION RISK THRESHOLD

Ricardo Dobrovolski

Universidade Federal da Bahia

Moreno DI MARCO, University of Rome ; Rafael LOYOLA, Universidade Federal de Goiás ; Marcel CARDILLO, The Australian National University ; José Alexandre Felizola DINIZ-FILHO, Universidade Federal de Goiás

Species' extinction risk is determined by intrinsic and extrinsic factors. Among extrinsic factors, habitat destruction is the main threat to biodiversity. Here we combined information on habitat amount and intrinsic extinction risk of terrestrial mammal species to predict their threat status. We calculated the amount of natural habitat by overlaying the species' geographic distribution with a global land cover map. Intrinsic extinction risk was calculated from species' functional traits and phylogenetic information. We found that intrinsic extinction risk was able to predict threatened species with 60% of accuracy. When we included information on habitat amount information, accuracy raised up to 100%, showing a threshold response around the value of 15-30% of natural habitat remaining within their range. The value of this threshold was higher for species with higher intrinsic extinction risk. Applying this framework to predict threatened species among data deficient ones, we found that 37% of them are

threatened to extinction, considering a precision of 90%. This finding reinforces the effect of habitat destruction as a central mechanism responsible for extirpating biodiversity from our planet. Also, our approach has a potential application for predicting the future dimension of the global biodiversity crisis, considering available scenarios of global land cover change.

THE INFLUENCE OF FIRE ON AVIAN DIVERSITY AND COMMUNITY COMPOSITION IN SOUTH AFRICAN SAVANNA

Teegan Docherty

University of Durham

Philip STEPHENS, University of Durham ; Stephen WILLIS, University of Durham

With its exceptional diversity of wildlife, the South African savanna is recognized worldwide as an important priority for conservation. Savannas are one of the most threatened biomes on earth as a result of limited land protection combined with habitat loss and degradation from human encroachment, unsustainable agricultural activities, and inappropriate fire regimes. Savannas are fire-prone ecosystems and burning is an important driver of landscape change. As a result, many protected areas, including national parks and private reserves, use prescribed burning to simultaneously mimic natural savanna fire regimes and mitigate fuel loads. The impact of fire on grazing mammals has been well documented. Recently however, researchers and managers have begun to focus on the rest of the savanna community. In this study, we documented patterns of avian diversity across a landscape of different burn ages. Further, we tested two alternative hypotheses, food availability and vegetation structure, as potential mechanisms influencing avian diversity. We conducted avian point counts, sampled invertebrates and measured vegetation structure at 150 sampling points across a gradient of time since burn in North West Province, South Africa. No differences were detected in avian diversity across burn ages, however, species composition shifted after five months. Invertebrate abundance and richness peaked a year following burning and declined in subsequent years. Simultaneously, avian diversity was associated with a number of characteristics of vegetation structure. Ongoing work will attempt to disentangle the relative influence of food availability versus vegetation on avian diversity. With the continued use of fires in South Africa and the potential increase in fires due to climate change, the identification of specific mechanisms influencing avian diversity is a critical next step in developing management strategies for birds in savanna ecosystems and protected areas.

DIVERGENT RESPONSES OF BIRDS, MAMMALS AND REPTILES TO LANDSCAPE-SCALE WILDFIRE

Tim Doherty

Edith Cowan University

Robert DAVIS, Edith Cowan University ; Eddie VAN ETEN, Edith Cowan University ; Jim RADFORD, Bush Heritage Australia ; Neil COLLIER, Leuphana University ; Josef KRAWIEC, Edith Cowan University ; Floyd HOLMES, Edith Cowan University ; Chris KNUCKEY, MWH Global

Fire is a strong determinant of animal communities in fire-prone regions. We measured the response of birds, mammals and reptiles to a history of landscape-scale wildfire in semi-arid shrublands in south-western Australia. Using pitfall trapping, we surveyed small mammals and reptiles at 13 'young' sites (8-13 years since last fire), and 14 'old' sites (25-50 years since last fire). We also surveyed birds at 32 sites in a chronosequence ranging from 12 to >50 years since last fire. Small mammals and reptiles showed divergent responses to shrubland fire history. Five species were associated with young shrublands and four with old shrublands. No bird species were associated with young shrublands, although three species were most abundant in areas 34 to >50 years since last fire. These older shrublands also had the highest bird species richness and insectivore abundance. These results suggest that landscape-scale fire management is needed to maintain diverse animal communities. In particular, management should aim to preserve areas of long unburnt shrubland.

CITIZEN SCIENCE IN RURAL AFRICA: THE CONSERVATION AND MONITORING OF A THREATENED CARNIVORE BY MAASAI HUNTERS

Stephanie Dolrenry

Lion Guardians

Charles T.t. EDWARDS, National Institute of Water and Atmospheric Research ; Leela HAZZAH, Lion Guardians ; Laurence FRANK, Living with Lions, University of California-Berkeley

Although developing countries across Africa have high concentrations of threatened species and biological hot spots, there are few citizen science schemes currently running, particularly in the rural communities, with limited evaluation of these programs. We explore the convergence between citizen science and the conservation biology of threatened African lion (*Panthera leo*) populations. Specifically by using the traditional knowledge of Maasai hunters to have them engage in the broad-scale monitoring of lions. We investigate how participation in biodiversity conservation can transform hunters into citizen scientists. We examine, with empirical data, whether a citizen-science approach, with non-literate Maasai warriors, can produce quality data on an elusive carnivore.

Our study analyzes the accuracy of more than 350 verified reports from the hunters, as well as examining the increase in knowledge of the lions, both preceding and during the citizen science program. We model data collected by the hunters on transects to determine whether their data can accurately predict lion density from reported track density; a relatively simple technique to quickly estimate wildlife populations by community members. Our results show that data quality and quantity improved substantially with the engagement of the Maasai hunters. Engaging local community members in biodiversity conservation and monitoring can be a powerful approach, particularly in human-altered systems of rural Africa.

MICROBIAL DIVERSITY, INSECT EXTINCTION AND ECOSYSTEM FUNCTION IN BIRD'S NEST FERNS

Julian Donald

University of the West of England

Sam BONNETT, University of the West of England ; Pete MAXFIELD, University of the West of England ; Neil WILLEY, University of the West of England ; Farnon ELLWOOD, University of the West of England

Microbes are the dark matter of ecology. Although fundamental to nutrient cycling and energy transfer within ecosystems, little is known of the precise relationship between microbial diversity and ecosystem function. By using the bird's nest fern (*Asplenium nidus*) and its associated invertebrate community as a model ecosystem, we aim to quantify the process of decomposition in canopy soils, in response to simulated insect extinctions. For the first time, we will trace nutrients through an entire ecosystem, allowing us to elucidate the precise relationship between biodiversity and nutrient transformation. Sets of ferns were installed into replicate tree crowns within the rainforest biome at the Eden Project (UK), supported by a novel canopy-level irrigation system. The chemical composition of host tree leaves (the primary route for nutrients entering the system) were analysed using gas chromatography-mass spectrometry, before the microbial composition and activity of the fern soils were analysed using MicroResp plates, extracellular enzyme assays and phospholipid fatty acid analysis. Preliminary results reveal that the trees which host bird's nest ferns have leaves of significantly different chemical composition, and that the soil at their bases contain significantly different levels of organic matter. These differences highlight the importance of the host tree in determining the nutrient inputs of bird's nest ferns. Future steps will examine how suspended soil nutrient content changes when invertebrate decomposer communities are modified through simulated extinctions. This developmental research to reveal novel patterns in insect diversity and soil microbial activity paves the way for further unique studies of ecosystem function within the Eden Project and, eventually, for

transferring similar manipulation experiments to the rainforests of Borneo.

163-MONITORING AND EVALUATION OF ECOSYSTEM-BASED ADAPTATION PROJECTS

Camila Donatti

Conservation International

Madeleine C BOTTRILL, Conservation International ; David G. HOLE, Conservation International ; Amanda BOURNE, Conservation South Africa ; Maria Josella PANGILINAN, Conservation International Philippines

Ecosystem-based adaptation (EbA) is receiving growing attention from the conservation and development communities, given the significant overlap between people's dependence on ecosystems and their vulnerability to the impacts of climate change, coupled with the potential to provide significant biodiversity co-benefits alongside societal adaptation. However, there is still limited information on the effectiveness of EbA, in terms of its ability to reduce specific vulnerabilities or increase the overall resilience of people to climate change impacts. Specific challenges include the complexity of multi-objective strategies which encompass social and biophysical goals, the long time horizons required to observe social and environmental change, and the level of uncertainty surrounding current tools and approaches. We examined how two tools, Theory of change models and evidence synthesis, can be used in EbA monitoring through characterizing pathways to impact, identifying causal mechanisms, distinguishing relevant indicators, and recognizing areas of uncertainty, particularly in data poor environments where assumptions often substitute for evidence. We applied those tools in EbA case studies to address the merits of combining program theory and evidence synthesis in order to inform monitoring of EbA. Interventions from those case studies ranged from mangrove restoration and rehabilitation to reduce the vulnerability of coastal communities to projected increases in the power of tropical cyclones, to local capacity building and technology transfer to support livelihood security under climate change. We concluded that, when together, Theory of change models and evidence synthesis have the potential to expedite learning on which interventions are most effective, what indicators to measure, and how to deal with uncertainty in decision making, and argued that such an approach is essential for EbA projects to foster a culture of adaptive management and enable rapid learning.

INFORMATION NEEDED FOR DECISION MAKERS TO TAKE ACTION ON CLIMATE CHANGE ADAPTATION FOR SMALLHOLDER FARMERS-THE CASE OF CENTRAL AMERICA AND MEXICO

Camila I. Donatti

Conservation International

M. Ruth MARTINEZ, Conservation International ; Celia A. HARVEY, Conservation International ; Raffaele VIGNOLA, CATIE ; Carlos Manuel RODRIGUEZ, Conservation International

Even though it has been assumed that highly detailed information is key for policy makers to make strategic, improved and informed decisions, few studies to date have addressed if the lack of scientific or technical information is in fact one of the barriers that need to be overcome for decision makers to design and implement climate change adaptation policies. Here, we look at this issue regarding the climate change adaptation of smallholder farmers in Central America and Mexico. We implemented an online survey with policy makers from this region to answer the following questions: a) Is the lack of information a barrier for policy makers to take action on climate change adaptation for smallholder farmers? , b) How important are particular types of information to support policy makers to successfully implement adaptation plans for smallholder farmers?, c) To what extent have this information been used to develop or implement adaptation policies or programs for smallholder farmers? and e) What gaps exist in the information? Our survey with 105 policy makers from Costa Rica, El Salvador, Guatemala, Honduras, Mexico, Nicaragua and Panama shows that the lack of technical information is one of the most important barriers for policy makers to take action on adaptation for smallholder farmers. Participants identified the types of information that they consider to be very important to support policy makers to successfully implement climate change adaptation plans for smallholder farmers. Although specific types of Information were identified as very important to successfully implement climate change adaptation plans for smallholder farmers, they are rarely used by them, even when some of them are available. Therefore, there is a need to not only fill existing gaps, but also to ensure that decision makers are aware of the available or technical information and to deliver the information in a format that is relevant to existing decision-making procedures.

ROLE OF FIRE AND CONTINUOUS BROWSING IN CONTROLLING BUSH ENCROACHMENT IN THE ARID SAVANNAS OF THE EASTERN CAPE PROVINCE

Farai Dondofema

University of Venda

The study investigated the long-term effects of fire and herbivory on bush encroachment (1982-2001) in the arid savannas of the Eastern Cape Province of South Africa. Fire and herbivory were chosen as possible solutions because of their ecological recognition as factors of the environment in African Savannas and these methods are economically suitable for rehabilitation of veld which has inherent economic potential. Data collected using vegetation surveys were analysed using an Analysis of Variance where the treatment effects were first tested for significant differences using an F-Test. If the F-Test showed significant treatment differences then these individual treatment effects were determined using a t-Test in the form of Least Significant Differences (LSD's). The long-term effects of the treatments on the woody vegetation were investigated in terms of their effects on the density, phytomass and browsing potential of the bush, botanical composition of the dominant tree and shrub species. The long-term effects of fire and herbivory on the herbaceous component were investigated as botanical composition, basal cover and productivity of the grass sward. The long-term effects of the treatments on the grass sward were investigated in terms of their effects on veld condition, botanical composition of the dominant grass species and the basal cover of the grass sward. The general conclusion from the investigation into the effect of continuous browsing and application of fire on the bush indicated that this treatment successfully controlled bush encroachment and caused varying degrees of mortality amongst the different bush species. The effects on the bush density (plant per hectare-P/HA) showed Significant Difference ($P < 0.05$) = 148.650, while the bush phytomass (tree equivalents per hectare-TE/HA) showed Significant Difference ($P < 0.05$) = 448. The effects on the browsing potential (browsing units per hectare-BU/HA) illustrated Significant Difference ($P < 0.05$) = 22 as well as the effects on the Veld condition (percentage-%) showed Significant Difference ($P < 0.05$) = 1.738. If a livestock farmer or game rancher has a problem with bush encroachment in the arid savannas the application of fire and browsing can be effectively used to maintain high basal cover indices for grazing purposes and accessible bush for browsing.

#151_A TICKING TIME BOMB? LYME DISEASE IMPLICATIONS FOR CONSERVATIONISTS

Holly Donohoe

University of Florida

Sylvie BLANGY, Centre National de Recherche Scientifique

Lyme disease is a bacterial infection transmitted through the bite of an infected tick carrying one of several *Borrelia* pathogens. In humans, symptoms begin days to weeks after infection and while early symptoms include fever, muscle and joint pain, headache and chills, infection is often marked by the distinct erythema migrans or bull's eye rash that appears

on the skin. If left untreated, the pathogen can spread to the brain, heart, and joints causing cognitive impairment, stroke, paralysis, cardiac problems, and in some cases death. In the decades proceeding its identification and subsequent epidemiological tracking, Lyme disease has become the most common vector-borne disease in North America and the most common tick-borne disease in Europe. The geospatial reach of the pathogenic agent, the ticks that carry it and the reported cases of human and animal infection have expanded beyond biological endemic regions of the US and Europe and it has now been reported in over 40 countries worldwide. The scientific literature indicates that working in rural or natural environments, working in proximity to wild and domestic animals, participating in outdoor recreation activities (hiking, camping) and visiting Lyme endemic areas for touristic experiences (e.g. ecotourism) are the most significant human risk factors for infection. Ominously, the very nature of the conservation profession presents an occupational risk for contracting Lyme disease. Through the personal narratives of environmental and conservation researchers who contracted the infection while conducting field work in endemic areas, this presentation will provide an overview of Lyme disease etiology, the occupational risks for conservation professionals, the prophylactics available to guard against infection, as well as the research that is needed to better understand the human ecology of this infectious disease.

MANAGING WATER FOR THE ENVIRONMENT IN AUSTRALIA - A POLICY FRAMEWORK FOR ALL SEASONS

Jane Doolan

University of Canberra

Under its National Water Initiative, Australia has made significant advances in providing water for the environment to maintain and improve the environmental condition of rivers and wetlands. Environmental water provisions are now in place for all major water systems considered to be at risk. In a number of over-allocated systems, Governments have made investments to recover water for the environment and improve the balance between environmental and consumptive use. The most notable of these is in the Murray- Darling system where programs are in place to recover the equivalent of 2750GL of water, with these water entitlements held by environmental water managers. As a result of these initiatives, environmental water managers now hold significant volumes of water entitlements which are highly valuable public assets. For environmental water managers, the challenge is now to use this water effectively to achieve the desired environmental outcomes, efficiently to show that investment levels were justified and transparently to ensure there is public confidence in their management. This paper describes the governance

arrangements and the policy framework for the management of environmental water in Victoria and the Murray-Darling Basin. The governance arrangements were developed to be robust, transparent and appropriate for the level of public investment and asset ownership. The policy framework for the management of environmental water is scientifically based, logical, easily understood by the community and is designed to work under all climatic scenarios. The approach was used both during and after the Millennium Drought in Australia and was ultimately accepted by the community even in times of extreme water scarcity.

THE OLD MEN AND THE SEA - UTILIZING HISTORICAL DATA AND LOCAL KNOWLEDGE OF FISHERMEN TOWARD SHARK CONSERVATION

Mareike Dornhege

Sophia University

Anne MCDONALD, Sophia University

While long accepted in various disciplines including terrestrial conservation management, historical data is still not commonly applied in marine conservation and fisheries management. Yet, management based on recent data alone, ignoring historical information, typically results in too optimistic conservation statuses and fisheries quotas that are higher than if long-term data were considered. Japan manages the 8th largest shark fishery in the world. Until 1993, shark catches were recorded in logbooks under the single general category "shark", including both coastal and pelagic sharks, making prior stock assessments impossible. Currently, historical data is not utilized and the fisheries are managed top-down through international, local and regional bodies based on recent stock assessments. In Japan's biggest landing port for sharks, Kesenuma in Miyagi Prefecture, interviews with captains of long line vessels with at least 20 to over 60 years of experience were conducted, recording observations of stock changes and local knowledge of shark populations. Additionally, shark landing data for the past 20 years were analyzed. Results showed a clear divide: While younger fishermen reported no observed change, fishermen with more than 40 years of experience reported that stocks have been reduced up two thirds. Several fishers proposed management measures, suggesting MPA locations, catch limits and seasonal fishing regulations. Ignoring historical information on past population sizes and species composition can lead to shifting baselines and includes a risk of ineffective management of ecosystems. While collecting anecdotal historical data and local knowledge has its limitations, the study suggests that conservation management based on stock assessments post 1993 alone may be misleading. The study can further give valuable impulses for scientific investigation to confirm the potential of the proposed conservation measures.

WAYS OF PLANT CONSERVATION AND RECOVERY OF SIBERIAN ENDANGERED SPECIES (RUSSIA)

Olga Dorogina

Central Siberian Botanical garden

Tatyana NOVIKOVA, Central Siberian Botanical garden ;

Alexandra NABIEVA, Central Siberian Botanical garden

Since the 1970s many botanic gardens in Russia have been collecting rare and endangered species. Central Siberian Botanical Garden contains considerable gene pools of rare species ex situ including field gene bank (208 species), seed bank - 161 species and in vitro bank of germplasm. The goal of our work is to develop the methodology of plant conservation and recovery of endangered species of Siberian flora. Material for conservation and ex situ reproduction (seeds, rhizomes, roots and whole plants) was collected during in situ study. Proper sampling ensured the maximum preservation of existing genetic variation. An analysis of variability using storage proteins and DNA – markers was proved to be of great importance when studying the genetic structure of populations. We have developed a method of express - assessment of natural and introduction populations of rare and endangered species of plants in order to determine their current ecological state using morphological, biochemical (storage proteins), molecular - genetic (DNA) characteristics as markers. In the nursery of Botanic Garden (field gene bank) 208 species from 68 self-preserving populations (33%) and 139 small populations (67%) which are close to extinction are grown. Artificial populations through planting seeds collected in endangered populations of rare species *Hedysarum theinum* Krasnob. and *Viola incise* Turcz. were created in 2009 and 2011, respectively at Red Mountain and the Seminsky Pass in the Altai Republic in collaboration with researchers of the Altai Botanical garden. As a result, recommendations to restore some endangered species of Siberia were given. Thus, Central Siberian Botanical Garden is close to reaching main goal as stated by the Global Strategy of Plant Conservation to preserve ex situ 60% of threatened species nationwide and including 10% of them in recovery and restoration programs.

LESSONS IN CONSERVATION: TEACHING AND TRAINING MATERIALS FOR CAPACITY DEVELOPMENT IN CONSERVATION

Kristin Douglas

American Museum of Natural History

Ana Luz PORZECANSKI, American Museum of Natural History ;

Kimberley LANDRIGAN, American Museum of Natural History ;

Tara CORNELISSE, American Museum of Natural History ;

Nadav GAZIT, American Museum of Natural History ; Eleanor STERLING, American Museum of Natural History

The Network of Conservation Educators and Practitioners (NCEP), a collaborative project of the American Museum of Natural History's Center for Biodiversity and Conservation (CBC), works to enhance conservation capacity worldwide. As one of our strategies, NCEP produces peer-reviewed, open-access teaching and learning resources (or "modules") on a range of conservation topics tailored to local contexts. To date, we have a collection of over 140 training modules in eight languages freely available online (<http://ncep.amnh.org>) and published selectively through NCEP's official journal, *Lessons in Conservation*. This journal is designed to introduce NCEP modules to a broad audience, and each issue focuses on a topical theme, such as selected NCEP syntheses and case studies on freshwater ecosystems, or conservation challenges and solutions in the Southern Tropical Andes. In our current issue, we feature selected resources developed with our partners in Madagascar, including "Characteristics of endangered species of Madagascar" and "Community natural resource management." Developed in the French language and adapted to the Malagasy context, these modules reflect our efforts over ten years to improve the breadth and quality of conservation training available in Madagascar, and worldwide. All module components can be used in a variety of academic or training courses and include questions designed to promote use of effective teaching practices in the classroom, such as active learning techniques, and the development of critical thinking skills. By supporting long-term planning for capacity building and targeting the teachers of conservation professionals, NCEP expects to have an amplified and sustained impact, as students become the researchers, managers, and decision-makers of the future.

ID7- CRAVING FOR MEAT: PSYCHOCULTURAL DISORDERS INDUCED BY A DEPLETION OF BUSHMEAT IN THE DIETS OF CONGO BASIN FOREST DWELLERS

Edmond Dounias

IRD-CIFOR

Unlike the situations occurring in the Sudano-sahelian region, which are characterized by severe periodic depletions in food availability causing drastic hypocaloric diets, tropical rainforests are known to provide a constant supply of diverse potential foods that mitigates the risk of food shortage. Nevertheless, forest dwellers undergo what they perceive as 'lean periods' in food supply. Although game is vanishing in certain forest areas, it remains a food of paramount importance. In several forest dweller languages, specific terms are used to distinguish various forms of hunger induced by food shortage: one of

these terms refers to a 'lack of meat'. The craving for meat corresponds to a pronounced decrease in animal protein intake, but does not necessarily translate into acute nutritional deficiencies. The temporary rarefaction of meat consumption is generally compensated by vegetal sources of protein and fat. However this meat hunger is perceived dramatically and constitutes a definite stress. The meat hunger is a cultural form of hunger that can be interpreted as a psychological disorder to be linked to a qualitative variation in diet: a reduced availability of the most culturally valued food. Based on first hand studies carried out in Cameroon and DRC, this communication stresses that this psychological unrest may in turn have negative biological consequences, such as cardiovascular ailments, vulnerability to infection or low growth rates among children. Even in the absence of concrete dietary insufficiencies, meat is locally perceived as essential for health, and meat hunger is said to bring about tiredness, loss of vital strength and induced illness resulting from effects expressed at very diverse levels with a blending of material and symbolic aspects. The impact of seasonality, which appears moderate in the tropical forests, may in fact far exceed the biological incidence of the variations in food availability.

LANDSCAPE CHANGE, HUMAN POPULATION GROWTH AND OIL DEVELOPMENT IN A UGANDAN PROTECTED AREA LANDSCAPE: A CASE-STUDY FROM MURCHISON FALLS CONSERVATION AREA

Nicholas Dowhaniuk

University of New Hampshire

Joel HARTTER, University of Colorado ; Russell G. CONGALTON, University of New Hampshire ; Michael W. PALACE, University of New Hampshire ; Sadie J. RYAN, University of Florida

Protected areas in Sub-Saharan Africa are sanctuaries for rich biodiversity and are important economic engines for African nations, but they are becoming increasingly threatened by discoveries of mineral deposits within and nearby their boundaries. In 2006, viable oil reserves were discovered in Murchison Falls Conservation Area (MFCA) in northern Uganda. Exploratory and appraisal activities concluded in 2014, and production is expected to begin in 2016. The oil development is associated with a substantial increase in human population outside MFCA, with people seeking jobs, land, and economic opportunity. Concomitant with this change is increased truck traffic, a sprawling and denser road network, and infrastructure within the park, which could have large impacts on both the flora and fauna. We examined the broader protected area landscape and the potential feedbacks from resource development on the ecosystem and local livelihoods. Our analysis combines a land cover analysis using Object Based Image Analysis of Landsat data (2002 and 2014), migration patterns and population change (1959-2014), and qualitative interview data. Our results suggest that most of the larger-

scale impacts on the landscape and people are occurring in the western and northern sections, both inside and outside of the park. Additionally, oil development is not the only factor in the region influencing population growth and landscape change. Post conflict regrowth in the north, sugarcane production in the south, and migration to this region from conflict-ridden neighboring countries are also playing a vital role in human migration shaping the MFCA Landscape. Understanding the social and environmental changes and impacts in the MFCA and its surrounding areas will add to limited literature on the impacts of resource extraction on local, subsistence communities and landscape level change, which will be important as access and pressure for oil and minerals within protected areas continues to rise.

ID (117) LAND SHARING NOT SPARING IN THE "GREEN ECONOMY": THE ROLE OF LIVELIHOOD BRICOLAGE IN CONSERVATION AND DEVELOPMENT

Wolfram Dressler

University of Melbourne

In Southeast Asia's green economy, conservation interventions intensify the production of resources as commodities through land sparing activities and zoning in extensively used landscapes. Such initiatives encounter problems where poor resource users diversify livelihoods in multi-functional landscapes over time. In terms of 'livelihood bricolage' – the mixing, matching and building of portfolios– we describe how forest users enhance security by spreading risk across livelihood portfolios. Philippine case studies show how disrupting livelihood bricolage in multi-functional landscapes with 'intensifying interventions' constrains livelihood security and conservation objectives. We conclude that more equitable forest governance supports land sharing with diverse, extensive livelihoods in varied landscapes.

HOW BIODIVERSITY INDICATORS SHAPE THE BIODIVERSITY/FOOD PRODUCTION RELATIONSHIP

Camille Dross

INRA[INSTITUTE]AgroParisTech

Frédéric JIGUET, MNHN ; Muriel TICHIT, INRA[INSTITUTE] AgroParisTech

The land sharing/sparing framework has been proposed as a strategy to reconcile food production and biodiversity. The relative utility of sparing vs. sharing depends on the shape of the biodiversity/food production relationship. Yet numerous studies show that the shape and the direction of the relationship are themselves highly dependent on the biodiversity indicator used. Biodiversity indicators can differ because they focus on different taxa. They can also carry information about different characteristics of the observed individuals, such their taxonomy, their phylogeny or different

functional traits. Finally they can differ in the metrics used to aggregate these characteristics into a group level quantity, such as species richness, phylogenetic or functional diversity. Focusing on common birds, our objective was to determine whether the relationship between food production and biodiversity depended on the metric used, or only on the underlying choice of the considered characteristic. We computed food energy production on a nation-wide gradient covering French agroecosystems. Biodiversity data were provided by the French Breeding Bird Survey (FBBS). Several indicators describing bird biodiversity from the point of view of phylogeny, taxonomy, habitat specialization and diet composition were computed in 849 different sites of the FBBS. Both data sets were combined using generalized mixed models. Most of the indicators tested exhibited a negative relationship with energy production. Indicators based on habitat specialization, however, exhibited a positive relationship with energy production. When significant, the direction of the relationship depended only on the underlying choice of the considered characteristic and not on the metric. Significativity depended on both. Our results suggest that conserving different characteristics of biodiversity may entail different land-use strategies.

THE EFFECTS OF SMALL LIVESTOCK FARMING ON THE DIVERSITY, DISTRIBUTION AND ACTIVITY PATTERNS OF WILDLIFE IN A SEMI-ARID REGION OF SOUTH AFRICA

Marine Drouilly

University of Cape Town

M. Justin O'RIAIN, University of Cape Town ; Nicoli NATTRASS, University of Cape Town

Human activities are known to impact adversely on wildlife and may manifest as chronic conflict between humans and wildlife for critical resources. In South Africa, small-livestock farming in the semi-arid region of the Karoo is reported to impact adversely on biodiversity in general and predators in particular. Here we attempt to quantify the potential impacts of small livestock farming by comparing biodiversity and predator presence on farmland and protected areas within the Karoo. We used camera-traps established within a grid (0.5 camera/km²) to sample medium and large terrestrial mammals and large species of ground birds. We deployed cameras at 379 locations – 191 in the farms and 188 in the protected area and used the photographs taken during this period to estimate richness, occupancy and activity patterns of medium to large sized fauna. We obtained more than 12 000 independent images with a total sampling effort of 23 796 camera trap nights. Biodiversity on farmlands was higher than expected. Large predators were absent and there was a higher abundance of small to medium-size prey species. Predictably sheep were the most commonly detected species on farmland followed by

two medium-sized ungulates (common duiker and steenbok). In the protected area chacma baboon and oryx were the most common species and surprisingly two carnivores common on farmland were not detected. Activity of jackals and caracals on farmlands was mostly nocturnal while in the protected area it was cathemeral. Both species showed a habitat preference. Together our results show that biodiversity conservation can be achieved outside protected area, with small-livestock farms hosting a significant proportion of mammal and large ground bird communities.

ESTIMATING TRUE ABUNDANCE OF A NILE CROCODILE POPULATION USING A BINOMIAL MIXTURE MODEL FROM REPLICATED COUNTS: A CASE STUDY IN THE KUNENE RIVER SYSTEM, NAMIBIA.

Pierre Du Preez

Ministry of Environment & Tourism

Piet BEYTELL, Ministry of Environment & Tourism ; Arnaud Lyet, World Wildlife Fund ; Ruhan SLABBERT, Department of Genetics, Stellenbosch University ; Alison LESLIE, Department of Conservation Ecology and Entomology, Stellenbosch University ; William VERSFELD, Department of Genetics, Stellenbosch University

The Nile crocodile *Crocodylus niloticus* is found throughout sub-Saharan Africa, including in countries such as Namibia, Botswana and Angola. The species was transferred from CITES Appendix I to Appendix II in 2004, although it is recognised as peripherally endangered in Namibia due to diminishing habitat availability from human encroachment. In 2014 a species management plan was approved in Namibia to assess the management of the Namibian Nile crocodile populations, as the species plays an important role within the ecosystems that it occupies in the form of tourism and trophy hunting. The Nile crocodile population in the Kunene river system needs to be assessed as there are no previously published data available primarily due to the logistical difficulty in accessing large parts of the river system. An aerial survey was conducted to provide a true population estimate, making use of a recently developed N-mixture model for estimation of abundance and spatial variation. Detection of crocodiles from the air can be difficult and is also animal-size dependent, however an estimated 806 individuals were counted along the 352 km of the Kunene river system with a naïve estimate of 562 crocodiles regardless of size. The parameter estimates generated by the analysis demonstrated that the class-structured model can produce precise, unbiased estimates of total abundance and reliable estimates of local abundance for this population in the Kunene river system.

THE PEATLANDS OF THE HIGHLANDS OF LESOTHO - A UNIQUE AQUATIC SYSTEM UNDER THREAT

Pieter Johannes Du Preez

University of the Free State

Leslie R BROWN, *AApplied Behavioural Ecology & Ecosystem Research Unit*

Numerous hill-slope seeps and valley-bottom peatlands occur in the high-altitude headwaters of the Senqu River in Lesotho. These peatlands deliver important ecosystem services such as water retention, purification and slow release of water as well to sustain a unique plant and animal diversity. Due to the high altitude (mostly above 2 000m above sea level), a slow process of peat formation occur. On these peatlands a very unique plant community exists. Several plant species are peatland endemics. A communal grazing system exists in the highlands of Lesotho and these peatlands are one of the main sources of pasture for domestic stock. In order to describe the vegetation and species composition of these peatlands sample plots were randomly placed within these peatlands. All species were noted and their cover-abundance values were assessed according to the Braun-Blanquet scale. Environmental data such as slope, aspect, grazing, degree of erosion of the peatland were noted, while average height of plants were also noted. Data analysis was done using TWINSPLAN classification as well as CANOCO. The results reveal that the thurfur (elevated humps of peat) on the peatland supports a different plant association in comparison to the surrounding water-logged areas. Environmental factors such as wetland hydrology, drainage, erosion and biotic impact are playing important roles in the distribution of wetland-associated species. Several impacts are threatening to destroy these high-altitude wetlands and drastic conservation measures are needed to protect these unique ecosystems from total destruction.

A.P.E.S.: MERGING LOCAL SURVEY EFFORTS AND A GLOBAL PERSPECTIVE ON GREAT APES

Louwrens J. Du Toit

Max-Planck Institute for Evolutionary Anthropology

Tene SOP, Max-Planck Institute for Evolutionary Anthropology

; Ruppert VIMAL, Max-Planck Institute for Evolutionary Anthropology ; Hjalmar S. KÜHL, Max-Planck Institute for Evolutionary Anthropology

All great ape species are endangered according to the IUCN Red List. Global and regional information on population abundance, distribution, and spatio-temporal trends are key to informing conservation policy-making and buffering against emerging threats. Despite the many efforts in collecting great ape population data at numerous locations across Africa over the past 30 years, comparable country-, ape-range- and eco-region-wide information remains scarce. Together with partners of the ape conservation community, we initiated the

IUCN SSC A.P.E.S. (Ape Populations, Environments and Surveys) Portal (<http://apesportal.eva.mpg.de>), a platform that serves to centralize and standardize all existing ape survey information and provide access to extensive spatial and non-spatial information and analytical tools to assess ape population status, threats to their survival and conservation initiatives for their protection. Since its official launch in 2012, uses of the almost 300 data sets currently stored in the database have included the identification of important research and conservation gaps in Africa, the development of a model to predict range-wide ape distributions, regional threats and population changes over the past 20 years, an assessment of conservation effectiveness at all African great ape sites and site-specific risks of population extinctions. Furthermore, we investigated the effects of socio-economic constraints on great ape abundance to propose effective conservation strategies across increasingly human-dominated landscapes. Current projects include the development of a world-wide abundance model for all great ape species, the evaluation of co-benefits of carbon credits for climate, great apes and biodiversity protection, and the further development of web-based, interactive tools that allow scientists, stakeholders, and managers to analyze pressures impacting species within important ape sites and to support broad-scale site comparisons.

MANAGING EUROPEAN LARGE CARNIVORES AT THE TRANSBOUNDARY POPULATION LEVEL: THE ADDED VALUE OF THE ALPINE CONVENTION AND CARPATHIAN CONVENTION REGIMES

Jennifer Dubrulle

Tilburg University

Most European populations of brown bear (*Ursus arctos*), wolf (*Canis lupus*) and Eurasian lynx (*Lynx lynx*) are shared by two or more countries (8 of 10 bear populations; 8/10 for wolves; 10/11 for lynx). Most European states cannot host viable populations on their own. It is thus widely accepted that conservation planning for these species should be adjusted to the biological unit of each population, rather than to international frontiers. Detailed criteria for such transboundary population level management (TPLM) are set out in the Guidelines for Population Level Management Plans for Large Carnivores (Carnivore Guidelines), endorsed by the European Commission in 2008. I analyse the role of the applicable international legal framework as regards the implementation of TPLM, employing standard international law research methodology. Chief instruments are the Bern Convention on European Wildlife Conservation and the EU Habitats Directive. For two sets of large carnivore populations, the Alpine and Carpathian ones, additional legal instruments are in place, i.e. the Alpine and Carpathian Conventions with their Protocols on

biodiversity. Crucially, the geographic scope of these regimes is not defined by state boundaries but coincides approximately with the occurrence of the carnivore populations. Using the Carnivore Guidelines as benchmark, I assess to what degree each of the mountain regimes fulfils its apparent potential to serve as a forum for operationalising TPLM. The assessment covers the instruments' mandates, parties' duties, institutional frameworks, and actual steps towards TPLM of large carnivores. A comparison is made on these counts with populations that are only covered by the Habitats Directive and/or Bern Convention. Results indicate that, even if fully-fledged TPLM has not yet been achieved for any population, the two mountain regimes clearly give the Alpine and Carpathian bear, wolf and lynx populations an edge as compared to other European populations.

SCIENCE AND CIVIL SOCIETIES FOR CONSERVATION OF ENDANGERED, ENDEMIC BIRD SPECIES IN FRENCH OVERSEAS DÉPARTEMENTS.

Alison Duncan

Ligue pour la Protection des Oiseaux
François-Xavier COUZI, Société d'Etudes Ornithologiques de La Réunion ; Nyls DE PRACONTAL, Groupe d'Etude et de Protection des Oiseaux de Guyane ; Jean-Raphaël GROSDORMEAUX, Centre National de Recherche Scientifique ; Alizée RICARDOU, Groupe d'Etude et de Protection des Oiseaux Guyane ; Marc SALAMOLARD, Parc National de La Réunion ; Anna STIER, Groupe d'Etude et de Protection des Oiseaux Guyane ; Anne-France TOUVERON, Ligue pour la Protection des Oiseaux

Overseas entities harbour a key part of world biodiversity, and France is ranked 10th for the number of globally threatened bird species, on islands and in the 80,500km² of tropical rainforest in French Guiana. In 2007, the EU budget-line LIFE Biodiversity was opened to outermost regions (ORs), and LPO/BirdLife France prepared a project with local partners (ornithological NGOs and a National Park) in 3 ORs to conserve globally threatened species and one very rare habitat, and to allow networking for the NGOs. Each project is steered by a committee with stakeholders from research, government agencies, conservation management and civil society. This new funding instrument gives the small NGOs access to modern technology to acquire knowledge necessary for effective conservation and for the relevant actions; conservation has changed level in these vulnerable territories. In French Guiana, inselbergs contain leks of Cock of the Rock (*Rupicola rupicola*): telemetry allowed the movements of these birds to be discovered. Conflict between protection of the birds and different uses (by foresters, mining companies, tour operators) is reduced by better use of the sites by people. The world largest colony of Agami heron (*Agamia agami*) is in the Kaw Marshes, accessible only by helicopter. Satellite

transmitters enabled the key habitats and migration of this little-known species to be discovered for an Action plan. In La Réunion, a new method of controlling rats has led to an increase in the critically endangered Réunion cuckoo-shrike (*Coracina newtoni*, only 30 pairs in 2010). To discover the preferred habitat of White-breasted Thrasher (*Ramphocinclus brachyurus*), song-meters and Ecko-sensors were used in Martinique. Management of visits to the site has been improved and new sites identified for translocation. The network of the small NGOs in French ORs, supported by LPO, an experienced NGO in metropolitan France has enabled considerable growth in their capacity.

OVERWINTER SITE SELECTION OF A NORTHERN POPULATION OF WESTERN PAINTED TURTLES (*CHRYSEMYS PICTA BELLII*) IN A HYDROELECTRIC RESERVOIR ENVIRONMENT

Amy Duncan

Thompson Rivers University
Karl LARSEN, Thompson Rivers University

Winter represents a critical life cycle phase for many temperate species, often involving the use of specific sites that provide suitable overwintering conditions. Animals inhabiting anthropogenic environments may face additional challenges locating suitable overwintering sites, requiring different tactics to deal with different situations. In Western Canada, the Painted Turtle (*Chrysemys picta*) may spend up to five months overwintering submerged under ice. Within a hydroelectric reservoir in British Columbia, two main overwintering tactics (dispersive and communal positioning) have been observed between subpopulations. To investigate the factors responsible for this variation in behaviour, we (i) identified habitats used by overwintering turtles, (ii) evaluated habitat availability in the reservoir, and (iii) investigated reasons for the variation in spatial display. Turtles at both locations used overwintering sites typical of other populations of northern Painted Turtles: shallow depths (35 ± 19 cm), cool water temperatures (0.6 ± 0.8°C), normoxic oxygen content (> 0.5 mg/L) and loose substrate for burrowing (31 ± 25 cm). Tactics also shifted between years; turtles in the first study year displayed two distinct tactics between subpopulations, in the second year turtles in the previously congregated subpopulation displayed both tactics. Turtles exhibited under-ice movements between consecutive winter months which were correlated to water fluctuations; although this did not appear to affect turtle survival during winter. In conclusion, the variation in tactics shown does not appear to be correlated with the different environmental conditions that I studied (temperature, dissolved oxygen and water depth). The results of this work contribute to the knowledge of behavioural plasticity in animals, and also aid in the creation of conservation efforts for species inhabiting human-influenced environments.

BIODIVERSITY INFLUENCES ON MANGROVE FOREST MULTIFUNCTIONALITY AND ECOSYSTEM SERVICES PROVISION

Clare Duncan

Institute of Zoology (ZSL) & University College London
Jurgenne PRIMAVERA, Zoological Society of London & SEAFDEC Aquaculture Department (Iloilo, Philippines); Julian THOMPSON, University College London; Heather KOLDEWEY, Zoological Society of London; Nathalie PETTORELLI, Institute of Zoology

A recent shift away from traditional 'fortress conservation' toward ecosystem approaches to land management has seen an increase in focus in the dual goals of conserving biodiversity and the goods and services (ES) derived from the world's ecosystems. The potential success of such approaches demands a mechanistic understanding of how biodiversity and ecosystem functioning and ES provision are related. Currently, however, this understanding is hindered by a lack of research into multiple mechanisms (e.g. niche complementarity, mass ratio, selection effect) by which biodiversity may influence ES provision in real systems at scales at which the multiple ecosystem processes driving ES occur. Our study explores ecosystem multifunctionality and ES provision in mangrove forests in Panay island, Philippines. We examine how species richness, alpha, beta and gamma diversity, and functional richness and trait dominance (multiple mangrove species traits: growth form, maximum height, salt tolerance, rooting system complexity, average leaf area and litter fall rate) of mangrove species influences multiple ES provision (as indexed by soil organic carbon content, above- and belowground mangrove carbon storage, harvestable timber production, charcoal production and storm attenuation potential (as indexed by a combination of forest structure parameters (tree DBH and height differentiation and dominance factors))). We assess the biodiversity drivers of mangrove ES provision across two scales (within-site (plot level) and between-site), and discuss the relative mechanisms by which biodiversity drives multiple mangrove ES as well as discrepancies between the spatial scale considered. Our findings reveal important implications regarding the metrics and scales considered in B-ES research, as well as for mangrove forest rehabilitation and restoration efforts for the maintenance of their crucial ES worldwide.

ASSESSING THE ECOLOGICAL CONSTRAINTS ON MANGROVE FOREST RESILIENCE TO SEA LEVEL RISE GLOBALLY

Clare Duncan

Institute of Zoology (ZSL) & University College London
Jurgenne PRIMAVERA, Zoological Society of London & SEAFDEC Aquaculture Department (Iloilo, Philippines); Julian THOMPSON, University College London; Heather KOLDEWEY,

Zoological Society of London; Nathalie PETTORELLI, Institute of Zoology (ZSL)

Mangrove forests are highly important ecosystems, providing habitat and resources for biodiversity and a plethora of ecosystem services benefits to humanity. At a global scale they play a vital role in climate regulation as some of the most carbon-rich forests in the tropics, and locally afford coastal protection from extreme weather events such as hurricanes and tidal surges, and food and timber resources. However, due to the effects of multiple interacting global threats of land-use (particularly for aquaculture) and climate change, mangroves are now one of the world's most threatened biomes. Mangrove forests are highly sensitive to environmental and ecological changes. The future outlook for mangroves is thus severely compromised by climate change, and particularly by sea level rise (SLR). Mangroves can exhibit resilience to SLR through expansion at their inland fringes. However, the strong influence of hydrology and inundation on mangrove ecology and zonation means that inland expansion is only possible if appropriate sloping conditions exist. Applications of remote sensing analyses to these largely remote areas have enabled the mapping of both mangrove coastline retreat and inland expansion under SLR. However, tropics-wide coverage of studies is limited, restricting our understanding of potential generalities in the contextual and ecological requirements promoting resilience to SLR, and hindering the direction of management priorities for land-use planning. This work aims to fill this knowledge gap, utilising moderate resolution radar and multispectral satellite data (ALOS PALSAR, Landsat 5 TM and ASTER) across 12 mangrove sites currently affected by SLR to explore conditions (elevational and climatic) under which mangrove inland expansion is promoted. This poster discusses the methodologies that will be employed in this study, and presents some preliminary findings from one study site in the Ruvuma Estuary Marine Park on the border of Tanzania and Mozambique.

SYMPOSIUM#163_ECOSYSTEM-BASED ADAPTATION AND TRANSFORMATION: ADAPTATION SERVICES AND PATHWAYS

Michael Dunlop

CSIRO

Russell WISE, CSIRO; Sandra LAVOREL, CNRS; Matthew COLLOFF, CSIRO; Russell GORDDARD, CSIRO; Paul RYAN, Australian Resilience Centre; David HOLE, Conservation International

Many ecosystems have the potential to be resilient to small amounts of climate change, thereby preserving biodiversity and helping people adapt to climate change. However, widespread and significant impacts on ecosystems are possible by the second half of the century. How does this affect their

ability to conserve biodiversity and sustain livelihoods? Are the two complementary or alternatives? What sort of ecosystem management might be effective? The answers to these questions will depend critically on the range of trajectories of ecological change that are possible in different contexts. Some ecosystems may be able to transform, remain healthy and continue to sustain livelihoods. However, others may become more vulnerable to being degraded by the actions of ecosystem-dependent communities, losing biodiversity and failing to support livelihoods: a lose-lose outcome. Trajectories of change may be known for some ecosystems and in the near-term. However, future ecological trajectories in the face of more significant climate change, and the extent to which changing ecosystems can sustain human impacts, are likely to be unknown for many ecosystems. We discuss how an adaptation pathways approach could be used to help communities and their partners plan for future but uncertain ecological change, avoiding maladaptive decisions and creating and maintaining future adaptation options. The approach considers the range of ecological trajectories in response to climate change and other factors, different ecosystem services and livelihood options potentially available under different trajectories, the decisions needed to manage ecological change and the delivery of ecosystem services, how knowledge, social and institutional factors may inhibit or enable decisions, and temporal dependence of climate change, ecological responses, decision making and social change. Discussion will draw on examples from around the world.

HEARD BUT NOT SEEN: EXPLORING ACOUSTIC MONITORING METHODS FOR WILD TIGER POPULATIONS

Courtney Dunn

Dallas World Aquarium

Development of new methods of remote monitoring is essential for more efficient as well as minimally disruptive census of species where dense jungle prohibits visual confirmation. This is particularly important for *Panthera tigris* whose populations have plummeted by over 50% within the past century and whose ranges have been reduced to 7% of their historic lands. With the population decline of many other forest-dwelling species following that of this flagship species, it is important now more than ever to establish an efficient, all-encompassing census method for such landscapes. We sought to determine what makes an individual tiger's call unique in hopes of developing a non-invasive acoustic monitoring system within rangeland countries. To answer this question, spectrogram outputs of 265 bouts from approximately 1,618 hours of recording were analyzed to determine vocal characteristics from eight female and nine male adult Bengal tigers residing in controlled, ex-situ conditions. Volunteers

extracted data on minimum and maximum fundamental frequencies, duration of bouts, inter-call intervals, average call duration, first call duration, and the time of day a vocalization occurred. Comparison of acoustic parameters among the 17 individuals revealed a significant difference existed between sexes as well as among individuals. We are beginning to collect vocalizations from Amur, Sumatran, and Malayan subspecies to determine if these differences continue species wide. The apparent complexity of tiger vocalizations will potentially enable a vocal "fingerprint" to be assigned to individuals, which, in turn would allow for censusing when using microphone arrays placed strategically over tigers' home ranges. Increasing ease of access to bioacoustics tools has also expanded interest to not just other scientists but government agencies which can benefit from the automated detection of threatened native species which rely largely on vocal communication.

PROTECTED AREA PLANNING, INSTITUTIONAL DESIGN, & IMPLICATIONS FOR ECOSYSTEM SERVICE DELIVERY: A COMPARATIVE ANALYSIS OF INDONESIAN REEF COMMUNITIES

Kelly Heber Dunning

MIT

Common pool resource management theory tells us that given an appropriate institutional design, shared resources can be managed to ensure that dependent communities benefit from healthy environments. These benefits can be conceptualized as ecosystem services, and in coastal communities these include fisheries provisioning, incomes from eco-tourism, and erosion and extreme weather buffering. An ever-expanding institutional framework to enhance ecosystem service delivery is the marine protected area (MPA). This study examines participatory planning in MPAs, theorizing them as institutions for shared resource management, and hones in on 1) collaborative planning for risk, and 2) adaptive learning. The research explores what specific form participation, risk planning, and learning can and should take in order to ensure ecosystem service delivery in communities implementing MPAs. I use two cases in Bali, Indonesia where co-management of MPAs is occurring, where instead of a top down bureaucratic formulation of natural resource management, the central government has instead devolved responsibility to communities who are dominated by reef-dependent livelihoods such as subsistence fishing and dive or snorkel tourism. This study is a comparative one, where case communities have bounced back from years of dynamite fishing but with different biophysical and social outcomes. I use qualitative and quantitative methods to formulate my independent variable (institutional makeup around participatory reef governance via an MPA), and

biophysical reef surveys to formulate my dependent variable. My findings include: 1. Participatory risk planning did not occur in the community with healthier reefs as hypothesized. 2. Cooperative education programs where tourists and visitors were the intended audience did occur in areas with healthy reefs. 3. High levels of participation and interpersonal trust did not predict healthier reefs.

VULTURE ATTACKS? THE IMPORTANCE OF CONSIDERING PUBLIC AWARENESS AND COLLABORATION FOR A BETTER UNDERSTANDING OF VULTURE/LIVESTOCK INTERACTIONS

Olivier Duriez

CEFE-CNRS

Raphaël NEOUZE, Ligue pour la Protection des oiseaux ; Régis GALLAIS, Office National de la Chasse et de la Faune Sauvage

In southern Europe, vultures evolved together with extensive livestock farming. The quartering service provided by these scavengers has been used and appreciated by farmers since Antiquity. With the decline of vultures in the 20th century, this ancestral relationship was broken, and only re-established with the recent recovery of vulture populations, particularly in Spain and France thanks to conservation and reintroduction programs. In French Grands Causses along with a reintroduction program started in 1981, farmers are voluntarily creating feeding stations to benefit from vulture scavenging services. However, complaints about vultures attacking livestock appeared in both countries in 1995, with media reporting changes in vultures' behavior. After a wave of complaints in the Pyrenees, the cases also increased since 2007 in Grands Causses. To understand these events, the local partners created a "vulture & livestock committee", gathering farmers, conservationists, animal health services and state agencies. It works on 4 themes: census of events, carrion management, communication and procedures. Since 2010 for each complaint, a standardized procedure is followed by a state warden and a veterinarian, to determine the cause of the animal's death and the role of vultures. We analyzed 156 official reports. Complaints generally occurred at the periphery of vulture home range (determined by GPS tracking) and close to known feeding sites. Cause of the death could be assessed for 59 reports and vultures were never the primary factor. On 17 cases, vultures consumed ante-mortem an animal, already condemned and suffering partial or total immobility. Since most complaints happened in areas sparsely visited by vultures, our analysis suggests that the perception of attacks is mostly due to a lack of awareness about vulture natural feeding behavior and environmental education in these areas. Also, the role of mass media in spreading rumors is not negligible.

COMPLEX INTERACTIONS BETWEEN LONG STANDING INTRODUCED RATS AND NATIVE PLANTS IN A NEW-CALEDONIAN RAINFOREST

Quiterie Duron

Institut Méditerranéen de Biodiversité et d'Écologie marine et continentale (IMBE), Aix-Marseille Université, UMR CNRS - IRD - UAPV, Centre IRD Nouméa - BP A5, 98848 Nouméa Cedex, Nouvelle-Calédonie

Edouard BOURGUET, Institut Méditerranéen de Biodiversité et d'Écologie marine et continentale (IMBE), Aix-Marseille Université, UMR CNRS - IRD - UAPV, Centre IRD Nouméa - BP A5, 98848 Nouméa Cedex, Nouvelle-Calédonie ; Oriana GARCIA IRIARTE, Institut Méditerranéen de Biodiversité et d'Écologie marine et continentale (IMBE), Aix-Marseille Université, UMR CNRS - IRD - UAPV, Centre IRD Nouméa - BP A5, 98848 Nouméa Cedex, Nouvelle-Calédonie ; Sarah SCUSSEL, Institut Méditerranéen de Biodiversité et d'Écologie marine et continentale (IMBE), Aix-Marseille Université, UMR CNRS - IRD - UAPV, Centre IRD Nouméa - BP A5, 98848 Nouméa Cedex, Nouvelle-Calédonie ; Mélanie BOISSEININ, IAC (Institut Agronomique néo-Calédonien), Axe 2 Diversités biologique et fonctionnelle des écosystèmes terrestres- BP 73- 98890 Païta, New Caledonia ; Fabrice BRESCIA, IAC (Institut Agronomique néo-Calédonien), Axe 2 Diversités biologique et fonctionnelle des écosystèmes terrestres- BP 73- 98890 Païta, New Caledonia ; Eric VIDAL, Institut Méditerranéen de Biodiversité et d'Écologie marine et continentale (IMBE), Aix-Marseille Université, UMR CNRS - IRD - UAPV, Centre IRD Nouméa - BP A5, 98848 Nouméa Cedex, Nouvelle-Calédonie

The new-Caledonian archipelago is listed as one of the 35 biodiversity hotspots with an unusual rate of endemism on flora (80%). Unfortunately, this heritage is threatened by various invasive species including rats. Number of studies worldwide quote strong negative rat impacts on plants by seed and fruit predation but few others suggest potential rat positive roles in native seed dispersion. Thus, studying the interactions between invasive rats and native plants is crucial to make adequate management decisions. We studied the effects of two sympatric invasive rat species (*Rattus rattus* and *R. exulans*) on native new-Caledonian plants in a dense evergreen rainforest through three experiments: i), we intensively studied rat diet by evaluating the abundance of native plants items in 330 rat stomachs, collected in 3 different seasons; ii), we set up an in situ fruit consumption experiment using camera traps testing 3 major palm tree species; iii) we studied the effects of fruit predation by rats on seed germination performances via captive feeding trials and seed germination experiments compared with effects of native dispersers (flying foxes and frugivorous birds). Results showed that native flora make up a large proportion of rat diet: 76% of

R. rattus and 38% of *R. exulans* diets. Palm fruit predation rates observed during 7 days differed between the 3 species tested (11-92%). Conversely, small seeds remained intact after rat predation and may be dispersed by rats. The results showed strong interaction between rats and native plants, especially for *R. rattus*. However, even if invasive rats were proved to induce severe deleterious effects on native flora, our study also confirmed that they may help maintaining ecosystem functions and contribute to new ecosystem equilibriums. Such cost-benefices analysis has to be taken into account to evaluate the opportunity to control invasive rats for restoring native biodiversity.

DIVERSITY IN INVASION: VARIATION IN THE INVASIVE ECOLOGY OF AUSTRALIAN POTAMOPYRGUS ANTIPODARUM CLONES

Adrian Dusting

University of Canberra

Paul SUNNUCKS, Monash University ; Dianne GLEESON, University of Canberra ; Ross THOMPSON, University of Canberra

The distribution and spread of an invasive species is governed by many stochastic, environmental and evolutionary factors. In particular it has been established that genetic diversity and evolutionary factors may affect the ecological processes that govern species distributions. Despite this it has often been taken for granted that the way in which an invader interacts with its environment is homogenous among invasive populations. We measured the variation of ecological responses of distinct clonal lineages of an invader of Australian freshwaters, *Potamopyrgus antipodarum*. *Potamopyrgus* is an invasive freshwater snail of global significance, having invaded waters in Europe, Australia, Asia and North America. Using genetic markers, three clonal lineages were identified amongst south-eastern Australian populations. The lineages were then exposed to environmental stressors and their survival, growth and reproductive output were measured. We found differences amongst clonal lineages in their ecological responses to environmental stressors. Some of these differences were associated with the distributions of different lineages across their invaded range in south-eastern Australia. These findings illuminate the role of important environmental variables in shaping the spread of *P. antipodarum* and imply that some clonal lineages may be more "invasive" than others. The findings of this study also have implications for models used to forecast invasive range of species, violating a common assumption of homogeneity in species ecology across invasive populations.

ID #191: THE EFFECTIVENESS OF CELEBRITIES IN CONSERVATION MARKETING

Elizabeth Duthie

Imperial College London

With the increasing recognition that conservation is ultimately dependent on human behaviour and attitudes, there is a growing need to ensure that communications between the conservation community and the public are effective. Whilst there is a strong emphasis on monitoring and evaluation in other areas of conservation, there is limited or no testing and analysis of the methods used to communicate with different stakeholders by the majority of conservation NGOs. Given the importance of remaining visible and relevant on the global stage, conservation NGOs should be ensuring their marketing outputs and communications are in line with current best practice. Celebrity endorsement is a popular, and often used, technique for generate income and awareness, both for commercial brands, and for non-profit organisations. Conservation marketers use celebrities such as Leonardo DiCaprio, HRH The Duke of Cambridge and Yao Ming to raise awareness, generate funding and effect behaviour change. However, whilst celebrity endorsement effectiveness is extensively evaluated in other marketing fields, we found no evaluation or testing of the effectiveness of celebrity endorsement has been conducted by researchers or conservation organisations to date. Without this analysis, conservation NGOs are unable to ensure their celebrity campaigns are reaching the correct audience or communicating the message successfully. We assessed the effectiveness of celebrity endorsement against several advertising key performance indicators. Whilst we found that celebrities are more effective than non-celebrities in generating positive Willingness-to-Engage behavior, celebrities are less effective at generating campaign message recall than non-celebrities. Furthermore celebrity endorser credibility is a key factor in determining public engagement. I will discuss these findings and their implications, and look at other areas that require research to ensure conservation is being communicated effectively.

COMMUNITY-BASED CONSERVATION - A KEY TO SUCCESSFUL CONSERVATION IN MAIO ISLAND, CAPE VERDE

Amanda Dutra

Maio Biodiversity Foundation

Daniel SANTOS, Maio Biodiversity Foundation ; Victor STIEBENS, Maio Biodiversity Foundation ; Franziska KOENEN, Maio Biodiversity Foundation ; Leno PASSOS, Maio Biodiversity Foundation ; Edita MAGILEVICIUTE, Maio Biodiversity Foundation ; Arnau TEIXIDOR, Maio Biodiversity Foundation ;

Elisa DIERICKX, Maio Biodiversity Foundation ; Tamas SZEKELY, Maio Biodiversity Foundation

Maio Island is largest remaining island in the Cape Verdean Archipelago that has escaped mass tourism. The island is a major nesting site for endangered loggerhead sea turtles, it has significant whale and dolphin populations, and important breeding shorebird populations. Maio Biodiversity Foundation (FMB) was established in 2010 to protect wildlife, with the support of local communities. Before FMB's turtle conservation project, the island had the highest rates of killed females and poached nests in Cape Verde. In 2013 FMB developed a new conservation strategy: from July to September protection teams were placed in 8 coastal villages around the island to patrol 25km of nesting beaches. Night patrols ensured the protection of turtles and also the first daily data collection ever done on Maio's nesting beaches. As a result, the number of killed females was reduced by 75% on the protected beaches as compared to the same area the previous year (152 versus 38 in 2012 and 2013, respectively), and only 2% of the nests were poached. The integration of the teams in the communities made the conservation efforts more visible to the villagers, which had opportunities to join patrols and awareness events. In addition, host families received financial benefits for their hospitality. The combination of direct protection, practical education and turtle friendly income opportunities was the key to the success of this strategy. Based upon these experiences, in 2014 FMB started training community-lead monitoring of the largest protected area in Maio Parque Natural da Ilha do Maio as well initiated participatory monitoring of marine megafauna species such as whales, dolphins, turtles and sharks.

CONNECTING THE DOTS: CONNECTIVITY MAPPING FOR TIGERS IN CENTRAL INDIA

Trishna Dutta

Columbia University

Sandeep SHARMA, Smithsonian Conservation Biology Institute ; Brad MCRAE, The Nature Conservancy ; Ruth DEFRIES, Columbia University

Connectivity between Protected areas (PAs) is an important feature of a conservation landscape because it maintains natural dispersal pathways for wildlife. Due to their inherent wide ranging movement patterns, large carnivores are excellent focal species for connectivity and landscape level conservation planning. In order to conserve viable populations of species that depend on long distance movement and dispersal, conservation needs to take place at a level larger than individual PAs, such as a larger landscape or at a regional scale. Tigers (*Panthera tigris*) act as a flagship species for the conservation of forested ecosystems throughout their range in Asia, and typify the challenges and opportunities of large carnivore conservation elsewhere. Dispersing tigers are very

important in the viability of the population because they have the potential to colonize new areas, and spread their genes with other populations. These individuals need pathways that connect good habitat patches that are conducive to successful animal movement and dispersal. In developing countries such as India that have burgeoning human populations and shrinking forest areas, it is a challenge to maintain and carve additional protected areas. The existing PAs are too small, scattered, and insufficient to support viable populations of wide-ranging species in the long term. We mapped connectivity in the Central Indian Landscape, and examined landscape features that are important to tigers during dispersal. This landscape is part of the Global Tiger Recovery Program, and holds a significant population of the country's wild tiger population. Here, I discuss the existing connectivity in the region, and identify pinch points, i.e., sections of the corridors that are of disproportionately high conservation value. We anticipate that the outcomes of this study will be used in the planning and management of the landscape.

THE GLOBAL DATABASE ON PROTECTED AREA MANAGEMENT EFFECTIVENESS: HISTORY, GLOBAL STATISTICS, AND FURTHER DEVELOPMENT.

April Eassom

UNEP World Conservation Monitoring Centre

Nina BHOLA, UNEP World Conservation Monitoring Centre ; Marcelo GONCALVES DE LIMA, UNEP World Conservation Monitoring Centre ; Naomi KINGSTON, UNEP World Conservation Monitoring Centre

Reliable information on the effectiveness of protected area management is essential to assess the performance of protected areas. Building upon the World Commission on Protected Areas (WCPA) framework for assessment of protected areas, in 2006, WWF and TNC established the Global Database for Protected Area Management Effectiveness (GD-PAME). The GD-PAME has been redeveloped and linked to the World Database on Protected Areas (WDPA) and is managed by UNEP-WCMC. It is the most comprehensive global database of methodologies and associated indicators designed to assess protected area management effectiveness. The database contains 95 methodologies and over 17,000 assessments for many different protected areas globally. The results of the assessments are converted to a common reporting format which is used by national ministries and international organizations to: improve protected area management, better allocate resources and measure progress towards global conservation biodiversity targets. However, the GD-PAME is not without its limitations. For example, only a few PAME methodologies include quantitative social and biological data, making it difficult to evaluate whether effectiveness of protected area management translates into positive biodiversity outcomes. . Furthermore, there is an

under-representation of assessments in several regions across the world's protected area estate. To address these limitations, efforts are being made to integrate biodiversity and social information into the GD-PAME and bring existing data from these regions together in order to offer a more globally complete dataset. We review the evolution and application of the GD-PAME, highlighting key statistics derived from recent analyses, and caveats associated with analytical decisions made in preparing the database. We then explain the recent improvements made to the database and how these will help move the conservation agenda forward.

USING POPULATION CONNECTIVITY MEASURES OF FISHERY-TARGETED CORAL REEF SPECIES TO INFORM MARINE RESERVE DESIGN

Erin Eastwood

Columbia University

Elora LÓPEZ, Columbia University

Coral reefs are some of the most beautiful and diverse ecosystems on the planet, yet are vulnerable to mounting anthropogenic pressures such as overfishing. Marine protected area (MPA) networks have become important tools for mitigating these pressures, but their implementation requires multiple pieces of scientific information to ensure that they are effective. One of the most critical factors in determining spatial design for MPA networks is the degree of connectivity among different populations of species targeted for protection. In order to delineate this connectivity, it is important to calculate the magnitude and direction of gene flow occurring among populations. In this study, we investigate the connectivity patterns of three species commonly targeted by fisheries in Fiji, in order to inform the spatial design of a large MPA network within the country. Using mtDNA sequences, we characterize the degree to which different populations within five regions of Fiji were related, estimate per generation migration rates, and describe the ability of upstream populations to provide larvae to downstream areas. Taken together, these data provide important information to management officials for the protection of economically as well as ecologically important species through the creation of MPA networks.

ESTIMATING IMPACT LEVELS FOR SUSTAINABILITY RISK ASSESSMENT OF NEW ZEALAND DEEPWATER FISH STOCKS

Charles Edwards

NIWA

Marie-Julie ROUX, NIWA

Until recently, the majority of by-catch species in New Zealand have been managed using qualitative indicators of status, without reference to estimates of productivity or exploitation rate. A semi-quantitative sustainability risk assessment for non-

target fish species captured using trawl and bottom longline methods in New Zealand deepwater fisheries is presently under development. The assessment framework relies on the impact/threshold approach to risk evaluation, which consists in the estimation of a spatially-explicit fisheries by-catch level relative to a population size proxy, and a maximum impact sustainable threshold derived from productivity parameters. A number of alternative methods are being developed for estimating fisheries by-catch and impact levels with reference to the information needs of fisheries managers charged with managing impacts on non-target species by New Zealand fisheries, and the known availability of data and ecological knowledge to inform inputs into the risk assessment process. This presentation will give an overview of progress made, with preliminary applications to selected by-catch species.

ID 161: MARINE SPATIAL PLANNING: TOWARD ECOSYSTEM-BASED MANAGEMENT

Charles Ehler

Ocean Visions Consulting [INSTITUTE] UNESCO

Fanny DOUVERE, UNESCO

Among many coastal countries Marine Spatial Planning (MSP) has become the preferred management approach to address increasing conflicts among multiple uses of coastal and marine areas, including their contiguous exclusive economic zones (EEZs)—about 40 countries are now experimenting with MSP. Over the next decade another 30 countries, including the 23 coastal countries of the European Union (EU) and North America, will develop and approve marine spatial plans that will cover about a third of the surface area of the EEZs of the world. A common theme underpinning these concepts is the importance of ecosystem-based approaches to manage human uses and sustain ecosystem services while adapting to the impacts of climate change. The new challenges of climate variability and change, alongside the other existing drivers that cause depletion and degradation within coastal and marine ecosystems, increases the urgency and the need to scale up these efforts at national and regional scales. There is now a need to support adaptive ecosystem-management and governance that is informed by and evolves through on-going learning and adaptive processes, to help increase the resilience of marine ecosystems and well-being of societies dependent on marine goods and services. MSP is a practical, operational approach that has the promise of implementing marine ecosystem-based management. The status of MSP around the world will be described, including an assessment of how many of these initiatives actually take an approach that can be described as "ecosystem-based." Lessons learned regarding the success of ecosystem-based MSP initiatives will be identified.

LANDSCAPE-SCALE EFFECTS OF PRESCRIBED FIRE AND WOLVES ON ELK UTILIZATION OF ASPEN IN THE CANADIAN ROCKY MOUNTAINS

Cristina Eisenberg

Earthwatch Institute

David HIBBS, Oregon State University ; Daniel DONATO, Washington Department of Natural Resources

We conducted a landscape-scale study of aspen (*Populus tremuloides*) and elk (*Cervus elaphus*) response to a 2008 prescribed fire (1200 ha) in Waterton Lakes National Park, AB. Parks Canada set the fire in an aspen parkland in elk winter range, to reduce aspen land cover and restore fescue (*Festuca* spp.) within the burn unit. At this site, which contains 1-2 wolf (*Canis lupus*) packs, aspen provide a key elk food, and elk are the dominant herbivore by biomass. Previous research in non-wolf systems found a strong positive relationship between aspen sprouting, fire severity, and elk browse, with little to no aspen recruitment. We hypothesized that in a wolf-elk-aspen system, elk would avoid areas of highest fire severity, due to the high predation risk created by thick vegetation and coarse woody debris at such sites. We measured aspen and elk response to the fire annually for 6 years (2008-2013). We used an information theoretic approach to test our hypothesis, generating predictive models to examine the influence of fire severity (snag basal area), site index (a measure of productivity), shrub cover (proportion), aspen sprout density (per ha), and distance to edge of the aspen parkland (m) on the proportion of aspen sprouts browsed. We used GPS-collar data to confirm elk use of the parkland and camera traps to confirm wolf activity. Elk browse declined with increasing distance from the edge of the parkland ($p=0.0008$). We examined models $< 4 \Delta$ AIC values of the best-fitting model. Fire severity ($p<.0001$), aspen sprout density ($p<.0001$), and site index appeared in the best-fitting models, with increases in these variables linked to a decrease in elk browse. Elk avoided areas with the highest sprout density, productivity, or fire severity. This avoidance may be associated with a preference for the heightened post-fire nutritional value of fescue, energy conservation due to the higher energetic cost of moving through burned forest, and avoidance of wolf predation.

DO LIMITS TO THE GLOBAL OIL SUPPLY INCREASE THE RATE OF DEFORESTATION AND BIODIVERSITY LOSS?

Rowan Eisner

University of Queensland

Leonie SEABROOK, University of Queensland ; Clive MCALPINE, University of Queensland

Biodiversity loss is driven globally by the expansion of human land-use, in particular, agriculture. The expansion

of agriculture has slowed over the last 50 years due to the green revolution, with an increase in agricultural intensity achieved largely through the use of petrochemical-based fertilisers. The mid 2000s saw a transition in oil production where the supply became unresponsive to increased demand pushing up the price of petrochemicals and the products made from them, including fertilisers. Such constraints to the oil supply threaten to reverse the agricultural intensity gains of the green revolution and put increased pressure on biodiversity. Land and food speculation and the search for alternative energy sources which ensued from the oil transition also increase the demand for land. This study measures the change in the rate of deforestation and maps the resultant change in threat to biodiversity as the oil supply became inelastic. The rate of deforestation increased by 29% in the second half of the 2000-2012 period, resulting in the loss of an additional 290,000 km² of forest. Spatially, the areas of increased forest loss broadly corresponded with the areas of highest biodiversity but there was little correspondence with the land-grabbing phenomenon (large-scale, corporate land acquisition). Statistically significant areas of increased threat to biodiversity generally lie in a band through the tropics, in Asia from southern China to Indonesia, across Africa from Angola to Madagascar and in the Americas from Paraguay to southern Mexico. Conservation efforts need to be aware of the accelerating rate of loss, and of the coincidence of the loss with the areas of highest biodiversity.

THE EFFECTIVENESS OF THE PROTECTED AREA NETWORK IN MADAGASCAR

Johanna Eklund

University of Helsinki

Guillaume BLANCHET, McMaster University ; Tarmo VIRTANEN, University of Helsinki ; Ricardo ROCHA, University of Lisbon ; Mar CABEZA, University of Helsinki

Networks of protected areas form the backbone of biodiversity conservation. However, pervasive threats such as illegal deforestation are high within protected areas, jeopardizing the success of this conservation measure. Analyses of the effectiveness of protected areas have revealed that confounding factors correlated with both protection and extractive behaviors affect effectiveness perceptions. We investigated the effectiveness of the Madagascar protected area network in reducing deforestation rates while accounting for confounding factors such as remoteness and accessibility. We developed a novel, computationally efficient methodology to get an overall assessment of the effectiveness of the protected area network as a whole, accounting for distance to roads, rivers, major cities and altitude/slope. The assessment was independently conducted for two different time periods, 1990-2000 and 2000-2005, linking the differences to trends in the political discourse in the country. We find lower

deforestation rates inside protected areas than outside, but the network only mitigate the pressure of deforestation slightly, most of the decrease can just be attributed to the confounding factors rendering the land assigned for protection less likely to be deforested. This result emphasizes the need to improve the protected area management and the importance of expanding protected area networks in a systematic manner, based on ecological considerations. However, we also note important regional differences that need further assessments. Our methodology is computationally efficient and can be scaled up for larger studies. The work has clear practical implications for the conservation of Madagascar's biodiversity and the results are of potential interest for both NGOs and the Madagascar National Park administration.

BIOREMEDIATION OF PETROLEUM HYDROCARBONS FROM DIESEL CONTAMINATED SOIL WITH THE EARTHWORM - EUDRILUS EUGENIAE

Abraham Ekperusi

University of Benin

Felix AIGBODION, University of Benin

A laboratory study on the bioremediation potentials of the earthworm *Eudrilus eugeniae* Kingberg in soil contaminated with diesel was investigated at the main campus of University of Benin, Benin City, Nigeria. Dried and sieved soils were contaminated with 5ml each of diesel with replicates and inoculated with earthworms and monitored daily for 12 weeks. Physical and chemical parameters such as pH, total organic carbon, sulphate, nitrate, phosphate, sodium, potassium, calcium and magnesium were determined using standard procedures. Total petroleum hydrocarbons (TPH) was determined using Atomic Absorption Spectrophotometer (AAS), while benzene, toluene, ethylbenzene and xylene (BTEX) constituents and earthworms tissues were analyzed using Gas Chromatography with Flame Ionization Detector (GC-FID). The physical and chemical conditions showed a decrease; pH (3.0%), total organic carbon (49.22%), sulphate (60.59%), nitrate (60.65%), phosphate (60.80%), sodium (60.65%), potassium (60.67%), calcium (60.67%), magnesium (60.68%). TPH decreases by 84.99%. BTEX decreases by benzene (91.65%), toluene (100.00%), ethylbenzene (100.00%) and xylene (100.00%). Analyses of the tissues of the earthworm at the end of the experiment showed that the earthworms bioaccumulated/biodegraded 57.35/27.64% TPH, 38.91/52.73% benzene, 27.76/72.24% toluene, 42.16/57.85% ethylbenzene and 09.62/90.38% xylene. The results showed that the earthworms *Eudrilus eugeniae* could be used to bioremediate moderately polluted soil with diesel contamination in the Niger Delta region of Nigeria.

DOES AGRICULTURAL LAND-USE INTENSITY DRIVE THE LOSS OF RARE BEE SPECIES IN CENTRAL EUROPE?

Johan Ekroos

Lund University

Nico BLÜTHGEN, Technische Universität Darmstadt ; David KLEIJN, Alterra ; Eva KNOP, University of Bern ; Sara KÜHSEL, Technische Universität Darmstadt ; Henrik G SMITH, Lund University

An increasing number of studies find no relations between bee species richness and land-use intensity, or only for a subset of all species, but do find consistent relations with landscape structure. However, the effect of land-use intensity may have been underestimated as most individual studies consider fairly restricted intensity gradients. In particular, whether species loss leads to nestedness of bee communities caused by a systematic loss of rare species, or species with restricted foraging ranges, is not known. Here we investigate this relationship using 202 grasslands covering the whole range of low intensity, no-input systems, to high-input sites (>300 kg N/ha/year) across Central Europe. The data were collected in The Netherlands, Germany and Switzerland. The grasslands were embedded in agricultural landscapes varying from 0 to 100% agricultural land. We found that species richness of bees measured at the plot scale was not explained by nitrogen inputs or by percentage arable fields in the surrounding landscapes. In contrast, the proportion of rare species observed in the bee assemblages were non-linearly related to landscape structure, peaking in landscapes with intermediate amounts of arable land. Those bee communities containing high proportions of rare species also included the largest share of species with a restricted foraging range. Finally, we found that neither land-use intensity nor landscape structure caused significant nestedness in bee communities. This was explained by the fact that communities dominated by common species were species-poor, but species-poor communities could also largely consist of rare species. This created a high degree of turnover of species in bee communities across the studied grassland sites. Our results revealed surprisingly weak effects of land-use intensity on the species richness and community composition of bees. Possible implications at larger spatial scales relevant for conservation measures will be discussed.

EPIPELAGIC MESOZOOPLANKTON DIVERSITY AND DISTRIBUTION IN ATLANTIC COAST OF SOUTHERN MOROCCO (CAPE BLANC 21°N - CAPE BOUJDOR 26°30'N)

Laila Elarraj

Université Hassan II, Faculté des Sciences Ain Chock Casablanca

The purpose of this study is to attempt to explain how is epipelagic mesozooplankton distributed along the South Atlantic Moroccan shore and how fluctuate and intervene environmental parameters, as zooplankton has a main position in the trophic food web especially copepods; that are consumed by small pelagic fishes which are abundant in this area. Furthermore, this area is submitted to a permanent upwelling activity and is consequently the most productive zone of Moroccan shore. Actually, this work is part of CCLME program (Canary Current Large Marine Ecosystem). Two surveys were carried out in this area, one in November 2011 and another in July 2012 aboard the Norwegian ship 'Fridjof Nansen'. During cruises, mesozooplankton were collected over 7 transects, within 5 depth ranges of the water column (0-25, 25-50, 50-75, 75-100 and 100-200 m) at several stations from Cape Blanc 21°N to Cape Boujdor 26°30'N. Some environmental parameters were measured in situ using a multiprobe CTD: chlorophyll 'a', temperature, salinity and dissolved oxygen. Vertical profiles of mesozooplankton's densities have shown that highest values are observed in the superficial and intermediate layers and were also higher in the shallower during both seasons. The group of copepods seems to be the predominant component all over the water column, they constitute more than 90%. In total, 74 copepod species were identified and cosmopolitan species were dominant. According to Shannon-wiener index, diversity was higher in summer than autumn. A Principal Component Analysis has been performed on copepods densities in relation to environmental parameters and method of clustering too. Vertical profiles of hydrological parameters have shown a cooler temperature and high chlorophyll 'a' concentrations in shallower stations. Key words: Southern Atlantic coast; Mesozooplankton; Copepods; Upwelling and environmental parameters.

BUILDING AN IMMUNOME FOR THE GOPHER TORTOISE: IS THERE A GENETIC BASIS TO UPPER RESPIRATORY TRACT DISEASE?

Jean P. Elbers

School of Renewable Natural Resources, Louisiana State University Agricultural Center and Louisiana State University
Sabrina S. TAYLOR, School of Renewable Natural Resources, Louisiana State University Agricultural Center and Louisiana State University

Genetic diversity at functional genes such as those involved in immune responses can influence individual fitness and population viability. Populations of threatened species typically have low overall genetic diversity and are depauperate in immunogenetic variation, which can negatively influence disease susceptibility. Most studies of immunogenetic variation in the threatened wildlife have focused on a handful

of genes, but genomic resources and next-generation sequencing now enable researchers to assess hundreds of immune genes simultaneously. In this study, we filtered the genome of the western painted turtle for genes involved in immune response (i.e., the immunome) and then designed reagents to acquire these genes from a species of conservation concern, the gopher tortoise (*Gopherus polyphemus*), to better understand the genetic basis of disease susceptibility. Gopher tortoises are associated with long-leaf pine forests of the southeastern United States and are susceptible to an infectious and occasionally deadly upper respiratory tract disease. We sequenced the immunomes of 16 gopher tortoises from 4 populations along an east to west gradient covering the range of the species and assessed population genetic diversity and differentiation. Nearly all desired genomic regions were represented, and we obtained approximately 20000 variable single nucleotide polymorphism (SNP) loci. Population genetic diversity and differentiation estimated with SNP loci paralleled patterns previously inferred by genotyping more than 19 tortoises per population using 10 microsatellite loci. Further work will involve sequencing immunomes from healthy and sick gopher tortoises to better understand what genetic variants are associated with susceptibility to upper respiratory tract disease. Our study illustrates the effectiveness of immunome sequencing as a practical tool for not only population but also conservation genomics.

PROMOTING SUSTAINABLE COMMUNITY-BASED SEA TURTLE CONSERVATION IN AKASSA WETLANDS, BAYELSA STATE, NIGERIA

Kelechi Eleanya

FEDERAL UNIVERSITY DUTSIN-MA

Henry IJEOMAH, UNIVERSITY OF PORT HARCOURT

Akassa wetland is located in the Niger Delta at the southernmost tip of Nigeria along the Atlantic coast. It lies between 4° 21' N and 5° 59' E and consists of three barrier Islands separated by the Nun River, the Sangana River and the Fishtown River. The wetland is highly threatened by the unsustainable forest harvesting and massive oil exploration in the region. Akassa sand beaches (Oginibiri beach, Okumbiri beach- turtle beach, Fishtown beach and Sangana beach) play host to migratory sea turtles and serve as nesting sites for these endangered species. Three species of sea turtles more frequently seen in Akassa are: Leather Back Sea Turtle (*Demochelys coriacea*), Green Turtles (*Chelonia mydas*) and Olive Ridley (*Lepidochelis olivacea*). The rates of migration are higher during the breeding seasons-between September and February yearly. Despite the threat of oil spill and restiveness in the region, community support for conservation of endangered sea turtles has been strengthened through awareness campaigns and rallies conducted across the Akassa wetland by the Sea Turtle Club (a voluntary club of over

100 members). The turtle club activities has helped increase community support for sea turtle conservation and reduced killing of sea turtles by 85% in five years. The construction of a turtle observatory at the turtle beach has also initiated concerted efforts to improve activities of the youth group and facilitate responsible ecotourism in the Akassa wetland. Sea turtle conservation initiatives in Akassa need to be prioritized; focused capacity building on techniques for preserving and protecting turtle eggs at the nesting sites, incubation technologies, materials and best practices for turtle tagging will facilitate sustainable sea turtle conservation activities in Akassa wetlands.

LOW-INPUT FARMING PRACTICES SUPPORT BETTER PEST CONTROL THROUGH HIGHER ABUNDANCE OF NATURAL ENEMIES IN HUNGARY

Zoltán Elek

MTA-ELTE-MTM Ecology Research Group, Eötvös Loránd University

Gergely BOROS, MTA ÖK Lendület Ecosystem Services Research Group; Réka ÁDÁM, MTA ÖK Lendület Ecosystem Services Research Group; Anikó KOVÁCS-HOSTYÁNSZKI, MTA ÖK Lendület Ecosystem Services Research Group; Dorottya Molnár MOLNÁR, MTA ÖK Lendület Ecosystem Services Research Group; László SOMAY, MTA ÖK Lendület Ecosystem Services Research Group; András BÁLDI, MTA ÖK Lendület Ecosystem Services Research Group

Modern agriculture in Europe has simplified the traditional agro-ecosystems and replaced the ecosystem services with increased external inputs of energy and chemicals. In order to search targets of sustainable development, agriculture needs to be more productive, while minimizing its negative environmental impact. The aim of the Liberation FP7 project was to achieve such ecological intensification by enhanced invertebrate communities and related ecosystem services through reduced level of management intensity. To quantify the impacts of ecological intensification on winter-wheat production, we tested how pest organisms and their natural enemies were affected by landscape properties and by local field management such as experimentally manipulated fertilizer and insecticide use in Hevesi-sík Region, Hungary, Central Europe. We stratified our 24-plot sampling design according to the proportion of semi-natural habitats in the landscape and soil organic matter content. The fertilizer application had no consistent effects on the phenology of the wheat, however the prevalence of pathogen fungi tended to be higher in low input plots than in high-input ones. The abundance of carabids and spiders was higher in the low-input plots than in the high ones. Aphids showed an opposite distribution, suggesting successful pest control in the low-input plots. These results supports the possibility of ecological

intensification that is to substitute agrochemicals with ecosystem processes without loss in yield.

SAMPLING DESIGN MAY DISTORT THE ESTIMATIONS OF MARK-RECAPTURE MODELS FOR CARABUS HUNGARCIUS

Zoltán Elek

MTA-ELTE-MTM Ecology Research Group, Eötvös Loránd University

Sándor BÉRCES, Duna Ipoly National Park Directorate; Annamária CSÓKA, Duna Ipoly National Park Directorate; Zsófia MOC SKONYI, Duna Ipoly National Park Directorate; György VERO, Duna Ipoly National Park Directorate

One of the most important question of mark-recapture studies for insects is whether the sampling design may bias the applied statistical models for estimation of population parameters such as survival or recapture rate. We intended to study the effect of different spatial arrangement of pitfall traps on the capture/recapture rate of *Carabus hungaricus* and in addition on the applied statistical model's estimations for capture history data such as Jolly-Seber/Cormarck Jolly-Seber models. The pilot site was a Pannonian sand steppe (*Festucetum vaginatae*) located in the vicinity of Táborfalva village, Hungary. We used two spatially different sampling grids of non-baited pitfall traps between September 1 and November 30, 2013. The inter-trap distance in the grid "A" was four meters, while in the grid "B" it was two meters, each grid consisted of 64 traps. We found that there was no difference in the number of captures (Grid „A”: 200 individuals, Grid „B”: 209 individuals). However, the survival rate (Grid „A”: 0.04 ± 0.004 , Grid „B”: 0.1 ± 0.02) and the estimation of population size (Grid „A”: 129 ± 9 individuals, Grid „B”: 329 ± 65 individuals) were different between grids suggesting that the applied common statistical models for mark-recapture data were sensitive for the spatial arrangement of sampling points.

CONTRIBUTION TO THE STUDY OF POLLUTION BY WASTE FROM THE TANNERY WASTEWATER AIN FAKROUN THE OUED SIGUS - OUM EL BOUAGHI-ALGERIA

Ilyes Elhatabi

étudiant en 1ère année doctorat sciences -université oum el bouaghi- Algérie

The aim of this study is to assess the level of pollution caused by the Tannery of Ain Fakroun - Oum El Bouaghi, and the influence of heavy metals (Cr, Pb, Cd, Hg) on Sigus' river. To evaluate these last ones' environmental risks, water samples were taken and subjected to a total digestion and analyzed for Cr, Pb, Cd, Hg. Concentrations of metals in the solutions were determined by atomic absorption spectrometry. The

results show that the concentrations of the studied heavy metals are high, especially for the Chromium (3.2mg/L), and exceeds in most cases the acceptable standards. In addition to the physico-chemical and biological parameters which indicate a strong pollution, and as a result of a survey conducted at the perimeter of the area, it is shown that the damage recorded from the year 2000 and on are catastrophic: one dead man, 50 poisoned patients, 70 dead cows, 60 dead sheep, contamination of wells ... etc. This study demonstrates that the waters of the river are heavily polluted, and this area of study requires building a water treatment plant at the main collector of Ain Fakroun city to decrease the risk of a total destruction of the ecosystem. Keywords: River, Ain Fakroun, tannery, heavy metal, pollution, ecosystem.

RESISTANCE OF COASTAL MARSH ECOSYSTEMS TO LARGE-SCALE PERTURBATIONS: REGIONAL EFFECTS OF HURRICANE SANDY ON SALTMARSH VEGETATION AND BIRD POPULATIONS IN THE NORTHEASTERN USA

Chris S Elphick

University of Connecticut

Christopher R FIELD, University of Connecticut ; Whitney A WIEST, University of Delaware ; Maureen D CORRELL, University of Maine ; W Gregory SHRIVER, University of Delaware ; Thomas P HODGMAN, Maine Department of Inland Fisheries and Wildlife ; Brian J OLSEN, University of Maine

Coastal marshes are limited in extent, vulnerable to sea-level rise, and have undergone substantial modification by humans. Consequently, many species that use these habitats are considered to be high conservation priorities. The landfall of Hurricane Sandy on the northeastern coast of the USA in October 2012 imposed a major disturbance on coastal habitats in a region already greatly altered by humans. We investigated the effects of this disturbance on saltmarsh plant communities and the populations of five specialist saltmarsh bird species. We used an extensive data set that sampled >1500 randomly-selected points distributed from Virginia to Maine (i.e., spanning the entire portion of the US coast affected by Hurricane Sandy) in the two summers prior to the storm, and again the following year. By sampling across the entire landfall region, our study mirrors a before-after control-impact study, allowing us to assess ecological changes at sites that experienced very different storm conditions and that have been subject to diverse combinations of anthropogenic conditions (e.g., upland urbanization, introduced species, historic management, contemporary protection, etc.). Using these data, we found little evidence for widespread effects of the hurricane on either vegetation communities or focal bird populations. Nonetheless, we did find evidence that plant communities are changing in a manner consistent with an

increase in relative sea level. This shift towards wetter marsh conditions is strongly supported by a longer term data set from 55 study plots distributed across 12 marsh systems in the center of our study region. These changes in marsh conditions have serious repercussions for the population viability of saltmarsh-nesting birds that are vulnerable to tidal flooding.

GLOBAL MOUNTAIN TOPOGRAPHY AND THE FATE OF MONTANE SPECIES UNDER CLIMATE CHANGE

Paul Elsen

Princeton University

Morgan TINGLEY, University of Connecticut

Increasing evidence indicates species throughout the world are responding to climate change by shifting their geographic distributions. Although shifts can be directionally heterogeneous, they generally follow warming temperatures poleward and upslope. Montane species are of particular concern in this regard, as they are expected to face reduced available area of occupancy and increased risk of extinction with upslope movements. However, this expectation hinges on the assumption that surface area decreases monotonically as species move up mountainsides. We analyzed the elevational availability of surface area for a global dataset containing 182 of the world's mountain ranges. Sixty-eight percent of these mountain ranges had topographies in which area did not decrease monotonically with elevation. Rather, mountain range topographies exhibited four distinct area-elevation patterns: decreasing (32% of ranges), increasing (6%), a mid-elevation peak in area (39%), and a mid-elevation trough in area (23%). These findings suggest that many species, particularly those of foothills and lower montane zones, may encounter increases in available area as a result of shifting upslope due to climate change. A deeper understanding of underlying mountain topography can inform conservation priorities by revealing where shifting species stand to undergo area increases, decreases, and bottlenecks as they respond to climate change.

A PROCESS FOR SELECTING PRIORITY SPECIES FOR DIRECT CONSERVATION ACTION BY THE ZOOLOGICAL COMMUNITY.

Sandra Elvin

Association of Zoos and Aquariums

Paul BOYLE, Association of Zoos and Aquariums

The Association of Zoos and Aquariums (AZA) recently launched SAFE – Saving Animals From Extinction (SAFE), a program to advance the role of zoos and aquariums in wildlife conservation. Each year AZA-accredited zoos and aquariums invest \$160 million in wildlife conservation and serve 180 million people providing opportunities for engaging people in conservation. SAFE initiatives focus efforts on selected threatened species and providing ways for people to assist

meaningfully in conservation actions related to those species. To prioritize species for conservation investment, AZA developed a set of qualitative criteria for nominating “eligible” species. AZA members working at the taxon advisory, species management, field conservation, and other levels were involved in nominating species for AZA SAFE. Nominated species were then assessed according to a separate set of criteria called “portfolio rules” to identify species as Candidates for AZA SAFE. The portfolio rules identified an inaugural group of ten SAFE species with the greatest potential for the AZA community to contribute expertise and resources to conservation success. Success is defined in terms of increasing the sustainability of a species by applying the unique expertise of the professional zoological community to conservation in the wild in ways that yield multiple stable, or increasing, populations of the species across its natural range. Prioritizing species is a complex undertaking that requires a clear and transparent process to foster trust and establish accountability. The use of qualitative criteria allows the nomination of threatened species to proceed while incorporating a wide array of relevant information including anecdotal knowledge from husbandry practitioners and quantitative results of field scientists. The use of qualitative criteria also affords the capacity to judge nominations based on a combination of the best available science and practical, animal handling experience.

165 AN OPERATIONAL MODEL FOR IMPLEMENTING EVALUATIVE THINKING IN CONSERVATION SCIENCE AND PRACTICE

Glenda Eoyang

Human Systems Dynamics Institute

Evaluative Thinking in Conservation (ETC) proposes to address multiple challenges to the quality of conservation practice. Those challenges, deriving from the complexity of conservation systems, include: 1) Interdependencies among economic, ecological, political, and cultural systems; 2) Nonlinear causalities of vertical relationships (across scales) and horizontal relationships (across domains within the same scales); 3) Ambiguous boundaries within and among physical and social systems; and 4) Contradictory perspectives among individuals, organizations, and communities. Within this complex landscape, it may be possible to design and implement a rigorous randomized controlled trial. The question is, “What can the restricted environment of a randomized controlled trial reveal about the extraordinarily unconstrained environments of conservation practice?” Complexity science, and its applications in dynamics of human systems, offers an evaluative thinking approach that leverages interdependencies to generate insights; engages in iterative cycles of data collection, meaning making, and action;

discovers and defines patterns within and between physical and social systems; and surfaces and resolves contradictory perspectives. This approach includes two, interdependent features. Pattern Thinking integrates qualitative and quantitative models to observe and explain conservation systems and practice. Adaptive Action defines a simple, iterative, algorithmic approach to data collection, analysis, and action. Together, Pattern Thinking and Adaptive Action provide a practical and rigorous method to implement ETC. This presentation introduces these ETC practices through a case study, in which the approach was used to evaluate and inform work across scales in a global research program focused on agro-ecological intensification. Models, methods, and additional resources are provided.

BORDER ZONE EXPANSION: NEW STATE APPROACH TO REGULATE ENVIRONMENTAL CRIMES IN NON-DEMOCRATIC REGIMES

Ilya Ermolin

Russian Presidential Academy of National Economy and Public Administration (RAPNE)

Linas SVOLKINAS, Russian Sturgeon Poaching Research Laboratory (RSPRL)

International treaties meant to protect critically endangered and endangered species mainly in the developing countries of Latin America, Africa and South – Eastern Asia are not working. For this reason both developed and developing countries are trying to test newly elaborated mechanisms for sustainable bio-regulation, such as the creation of Marine Protected Areas, co-management systems and etc., suggesting on one hand to integrate the system of traditional self-governance, but on other hand to give state officials the rights for participation in management. However, in many cases this adaptation of new mechanisms failed. It turned out that rigid autocratic (vertical) management system existed in many developing countries is not conducive to the developing the communal management system. The autocratic system prevents some communal stakeholders from the involvement in the regulatory policy. What can we do in this case? Based on three years study of sturgeon poaching issues in the Caspian Sea regions of Russia, Azerbaijan and Kazakhstan, the authors propose a discussion on how to develop the self – regulatory mechanisms in the local fishing community within a set of the autocratic decision-making structure. The authors will present a seamless attempt to introduce the border guards as integrated agents for changes in the community aimed and, at the same time, the implementations of strict anti-poaching measures. On one hand, we propose a scenario where the border guards’ field of action will extend into the public domain (control over expenditure of public subsidies for the development of small-scale fisheries), so to bypass a highly corrupt political environment and to overcome the existing monopolies.

Secondly, we discuss potential socio-cultural and ethical implications for the implementation of such policy.

ANALYZING SOCIAL VALUES AND PERCEPTIONS TO BETTER ADAPT BIOLOGICAL CONSERVATION STRATEGIES IN TWO MEDITERRANEAN DELTAS

Lisa Ernoul

Tour du Valat

Angela WARDELL-JOHNSON, School of Social Sciences, University of the Sunshine Coast

Social conflict is often an important obstacle in biological conservation. Identifying environmental values and perceptions is essential for conservation managers to adapt management strategies in each site that will effectively engage local decision-makers in biodiversity conservation. This study identified and compared local populations' values and perceptions of nature in two Mediterranean deltas (Rhône delta - France and - Gediz delta - Turkey). A total of 93 interviews were conducted in the deltas using a deliberative sampling methodology. Thirteen landscape values were evaluated and the results demonstrate that while nature is valued in both deltas, there were differences in the reasons for its importance. Participants in the Rhône delta valued nature for its symbolic and social values (biodiversity:58%; aesthetic:53%; and recreation:53%). While participants in the Gediz delta also valued nature for symbolic and social values, the specific values were different (the future:51%; intrinsic:48%; and recreation:49%). The results of our study also show that the stakeholders in each site attribute responsibility for nature differently. The Gediz participants favored macro and meso scale responsibility with less importance given to the micro-scale, while participants in the Rhône delta favored cross-scale responsibility. The differences in perception and values of nature, and the perception of responsibility between the two deltas demonstrates a need to adapt conservation strategies to social context in order to increase stakeholder buy-in into conservation actions.

PARTNERSHIP AS A TOOL FOR ANDES-AMAZON CONSERVATION: A CASE STUDY FROM THE COFÁN NATION IN ECUADOR

Michael Esbach

University of Florida

Randall BORMAN, Cofán Survival Fund

Ecuador lays a crossroads. Few countries support a greater proportion of the Earth's living diversity or a richer array of human ways of life and languages. This wealth is imminently threatened by large-scale resource extraction: petroleum exploitation, lumbering, and colonization continue to expand with little control, threatening living diversity and subsistence livelihoods across Ecuador. Leading the indigenous

conservation movement in Ecuador is the Cofán Nation. One of the oldest still-intact indigenous groups in Ecuador, the Cofán Nation has occupied the forests of Northeastern Ecuador for centuries. While much of their once-vast ancestral territories have been colonized during the past forty years, partnerships between Cofán leaders and international supporters have fought to protect the still-intact areas of forests that survive. As a result of their efforts, the Cofán have successfully recovered the rights to just over 500,000 hectares of their ancestral territories, effectively linking intact natural systems from the Andes to the Amazon. Further examination of these efforts helps to elucidate a framework for community-level partnership, a critical tool in conservation planning within an indigenous context. This framework focuses on 1) building social capital, 2) accepting diverse perspectives, 3) empowering local decision-making, and 4) a long-term commitment to the partnership. By adopting such a framework in tandem with a range of biological and social science methods, practitioners can improve local capacity, decision-making, and governance in ways that are directly linked conservation.

MEGAFUNA AND PURSE SEINE FISHERIES: INTERACTIONS AND SURVIVAL OF THE WHALE SHARK, THE WORLD'S LARGEST FISH

Lauriane Escalle

Université de Montpellier[INSTITUTE]Institut de Recherche pour le Développement

Anna CAPIETTO, Université de Montpellier[INSTITUTE]Institut de Recherche pour le Développement ; Pierre CHAVANCE, Institut de Recherche pour le Développement ; Laurent DUBROCA, Institut de Recherche pour le Développement ; Alicia DELGADO DE MOLINA, Instituto Español de Oceanografía ; Hilario MURUA, AZTI Tecnalia ; Justin Monin AMANDE, Centre de Recherches Océanologiques ; Daniel GAERTNER, Institut de Recherche pour le Développement ; John David FILMALTER, Institut de Recherche pour le Développement[INSTITUTE]South African Institute for Aquatic Biodiversity ; Fabien FORGET, Institut de Recherche pour le Développement[INSTITUTE]South African Institute for Aquatic Biodiversity ; David ROWAT, Marine Conservation Society ; Laurent DAGORN, Institut de Recherche pour le Développement ; Bastien MERIGOT, Université de Montpellier

The expansion of human activities is endangering megafauna in both terrestrial and marine ecosystems. Large marine vertebrates are often vulnerable and emblematic species, with many of their populations considered to be declining, primarily due to fisheries activities. In the open ocean, certain fisheries improve their efficiency of detecting tuna schools at the surface by locating and fishing close to some macro-organisms, such as whale sharks or marine mammals. While the whale shark, the world largest fish, is particularly vulnerable to

impacts and referenced by the IUCN and the CITES, collecting accurate data on the accidental capture and mortality of these organisms is a complex process. We analyzed a large database of logbooks from 65 industrial vessels with and without scientific observers on board (487 272 and 16 096 fishing sets since 1980 and 1995 respectively) in both the eastern Atlantic and western Indian Oceans. Distribution maps of Sightings Per Unit of Effort highlights major hotspots of interactions between the fishery and whale sharks in the oceanic near-shore area from Gabon to Angola in the Atlantic from April to September, and in the Mozambique Channel in the Indian Ocean between April and May. The incidence of apparent whale shark mortality due to fishery interaction is extremely low (two of the 145 whale sharks encircled by the net died, i.e.1.38%). To confirm this result on a longer term, post-release survival was investigated through satellite tagging of whale sharks encircled in purse seine nets. First assessments of post-release survival were performed on five whale sharks equipped with pop-up archival tags, with all tagged whale sharks surviving at least 21 days after encirclement. However, obtaining accurate estimations of the post-release survival of whale shark encircled by purse seine nets requires the deployment of further tags on accidentally encircled individuals, which may help define precise conservation management measures.

EFFECT OF CLEARCUTTING OPERATIONS ON THE SURVIVAL RATE OF A SMALL MAMMAL

Martin A. H. Escobar

Departamento de Ciencias Ambientales y Recursos Naturales Renovables, Universidad de Chile [INSTITUTE] Laboratorio de Ecología de Vida Silvestre, Universidad de Chile

Sandra V. URIBE, Laboratorio de Ecología de Vida Silvestre, Universidad de Chile ; Chiappe ROMINA, Laboratorio de Ecología de Vida Silvestre, Universidad de Chile ; Cristian F. ESTADES, Laboratorio de Ecología de Vida Silvestre, Universidad de Chile

Clearcutting is a common timber harvesting technique that represents a significant and abrupt change in habitat conditions for wildlife living in industrial forests. Most research on this type of impact has focussed on comparing populations or communities in mature forests/plantations and the resulting clearcut stands. However, this approach does not separate the effect of changes in habitat attributes from direct mortality produced by the intensive use of heavy machinery required for cutting down trees and dragging them to a road. Because knowing the fate of individuals after a disturbance is important for modelling landscape-scale population dynamics in industrial forests, we conducted a study in South-Central Chile to understand the short-term response to clearcutting operations of the long-haired Akodont (*Abrothrix longipillis*), a forest specialist mouse. Between

2009 and 2013 we radiotracked a total of 51 adult male Akodonts, before, during and after the clearcutting of the pine plantations in which they lived. A minimum of 52.4% of the individuals died as a direct cause of the timbering operations, being crushed by vehicles or logs during logging operations. Our observations suggest that, instead of fleeing the area, the response of long-haired Akodonts to the approaching machinery is to hide under the forest litter or in burrows, which exposes them to a serious risk of death. The real mortality rate associated to clearcutting may be higher than that estimated by us because of some methodological biases (i.e. individuals with crushed radiotransmitters not recorded) and the fact that additional mortality sources may affect the population in the weeks following logging operations (e.g. higher exposure to predation, effects of site preparation for the new plantation, etc).

USE THE SPOTLIGHTING FOR MONITORING ENDANGERED CHILEAN CHINCHILLA

Martin A. H. Escobar

Departamento de Ciencias Ambientales y Recursos Naturales Renovables, Universidad de Chile

Tahia A. RANNOU, Departamento de Ciencias Ambientales y Recursos Naturales Renovables, Universidad de Chile ; Jorge A. ABARCA, Departamento de Ciencias Ambientales y Recursos Naturales Renovables, Universidad de Chile ; Dario A. A. DE LA FUENTE, Departamento de Ciencias Ambientales y Recursos Naturales Renovables, Universidad de Chile ; Juan J. T. DE RAMÓN, Departamento de Ciencias Ambientales y Recursos Naturales Renovables, Universidad de Chile

The Chilean chinchilla (*Chinchilla laniger*) is a "Critically Endangered" (IUCN) rodent species, endemic to Chile. The strong decline of populations of the Chilean chinchilla was due to overhunting for its fur. In 1929, local authorities prohibited their capture, but the species was believed extinct in the wild. In 1975, the Chilean chinchilla was rediscovered. Currently, chinchillas are still facing major threats due to anthropogenic land use (e.g. livestock, mining), which threaten wild populations and their habitats. Despite the species lives in colonies formed by few to hundreds individuals, there is a high level of uncertainty about its population status. This lack of knowledge of chinchilla populations is mainly due to its nocturnal behavior and the negative effects of trapping on its survival. To address the urgent need for new sampling techniques which allow estimates of population abundance, we used "spotlighting" to estimate the relative abundance of five colonies of the Chilean chinchilla in Auco, north-central Chile. To evaluate each colony, we spotlighted along a 400 m transect located at the center of each site. In the same night, two passes were done on each transect, where all observed individuals were recorded. All evaluations were done one hour after sunset until 02:00 am. We recorded chinchillas at

all sites (from 1 to 6 individuals). The number of chinchillas recorded was significantly higher in the first pass than in the second ($W = 38$; $p = 0.04$). Most individuals were sighted upslope and perpendicular to transects, but these trends were not significant ($p > 0.5$). Our investigation suggests that 'spotlighting' can be an effective technique to study colonies of the Chilean chinchilla. This non-invasive technique can help improve our knowledge on the Chilean chinchilla and allow stakeholders better plan for the conservation of this critically endangered species.

THE CHECKLIST AND ABUNDANCES OF SMALL MAMMALS IN IDU, AKWA IBOM STATE, NIGERIA.

Imeh Esenowo

University of Uyo

Akaniyene AKPAN, University of Uyo ; Edwin EGWALI, University of Uyo ; Solomon JAMES, University of Uyo

A study of the abundances of small mammals was conducted in Idu, Uruan L.G.A of Akwa Ibom State Nigeria from April to December 2013. Indirect and direct methods for the observation of small mammals were employed in the area under study. A total of 36 individuals, consisting of 3 Orders (Rodentia, Carnivora and Pholidota) and 7 families of small mammals were encountered. The most abundant was *Thryonomys swinderianus* with a percentage of 63.88 followed by *Rattus rattus* 16.66, *Cricetomys gambianus* 8.33 while *Crossarchus obscurus*, *Atherurus africanus*, *Xerus erythropus* and *Manis tricuspis* accounted for 2.77 respectively. The *Thryonomys swinderianus* had the highest body mass of 3.9kg while, *Manis tricuspis* has the highest body length of 79.9cm.. The abundance and diversity index of small mammal encountered were low and this may be attributed to deforestation, habitat loss, hunting and other anthropogenic activities in the study area. There is therefore a great need for conservation and management practices to protect these vulnerable mammals and their habitats.

133: THE EXPERIENCE OF ETHIOPIAN ORTHODOX CHURCH IN CONSERVING FOREST AND OTHER BIO RESOURCES

Alemayehu Wassie Eshete

Bahirdar University

The Ethiopian Orthodox Tewahido Church (EOTC) has a long history of conserving forests which usually surround the churches. Although the main purpose of the churches is to serve as places for worship, burials, and religious festivals, they also provide secured habitats for plants and animals and green spaces for people. In the northern highlands of Ethiopia, patchy remnants of old-aged Afromontane forests can be found mainly around the EOT churches. When a traveler encounters a

patch of indigenous old-aged trees in the northern highlands of Ethiopia, he/she can be sure that there is an Orthodox Church in the middle. The local people refer to these churches with the surrounding trees as "debr" or "geddam" and consider them the most holy of all places. Their survival is the result of a patriotic conservation tradition of the EOTC which has strong biblical justification and theological thinking, but their survival is currently challenged by ecological and social concerns. Pilot studies suggest that these church forests might be relics of ancient forest ecosystems and hotspots of biodiversity for indigenous species that could be prioritized for combined in-situ conservation and maintenance of prestigious religious sites.

IMPACTS OF GRAZING MANAGEMENT UPON AFROALPINE VEGETATION AND PREY AVAILABILITY FOR ETHIOPIAN WOLVES

Girma Eshete

Institute of Environmental sciences, Leiden University
Jorgelina MARINO, Wildlife Conservation Research Unit,
Zoology Department, Oxford University

Abstract Human and livestock population growth is the main reason for ecosystem degradation in tropical mountains. The Ethiopian Afroalpine ecosystem and its numerous endemic rodents are threatened by livestock grazing in natural pastures, with potential impacts across the food web. This case study consider an Afroalpine area where five years ago the local communities implemented the area closure management to a portion of the range, to rehabilitate and maintaining biodiversity and ecosystem functions. Ecological data was recorded inside and outside the exclusion zone in 46 circular sample plots to study the effect of grazing on vegetation and on abundance of rodent prey for the Ethiopian wolf (*Canis simensis*), the most endangered canid of the world. There was a significant difference ($P=0.0038$) in vegetation cover but not ($P>0.05$) in vegetation height between protected and unprotected land uses, and rodent hole counts were highest in the protected area ($P=0.0006$), while rodents showed preference for medium height vegetation ($P=0.0230$) and areas with high vegetation cover ($P=0.0037$) and flat areas and moderate slopes (0.0126). Understanding the factors impacting an Afroalpine ecosystem has importance in conserving the rare and endemic biological associations of the area plus to encourage the local management strategies sustainably. Excluding livestock from Afroalpine habitats over five years have measurable impact on vegetation, favoring higher cover and more rodents. This case study is an important contribution in favor of habitat restoration as a management tool for the protection of Afroalpine areas under intense human pressure.

SYMPOSIUM 27: OVERVIEW OF BIODIVERSITY CONSERVATION RESEARCH IN MEDITERRANEAN-TYPE ECOSYSTEMS OF THE WORLD

Karen J Esler

Department of Conservation and Entomology, Stellenbosch University, Private Bag X1, Matieland, 7602

Jasper Alexander SLINGSBY, Fynbos Node, South African Environmental Observation Network, Private Bag X7, Rhodes Drive, Claremont 7735, and Centre for Statistics in Ecology, Environment and Conservation, Department of Biological Sciences, University of Cape Town, Rondebosch 7700 ; Nicky ALLSOPP, Fynbos Node, South African Environmental Observation Network, Private Bag X7, Rhodes Drive, Claremont 7735 ; Lluís BROTONS, CEMFOR - CTFC, InForest Joint Research Unit, CSIC-CTFC-CREAF, 25280 ; Grant WARDELL-JOHNSON, School of Science, Curtin University, GPO Box U1987, 6845, WA ; Danilo RUSSO, Wildlife Research Unit, Laboratorio di Ecologia Applicata, Dipartimento di Agraria, Università degli Studi di Napoli Federico II, via Università, 100, 80055 Portici

All five Mediterranean-Type Ecosystems (MTE) are global biodiversity hotspots, with exceptionally high densities of endemic species. These regions face disproportionately high conservation threats with only 4.3% of the total land area encompassed within protected areas. Their favourable climates and abundant resources render them highly desirable for human habitation, and all are now highly populated. This has led to the transformation of natural ecosystems to other land cover types, high levels of resource extraction, altered fire regimes, the introduction of useful and damaging species that invade and degrade ecosystems, and water extraction impacts on the ecological integrity of freshwater systems. This confluence of circumstances has stimulated MTE researchers to be world-leaders in conservation and environmental research. We present a global overview of academic literature and pivotal events stimulating conservation research in MTEs both globally and regionally. Our understanding of how best to conserve and manage MTEs has evolved rapidly over the past few decades and reflects the variability in the human-environment history and environmental changes affecting the different regions. This overview serves to highlight the advent of new conservation research tools and theory, and the initiatives that led to their discovery and development.

SHORT-TERM RESPONSE OF WILDLIFE TO CLEAR-CUTTING OF PINE PLANTATIONS IN CENTRAL CHILE

Cristian Estades

Universidad de Chile

Sandra URIBE, Universidad de Chile

Despite their clear differences with natural forests, exotic pine plantations in Chile can be habitat for several wildlife

species, and there is growing evidence that these artificial forests may play an important role in the conservation of many species at the landscape level. However, during clearcutting, habitat conditions change drastically for most species, likely causing the death or dispersal of many individuals. Besides, through the forced dispersal of wildlife it is expected that the remaining uncut vegetation (e.g. native forests) will receive potentially large numbers of immigrants, eventually causing the overcrowding of the local populations. During the past three years we have been studying the response of different wildlife species to clearcutting in pine plantations in seven sites in Central Chile. At each site we studied birds (point counts and mistnetting), small mammals (live trapping, radio-tracking) and carnivores (camera trapping), both in the native forest and adjacent pine plantations, before and after clearcutting. Two sites were not harvested and used as controls. Our results showed important changes in the abundance of most species in the plantations after harvest. However, we found little evidence for movements of evicted individuals from the plantations to native forests, which agrees with our failure to detect any significant overcrowding of wildlife in the uncut forests. Some potential explanations for this pattern include high mortality of some species during harvesting (telemetry data showed > 52% mortality of *Abrothrix longipillis* due to crushing by logging machinery) and site tenacity in some bird species (e.g. *Elaenia albiceps*). Finally, because clearcuts represented only 30-40% of the area of the studied landscapes (normal for the region), most individuals forced to disperse might have found suitable places where to settle without causing significant increases in density. (Fondecyt 1120314).

USING REMOTE SENSING TO INVESTIGATE PATTERNS AND DRIVERS OF VEGETATION CHANGE IN THE SERENGETI ECOSYSTEM FROM 1984 TO 2011

Anna Bond Estes

Pennsylvania State University

Avi Bar MASSADA, University of Haifa ; Tobias KUEMMERLE, Humboldt University Berlin ; Herman H. SHUGART, University of Virginia ; Volker C. RADELOFF, University of Wisconsin - Madison

Managing ecosystems for biodiversity conservation requires understanding the processes that shape them at multiple scales. Remotely-sensed data allow analysis of ecosystem changes over long periods of time and across broad spatial scales. This can help contextualize smaller-scale changes that are observable in the field, and upon which conservation decisions are often based. The Serengeti ecosystem in Tanzania is an area of global biodiversity importance, and changes in woody vegetation cover have long been a concern to managers and conservationists. We used time series of Landsat imagery to analyze long-term vegetation change in the Serengeti at a spatially-continuous landscape scale. We identified shifts between woodland and grassland in three

periods between 1984 and 2011 and compared these to known drivers of change in savanna ecosystems, namely elephant numbers and fire frequencies derived from the MODIS burned area product. We found frequent, small-scale increases and decreases in woody vegetation cover occurring simultaneously in all time periods, with over half of the woodlands and grasslands transitioning between states at least once between 1984 and 2011. But despite these small-scale, highly-dynamic vegetation changes, the magnitude of change aggregated over the entire ecosystem was relatively minor. At the ecosystem scale, we observed an increase in woody cover between 1984 and 1995 and consistent but moderate declines in woodland extent thereafter, from 62.5% in 1995 to 57.5% in 2011. While these changes coincide with changes in elephant numbers, our results suggest that fire frequency played a larger role in woodland declines in Serengeti than currently assumed. Some areas experienced as many as 20 fires in 10 years, and areas showing declines in woodland in the past decade had a higher mean number of fires. This indicates that management interventions to control woody vegetation loss could be targeted at reducing the number of human-caused fires.

IN THE SEARCH OF GOOD BIODIVERSITY SURROGATES: RAPTORS POOR INDICATORS IN THE BAJA CALIFORNIA PENINSULA DESERT?

Christian Estrada

CIBNOR

Ricardo RODRÍGUEZ-ESTRELLA, CIBNOR

Predators have been considered as good surrogates of biodiversity, raptors in particular, have been proposed and used as biodiversity surrogates. Assumption based on the general idea of concordance between two taxonomic groups that show a similar spatial/temporal structure, the aim is using one of the groups as a surrogate of the other. If a surrogate can be identified, then theoretical inferences can be made and conservation strategies can be established about the other. We evaluated the effect of spatial and environmental variability on the degree of assemblage concordance between top-order predators (i.e., raptors), as the surrogate group, and vascular plants, reptiles, birds and mammals, as target groups in order to measure the degree of relationship between the composition patterns. We also examined the potential causes of assemblage concordance and the degree to which the surrogate assemblage can predict the target groups in the southern Baja California peninsula. Data for the four biological assemblages collected from an array of sampling points throughout Baja California Sur were used for these analyses. Levels of assemblage concordance varied in all cross-taxon comparisons. We discuss the main mechanisms that better explain the patterns of assemblage concordance observed. We used Mantel tests to evaluate the level of community concordance and co-correspondence analysis to evaluate

how well one taxonomic group predicts the structure of other communities. We found that the concordance between raptors and birds is due to their similar responses to environmental gradients, whereas other patterns of assemblage concordance are more likely derived from interactions between groups. However, predictability was low and no particular taxonomic group significantly predicted all the other groups. The low and variable levels of assemblage concordance suggest that raptors are not good biodiversity surrogates in this desert ecosystem.

SYMPOSIUM 177 - TEACHING BIODIVERSITY CONSERVATION THROUGH COMPANION MODELLING: AN ORIGINAL WAY TO TACKLE SOCIAL AND ECOLOGICAL DYNAMICS

Michel Etienne

INRA

Companion modelling (ComMod) is an approach based on the use of models as tools to facilitate the understanding of multi-functionality, and adaptive management of socio-ecological systems. It uses multi-agent models and role-playing games as mediation tools stimulating the implementation of new ways to build and share information. Emphasis has been recently placed on using the approach as an educational tool to increase awareness of the interactions between stakeholders and resources, to experience mediation processes among users of the same land, and to simulate decision-making in the implementation of a concerted land management plan. The target of the educational programme was to adapt role-playing games used in real ComMod processes to make agronomy, anthropology, ecology, forestry, geography or landscape planning students understand the complexity of the interactions between agricultural activities, landscape dynamics and biodiversity management. The training course is based on the alternance of lectures, computer based exercises and interactive workshops. According to the duration of the course, the students go more or less deeply through the main steps of the companion modelling approach. First, they try to understand the complexity of the socio-ecological system by representing it in the form of a conceptual model describing the interactions between stakeholders and resources on a given territory. Then, they play the role of the main stakeholders in the system by living from inside the interactions with the other stakeholders and bearing the consequences of their decisions on the environment. Lastly, according to what they experienced during the role-playing game, they propose alternatives of management to improve the current situation, according to a set of available techniques. Examples are given on biodiversity conservation in Mediterranean forests (SylvoPast), limestone plateaus (MejanJeuBiodiv) and oceanic islands (MottePiquet).

ELEPHANTS ON THE EDGE: AN EXAMINATION OF ELEPHANT FENCE-BREAKING BEHAVIOUR

Lauren Evans

University of Cambridge

Human-elephant conflict, in particularly the problem of crop-raiding, is a complex and intractable problem in rural Africa that occurs wherever people and elephants share space. As elephant range decreases and human population and cultivation increases, the hard boundary along the human-elephant interface is lengthening. This, coupled with persistent political and media attention, is creating a growing culture of intolerance towards elephants. Electrified fences, constructed along the hard boundaries that separate elephant range from cultivation, are increasingly viewed as a panacea. By compartmentalizing landscapes into a place where elephants are tolerated from a place where they are not, fences offer a simple, and technical solution to a complex problem. However fences frequently fail in their objectives, as elephants adapt to break them and to due to the considerable institutional and financial capital required to maintain them. Yet little is known about how, where and why elephants break fences. Drawing on research from Laikipia County Kenya, this presentation challenges three assumptions concerning the nature and drivers of elephant fence-breaking behaviour: 1. Elephants will break any fence once they have learn that the electric shock won't kill them 2. Fence-breaking behaviour is unpredictable 3. Individual 'problem elephants' are responsible for fence-breaking The presentation also discusses why fences vary as barriers to elephant movement. This examination of elephant fence-breaking behaviour sheds new light on our understanding of the bull elephant socio-ecology and individuality and on the constantly shifting and evolving challenge of mitigating HEC.

122: IS NO NET LOSS POSSIBLE? EVALUATING POLICY INSTRUMENTS FOR REDUCING DEFORESTATION WITH A GROWING ECONOMY

Megan Evans

Australian National University

Grace CHIU, CSIRO Digital Productivity Flagship ; Andrew MACINTOSH, Australian National University ; Philip GIBBONS, Australian National University

Deforestation is a major driver of biodiversity loss and environmental degradation worldwide. International and national efforts to combat deforestation have taken a number of forms, ranging from policies which restrict forest clearing, to broader commitments to achieve 'no net loss' of vegetation. However, the efficacy of such policies is rarely evaluated. Data limitations and methodological challenges can impede the evaluation of policy impact in the presence of confounding

variables, time-lags and misalignment of spatial and temporal data. Such challenges in evaluation must be overcome to ensure policy effectiveness and the delivery of environmental benefits. We combine satellite imagery of forest loss, along with information on key macroeconomic and climatic variables within a novel statistical framework, to evaluate the impact of successive policies aimed at reducing deforestation in Australia. A wealthy nation with strong governance and high institutional capacity, Australia has introduced at least fifteen sub-national policies to combat deforestation since the 1980's, in addition to an overarching national goal to reverse deforestation by 2020. Despite these efforts, little is known of what effect these policies have had on the rate of forest loss over time. We analyze the change in forest cover across Australia between 1972 and 2012, and model trends in deforestation using a spatially explicit bent-cable regression framework. The bent-cable model provides a more realistic and flexible representation of system changes than traditional regression methods, and has a greater capacity to detect the impact of a policy intervention on the response of interest. We find that the introduction of policies generally had a limited effect on the rate of forest loss, while terms of trade, rainfall and amount of forest remaining had an overall greater influence. Our study provides much needed insight into how societal and environmental goals can effectively be balanced.

SYMPOSIUM 159: MAKING THE RIGHT CHOICES IN REWILDING HUMAN-DOMINATED LANDSCAPES

John Ewen

Zoological Society of London

Alienor CHAUVENET, University of Queensland ; Stefano CANESSA, Zoological Society of London

Reintroductions and other conservation translocations are an important but often controversial form of wildlife management. Whilst the benefits may appear clear (for example the successful reestablishment of a lost species, ecosystem function or human wellbeing) there are also a range of costs that should be considered (for example human-wildlife conflict, co-introduction of novel pathogens that can affect other wild species, agriculture or humans). The concept of rewilding within human dominated landscapes exemplifies tradeoffs between these costs and benefits, highlighting that reintroductions influence a wide range of stakeholders with potentially very different values. From a management perspective, rewilding through translocations are fundamentally sequences of decisions. How then do we approach these and make the best choices? We argue that the adoption of a more structured approach to translocation decisions can help do this. By using a range of decision analysis tools encompassed by structured decision making we can ensure translocations aimed at restoring or increasing the 'wildness' of human dominated landscapes are achieved in

such a way that the values of diverse human groups in this landscape are respected. Here we will introduce the key components of these decision tools and show how rational decisions can be made in the face of competing values.

MAPPING BUSHMEAT HUNTING SUSTAINABILITY AND HUMAN NUTRITION IN CENTRAL AFRICA

John Fa

Imperial College London

Jesus OLIVERO, Universidad de Malaga ; Raimundo REAL, Universidad de Malaga ; Miguel Angel FARFAN, Universidad de Malaga ; Ana Luz MARQUEZ, Universidad de Malaga ; Juan Mario VARGAS, Universidad de Malaga ; Robert NASI, CGIAR, Center for International Forestry Research

Wild animals are a primary source of protein (bushmeat) for tropical forest inhabitants worldwide. The impact of bushmeat harvests on wildlife populations is ideally monitored from estimates of offtake and size of prey populations. However, these data are difficult and expensive to obtain at large geographical scales. Here, we employed biogeographical modelling techniques, using favourability function models, to map species richness and vulnerable areas of all hunted mammals in central Africa. Based on a number of ecological traits, we first develop an index - the Potential Hunting Sustainability (PHS) - to assess the vulnerability to overhunting of each species. We use favourability values derived for all species pooled, and their PHS values, to identify weak spots, high diversity regions of high hunting vulnerability for wildlife, as well as strong spots, or high diversity areas of species with low hunting sustainability. Using these maps, and maps of the distribution of available standing biomass of hunted mammals and the inferred levels of bushmeat extraction, we then suggest that these new analyses can allow us to advance our understanding of the threat of overexploitation of wildlife in tropical forest regions.

EFFECTS OF UNPREDICTABILITY OF HABITAT MANAGEMENT TO THE CONSERVATION OF EARLY-SUCCESSION SPECIES

Henna Fabritius

University of Helsinki

Otso OVASKAINEN, University of Helsinki ; Mar CABEZA, University of Helsinki

A key challenge in the conservation of early-succession habitats is the need of their constant regeneration due to fast successional dynamics and overgrowth. Apart from schemes for maintaining traditional agricultural habitats, few institutional structures have been developed in the European Union that enable long-term commitment to the maintenance of specific early-succession habitat types. We studied the institutional setup of the conservation of

an endangered butterfly, the false heath fritillary (*Melitaea diamina*) in Finland. The false heath fritillary is a specialist species of wet *Valeriana sambucifolia* meadows and has been listed as a species of special conservation concern in Finland, which obligates regional environmental agencies to maintain a favorable conservation status for the species, but does not guarantee long-term resourcing for maintenance activities. The institutional study revealed a complex and uncoordinated structure of management resource allocation for this species, including small maintenance funds granted by several independent sources depending on the ownership category of habitat sites. Additionally, the study revealed high annual variation of resource availability at the regional environmental agencies, which complicated the execution of long-term habitat maintenance plans. We tested the consequences of a corresponding, high annual variation of resources and short-term decision-making by developing a dynamic metapopulation model based on false heath fritillary field data and studying false heath fritillary metapopulation viability under alternative scenarios of resource allocation and decision-making. Our results indicate that unpredictable, short-term provision of habitat maintenance resources can result in lower population sizes and higher extinction probabilities and thus impair the effectiveness of conservation for endangered early-succession species.

IMPACT OF HERDERS' HARVESTS OF FODDER PLANTS IN YANKARI GAME RESERVE, NIGERIA: PATTERNS AND EXTENT

Salamatu J. Fada

University of Jos, [INSTITUTE]Bangor University

James. M GIBBONS, Bangor universty ; Andrew. S PULLIN, Bangor University

Understanding the social drivers of resource use is of key importance in conservation and environmental management. We surveyed six tree and shrub species (*Azelia africana*, *Pterocarpus erinaceus*, *Strychnos spinosa*, *Balanites aegyptiaca*, *Khaya senegalensis* and *Tamarandus* = FTS) to determine trends in abundance and to identify any significant social drivers of change. These species are multi-use trees used widely in tropical Africa, heavily harvested in tropical Africa for a variety of uses and their populations are threatened in their natural environment. *Azelia africana* and *Khaya senegalensis* are currently classified as endangered by the IUCN Red List. Our surveys showed high rates of decline in these species of FTS. Previous research based on remote sensing data indicates human activities in the Reserve to be most prevalent within 5km of the Reserve boundary. We therefore investigated the degree to which observed changes in FTS may be being driven by herders' activities. We used a non-random cluster method to sample 82, 100x100m² plots, and recorded FTS abundance, diameter at breast height, plant height, harvest

rates and canopy cover. We also used visual estimates to record fire impacts on the plants. We found *Azelia africana* to be the dominant, and most disturbed, species of the Reserve. Using a regression model, we found no relationship between distance (km) from the Reserve boundary and harvest rate (%). In addition, we fitted Poisson regressions of the generalised linear model and found no relationship between distance from the Reserve boundary and the seedlings, saplings and adults of the FTS. We suggest that *Azelia africana* is the most heavily harvested FTS with weighted average harvest rates of 61-75% indicating severe harvest. Our findings suggest further research is needed to understand anthropogenic threats to FTS and predict how FTS may fare in the future.

HUMAN-BIRD CONFLICTS ARISING FROM CONSERVATION EFFORTS IN THE AMURUM FOREST RESERVE, JOS NIGERIA

Elizabeth Fadipe

A. P. Leventis Ornithological Research Institute
Mary MOLOKWU, Fauna & Flora International

Human-wildlife conflict (HWC) may occur due to increasing wildlife population resulting from successful conservation efforts. However, continued community support is essential for long-term conservation success. In the Amurum Forest Reserve (AFR), north-central Nigeria, created specifically for the conservation of birds, potential conflicts arising from crop damage by birds could lead to loss of the long existing community support. It is against this backdrop that this 12-month study was conducted in three villages around AFR to explore the socio-economic impact of and potential solutions to farmer-bird conflicts. Approach included: 1) social interviews; 2) experimental investigation of economic loss - construction of enclosures on a portion of the farm to prevent entry by birds and comparing yield between enclosed and exposed plots and 3) observation of farm bird activities to identify problem species. Over 90% of farmers interviewed were positive about the creation of the reserve and two-thirds were in support of conservation. However, 60% of respondents attributed crop damage to birds and linked it to conservation efforts in the AFR. All traditional methods employed to reduce bird damage on farms seemed unsuccessful except for the use of an owl model applied by only one farmer. The most frequent activity carried out by birds was foraging and the most consumed crop was *Acha Digitaria exilis*. Problem species identified through focal observations corroborated interview data. Crop yield in the enclosed farm plot was twice the yield in the exposed plot. Effective conservation of wildlife in the Amurum Forest stands the risk of being hindered by conflicts between farmers and birds if not properly addressed. Use of an avian predator model may be the most effective short-term means of controlling crop depredation by birds. However, an understanding of the ecology of bird pests may provide useful

information for developing appropriate long-term mitigation strategies.

COMMERCIAL ECOSYSTEM SERVICES: PLANTATION FOREST CONTRIBUTIONS TO US CARBON SEQUESTRATION

Matthew E. Fagan

NASA Goddard Space Flight Center
Doug C. MORTON, NASA Goddard Space Flight Center ; Bruce D. COOK, NASA Goddard Space Flight Center ; Jeff G. MASEK, NASA Goddard Space Flight Center ; Feng ZHAO, University of Maryland, College Park ; Chengquan HUANG, University of Maryland, College Park ; Hans-E. ANDERSEN, USDA Forest Service, Pacific Northwest Research Station ; Ross F. NELSON, NASA Goddard Space Flight Center

Quantifying and increasing the provision of ecosystem services from agricultural lands is a major goal of conservation biology. The southeastern U.S. is one of the most productive regions in the world for wood pulp and logs, based on large-scale management of pine plantations. Time series of satellite imagery offer a detailed account of forest loss and gain, but the potential contribution of plantation management in the southeast US to the US forest carbon sink has not been quantified. In this study, we used nearly 3,000 km of airborne remote sensing transects from Goddard's Lidar, Hyperspectral, and Thermal Airborne Imager (G-LiHT) to link Landsat-based estimates of forest cover change to height growth and carbon accumulation in plantation forests. Carbon accumulation in plantation forests was estimated using two methods—yield tables and lidar-biomass relationships derived from field measurements in the USFS Forest Inventory & Analysis Program. Scenarios of carbon accumulation were developed using plantation area and age information, derived from Landsat data using the Vegetation Change Tracker (VCT) algorithm. The ability to combine high-resolution (1 m) information from airborne lidar and long time series of Landsat imagery provided unique constraints on the height structure and spatial extent of plantation forests. Our results also highlighted the potential to further increase the carbon storage benefits of plantation forests through longer rotation ages to favor wood over pulp production. By estimating the current contribution of large-scale forest management in the southeastern U.S. to carbon sequestration, this study bounds the potential of additional regional reforestation to ameliorate climate change.

TARGETED REFORESTATION TO COMBAT DECLINES IN CONNECTIVITY FOR UNDERSTORY BIRDS IN A TROPICAL HABITAT CORRIDOR

Matthew Easton Fagan

NASA Goddard Space Flight Center

Ruth S. DEFRIES, *Columbia University*; Steven E. SESNIE, *USFWS*; Juan P. ARROYO MORA, *McGill University*; Robin L. CHAZDON, *University of Connecticut*

Re-establishing connectivity between protected areas isolated by habitat clearing is a key conservation goal in the humid tropics. In northeastern Costa Rica, payments for environmental services (PES) and a government deforestation ban have subsidized forest protection and reforestation in the San Juan-La Selva Biological Corridor (SLJSBC), resulting in a decline in mature forest loss and the expansion of tree plantations. We used field studies and graph models to assess how conservation efforts have altered functional connectivity over the past 25 years for four species of insectivorous understory birds. Field playback studies assessed how reforestation habitat quality affected the willingness of *Myrmeciza exsul*, *Henicorhina leucosticte*, *Thamnophilus atrinucha*, and *Glyphorhynchus spirurus* to travel outside forest habitat for territorial defense. *G. spirurus* travel was related to tree density and was high in native and non-native tree plantations. In the other species, matrix travel distances increased with understory density; open tree plantations were comparable to pastures. We modeled landscape connectivity using graph models that varied possible travel distances in tree plantations, gallery forests, and pastures. From 1986 to 2011, connectivity for all species declined in the SLJSBC landscape (5825 km²) by 14 to 21% despite only a 4.9% net loss in forest area and the expansion of tree plantations over 2% of the landscape. Plantation placement in the landscape limited their potential facilitation of connectivity. By mapping current connectivity bottlenecks and priority areas for future reforestation, we estimated that spatial prioritization could nearly double the benefits of reforestation efforts (i.e., a 1.8% improvement in connectivity for each 1% gain in forest cover). Our results indicated key locations where spatial targeting of PES within the SLJSBC would protect existing forest connectivity and enhance the connectivity benefits of reforestation.

DEMONSTRATING ECOSYSTEM SERVICE VALUES IN AFRICA: THE EXAMPLE OF DRIEFONTEIN GRASSLANDS IMPORTANT BIRD AREA, ZIMBABWE.

Togarasei Fakarayi

BirdLife Zimbabwe

Ken MWATHE, *BirdLife International*; Olivia ODHIAMBO, *BirdLife International*

Ecosystems play a major role in meeting the basic needs of the poor. The value of ecosystem services, the goods and services or benefits that humans derive from ecosystems is rarely quantified. However since the Millennium Ecosystem Assessment 2005, some efforts have gone towards quantifying and attaching a value to ecosystem services. BirdLife Zimbabwe has applied a Toolkit for Ecosystem Services Site-based

Assessment (TESSA) in Driefontein Grasslands Important Bird Area, Zimbabwe. The Driefontein Grasslands provides essential ecosystem services supporting a diverse of human livelihoods and biodiversity. However, there was a gap in knowledge on the value of ecosystem services in sustaining life. Using TESSA, three ecosystem services namely cultivated goods, harvested wild goods, and water services were assessed. The assessment was conducted at two sites, site in its current state (well managed) and alternative state (poorly managed) site. This study showed that benefits from ecosystem services in a well managed site are higher than those in a poorly managed site. For instance, contribution of ecosystem services were valued at about US\$1,364 and US\$4,631 per hectare per year for maize and beans crops respectively in a current state, while for the alternative site contribution of ecosystem services were valued at about US\$285 and US\$2,923 for maize and beans respectively. Economic values of harvested wild goods followed similar trend, showing a total net economic provisioning services was high in a current state site as compared to alternative state. Our study value US\$181 per household per year in a current state site and US\$129 in an alternative state site. Water generated useful knowledge on ecosystem services which has been instrumental in promoting active stakeholder participation and policy influence towards biodiversity conservation at site and national levels.

EVALUATION OF POTENTIAL PUAIOHI MANAGEMENT ACTIVITIES VIA POPULATION VIABILITY ANALYSIS

Jean Fantle-Lepczyk

Universtiy of Hawaii at Manoa

Andrew TAYLOR, *Universtiy of Hawaii at Manoa*; David DUFFY, *Universtiy of Hawaii at Manoa*; Lisa CRAMPTON, *Kauai Forest Birds Recovery Project, Hawaii Division of Forestry and Wildlife*; Sheila CONANT, *Universtiy of Hawaii at Manoa*

The Hawaiian Islands house a unique avian assemblage comprised of some of the rarest bird species in the world. Unfortunately, many of these species are highly endangered or have gone extinct. Despite numerous and potentially increasing threats and great effort aimed at saving endemic birds, we lack some of the basic science necessary for understanding species of concern. For instance, population models and population viability analyses (PVA) have not been conducted for 66% of Hawaii's endangered avifauna, which represents a critical gap in knowledge. One species lacking any PVA is the critically endangered (IUCN) Puaiohi (*Myadestes palmeri*), a historically rare songbird endemic to the island of Kauai and the only remaining native thrush on the island. At present, 75% of the Puaiohi's breeding population of about 500 birds occurs in just 10 km² of the Alakai Wilderness Preserve. To develop Puaiohi models, we collected demographic data from 2007-2012, and supplemented with

data from published sources. Using Vortex and RAMAS, we developed stochastic models to represent Puaiohi population dynamics under current and potential management scenarios to determine management's potential efficacy in aiding species recovery. Management scenarios modeled included rat control, supplemental feeding, general survival facilitation, and provision of nest boxes. Both Vortex and RAMAS produced similar results, indicating a current decline in abundance. Female and juvenile mortality/survival appeared to be the most influential parameters in the model, so we suggest that any proposed management focus on increasing female and juvenile Puaiohi survival. Rat control, even at more conservative levels, appeared to be the most effective method of increasing Puaiohi abundance. Our results indicate that real world, attainable management activities have potential to increase Puaiohi numbers and bring the species back from the brink of extinction.

HOODED GREBE AND THE INVASIVE AMERICAN MINK IN AUSTRAL PATAGONIA: A CONTROL STRATEGY BASED ON A TWO SCALES DESIGN OF COMBINED MANAGEMENT ACTIONS

Laura Fasola

Centro Austral de Investigaciones Científicas-Consejo Nacional de Investigaciones Científicas y Técnicas
Ignacio ROESLER, Laboratorio de Ecología y Comportamiento Animal, Departamento de Ecología, Genética y Evolución, Facultad de Ciencias Exactas y Naturales, Universidad de Buenos Aires

American mink is the most acute not natural threat faced by the critically endangered Hooded Grebe at its breeding grounds. A single American mink could kill over 30 reproductive adults on a short span of time. Mink predation is the main threat affecting adult grebes, and thus, the its future that is highly dependent on the adult survivorship. The control program area in the NW of Santa Cruz Province (Argentina), encompasses the Buenos Aires Lake plateau and its surroundings, covering 10000 km² of limited access, 9 semi-individual watersheds that belong to two different drainages and two localities (>5000 inhabitants). The objective of the Control Program is to remove all mink from a CORE area that includes the grebe's lakes and the head of the rivers that access the high parts, maintain a low abundances of mink on the surrounding BUFFER area and set a series of BARRIER-POINTS dividing the CORE and the BUFFER areas to prevent individuals flux. At the coarse scale, we seek for a combined strategy of employed work in the rural areas and a social based control in the suburban areas. At the finer scale, the strategy is characterized by a time-habitat dynamic combination of removal methodologies: lethal-live trapping, constant monitoring-patrolling and hunting together with monitoring of the management results. In its first year of

implementation in the rural areas, 37 mink were trapped, 4 were hunted and predation on grebes was avoided. Next steps are to develop a social based control program and start genetic and morphometric studies of the removed animals to improve allocation of control efforts by assessing the connectivity amongst sub-basins for animal flux and complete sex-age determinations of the captures. Finally, trapping and hunting assisted by sniffer-dogs will complete the set of removal methodologies.

OCCURRENCE AND DIVERSITY OF LARGE MAMMALS IN OMO-SHASHA-OLUWA FOREST LANDSCAPE SOUTH-WEST NIGERIA: A PRELIMINARY SURVEY

Michelle Fasona

University of Lagos

Queen OMOREGIE, University of Lagos ; Rosemary EGONMWAN, University of Lagos

The occurrence and diversity of large mammals study was done in the Omo-shasha-Oluwa forest reserves. The study area was stratified into four habitat type (Natural forest, Gmelina plantation, Teak plantation and Agricultural lands) based on the land-use of the study area. Transects were used to identify large mammals in each habitat type in the study area. A total of nine large mammal species were recorded during the study included; Red-capped Mangabey (*Cercocebus torquatus*), African Civet (*Civettictis civetta*), Bush Buck (*Tragelaphus sylvaticus*), Forest Buffalo (*Syncerus caffer nanus*), Forest elephant (*Loxodonta africana cyclotis*), Red River Hog (*Potamochoerus porcus*), Mona Monkey (*Cercopithecus mona*), Maxwell's duiker (*Cephalophus maxwelli*) and Black duiker (*Cephalophus niger*). Variation in species diversity was evaluated using diversity indices. The Maxwell's duiker had the highest relative abundance (45.6 %). It was observed that species were more abundant (Mean=9 ±3.009, S.D=9.027) in natural forest compared to Gmelina plantation (3.777 ±2.259, S.D=6.778), Teak plantation (1.5556 ±1.068, S.D=3.205) and Agricultural lands (0.777 ±0.323, S.D=0.971). Species diversity in natural forest was higher (H'=1.798) when compared to Agricultural lands (H'=1.475), Gmelina plantation (H'=1.136) and Teak plantation (H'=0.994). Urgent conservation measures and appropriate management plans are needed to conserve the wildlife diversity across the Omo-Shasha-Oluwa forest landscape.

SYSTEMATIC CONSERVATION PLANNING IN THE HIGH ANDES: A CASE-STUDY IN THE TUNARI NATIONAL PARK, BOLIVIA

Constance Fastré

University of Antwerp

Erik MATTHYSEN, *University of Antwerp*; Diederik STRUBBE, *University of Antwerp*

Defining conservation priorities represents a major challenge in developing tropical countries where biodiversity conservation often conflicts with the need for economic development. In order to facilitate reserve network design, systematic conservation planning tools have been created and allow combining information on biodiversity and other parameters such as socio-economic data and land-use. In this case-study, we use data from a national park located in the Andes of Bolivia where the anthropogenic pressure threatens biodiversity, which is mainly contained inside small *Polylepis* forest remnants, a highly threatened ecosystem. We assessed the current conservation state of *Polylepis* patches in the field and analyzed the composition of bird communities living in this fragmented habitat. Based on these data, Species Distribution Modeling techniques were used to model patterns of biodiversity for the Tunari National Park. By combining these data with information on ecosystem services and land-use, we will generate a flexible decision-system for conservation actions in the study area using Marxan and Zonation, the two most widely used conservation planning tools.

MAMMALS SPECIES BIODIVERSITY OF GEMA HUTAN LESTARI (GHL) LOGGING CONCESSION, BURU ISLAND, MOLLUCAS-INDONESIA

Sepus Marten Fatem

Forestry Faculty, The State University of Papua, Manokwari, Papua Barat Indonesia

Abstract In order to implement the concept of tropical forest certification for sustainable forest management, the research observed the diversity of mammalia in the concession area of PT. Gema Hutan Lestari Buru Island, on January to February 2012. The study conducted was a component of identifying high conservation value of forests and an effort to provide recommendations for their monitoring and management. The main study sites were primary and secondary forests around the villages which were also the concession areas of annual management plan of HPH PT. Gema Hutan Lestari Buru Island in Buru- Maluku. The data of mammals species was obtained through observation in the morning, day and night. Beside the use of various trappings such as traditional traps (dodeso), misnet and mouse traps was carried out in the field. Structural interview was taken place to wrap up the data. The study recorded that 28 species were collected, of which 16 mammals species were allegedly found inside the area of concession. However, it was assumed that there were other species that were not captured due to limited data, information and topography factors. To complete the missing data, literature study and local interview were considered. The result showed

that 4 mammals species were protected by Government Regulation No. 7 of 1999, 4 species were vulnerable and 1 species was endangered. In general, the diversity of mammals species was too low (less diverse). The logging activity was considered as a cause of species migration both endemic and non-endemic species. The survived mammals was assumed having high adaptation to the area by using the logging area as their habitat as well as playground. Therefore, the company is further necessary to actively monitor the condition of mammals species in the concession area.. Keyword: Buru Island, Mammals of Buru, Gema Hutan Lestari

PHYLOGENOMICS METHOD FOR RANKING POPULATIONS OF THE ENDANGERED ANADROMOUS ATLANTIC SALMON (*SALMO SALAR*) FOR CONSERVATION MANAGEMENT.

Laurélène Faye

SFU

Arne MOOERS, SFU

In an Age of Extinction, wildlife managers need tools to help conserve and manage genetic resources for the future. Wild Atlantic salmon (*Salmo salar*) is at risk across its range, and so genetic prioritization would seem prudent. Recently, Volkmann and his colleagues developed a new network-based tool allowing the ranking of populations by conservation importance based on their expected genetic contribution (Volkmann et al. 2014, doi: 10.1371/journal.pone.0088945). We tested the applicability of such measures for safeguarding species-level genetic variation using landscape genetic simulations on the Nemo platform (Guillamne & Rougemont 2006, doi: 10.1093/bioinformatics/btl415). Then, using *S. salar* genomic-scale >3000 SNPs and 15 microsatellite data we constructed the phylogenetic network of 50 populations representing all the legally designated at-risk populations in Canada and applied the network prioritization approach. We identify populations that are currently under-appreciated regarding their contribution to present and future *S. salar* genetic diversities. Such populations might be prioritized both for more active research into the genetic basis of local adaptation, and for conservation by managers, immediately.

CONSERVATION WITHIN AN EXTREME ENVIRONMENT: DISENTANGLING THE DEMOGRAPHIC STRUCTURE OF ARABIAN GULF FISHERIES

David Feary

University of Nottingham

Despite living in one of the most extreme marine environments in the world, biomass density of reef fish in the Arabian Gulf

can be high, with values up to 290 mt/km² being recorded. This high fisheries biomass is incongruent with the population structure and life history of Gulf fishes. Although there is no inherent barrier to species movement into the Arabian Gulf, the diversity of reef fish populations substantially reduces when moving from sites between the western Indian Ocean (WIO) to inside the Arabian Gulf (only 43 of the 134 reef fish species found within the WIO present), while lower average abundance of conspecific populations and lower size at age are apparent for the majority of Arabian Gulf reef fish populations. I argue that such discordance between population structure and high fisheries productivity may be associated with the structure and spatial configuration of coral reef habitats, and the resulting aggregation of fisher effort on small, spatially disparate fishing grounds. Such regionally specific fishing impacts have resulted in substantial reductions in Gulf fisheries resources, while also highlighting the importance of quantifying marine habitat throughout the region and the increasing role of marine reserves in protecting nationally important resources against widespread and increasingly destructive exploitation.

RESTRICTING AN INTRODUCED VERTEBRATE'S ACCESS TO INVASION HUBS REDUCES BOTH THEIR ABUNDANCE AND IMPACT ON A NATIVE PREDATOR

Benjamin Feit

University of Western Sydney

Jonathan Webb, University of Technology Sydney ; Tim Jessop, University of Melbourne ; Shawn Laffan, University of New South Wales ; Tim Dempster, University of Melbourne ; Mike Letnic, University of New South Wales

Many biological invasions do not occur as gradual expansions along a continuous front, but from expansion of satellite populations that become established at "invasion hubs". Targeted control at invasion hubs can be an effective way to suppress invaders' populations but there is little evidence that such control activities alleviate the impacts of invaders. Proliferation of artificial water points (AWP) to increase livestock production has fundamentally changed the ecology of dryland ecosystems by facilitating range expansions of water-dependent native and introduced species. In Australia's rangelands AWP that use earthen dams as reservoirs function as invasion hubs for introduced cane toads (*Rhinella marina*) by allowing toads to rehydrate during periods of hot dry conditions. We investigated whether restricting toads' access to water at AWP can reduce toad populations and alleviate their impact on a monitor lizard, the sand goanna (*Varanus gouldii*) at risk of being poisoned by toads. Over a 3 year period, we compared cane toad abundance and occurrence of goanna tracks along 10 km transects radiating away from AWP fitted with two types of reservoir, dams (n=10) and tanks (n=21). Toads could readily access water stored in dams, but not tanks. Cane toads were more abundant at dams than

tanks. Toad abundance decreased with distance from AWP. When distance to AWP was held constant, toads occurred in higher abundances in the vicinity of dams than tanks. Conversely, the probability of encountering goanna tracks was greater in the vicinity of tanks than dams when distance to AWP was held constant. Our results indicate that restricting access to invasion hubs, by eliminating or modifying invasion hub habitats, can reduce the abundance of invasive species and their impacts. In dryland ecosystems, water-exclusion strategies tailored for specific species can be implemented at AWP to control populations of water-dependent invaders and alleviate their impacts.

217. ORCHISAUVAGE.FR: AN AMBITIOUS PARTICIPATORY SCIENCE PROJECT SUPPORTING THE KNOWLEDGE AND CONSERVATION OF WILD ORCHIDS

Philippe Feldmann

Cirad

Sophie DAULMERIE, SFO ; Alain GÉVAUDAN, SFO ; Jean-Marie NADEAU, SFO ; Michel NICOLE, SFO ; Daniel PRAT, SFO

Session 217. Orchisauvage.fr is a collaborative project which aims at collecting and sharing orchid data throughout France using ITC and Internet tools. It is coordinated by the French Orchid Society (SFO). Its main objectives are conservation and knowledge sharing on orchid's data. This project is open to everyone. It covers the whole country (France mainland and Corsica). The data collected by the members are uploaded on line. The web site is user friendly. Data can be shared between all participants. The use of recorded data is regulated. Uploaded data are checked out through a validation process (experts). Since its release in February 2014. It has encountered a significant success with more than 1 000 registered people and about 80 000 orchid observations. The data providers are new and much younger than the initial SFO members. More than 80 %, are new, with 5 times more people under 40 years old than in the initial membership. Motivations of these new contributors will be discussed, in order to adapt Orchisauvage to their needs and expectations and to enable them to take part into the whole process. Orchisauvage is managed by volunteers. The web site coordinators and data providers are working on ways to keep a high rate of participation, expand the involvement in all steps of the web based project and understand the benefit of such a participatory science project. The second part of the 217 session discussion will help us to explore future developments aiming at sharing and merging data between different NGO's and stakeholders. It will look at how to disseminate the recorded information and how to develop new on-line tools (GIS, stats, communication,...) made available to participants, such as links to conservation actions and members pages

MAKING SPACE FOR NATURE: BALANCING FOOD PRODUCTION AND BIODIVERSITY CONSERVATION IN EUROPE

Claire Feniuk

University of Cambridge

Rhys GREEN, University of Cambridge ; Ben PHALAN, University of Cambridge ; Paul DONALD, Royal Society for the Protection of Birds ; Jaroslaw KROGULEC, Polish Society for the Protection of Birds (OTOP) ; Andrew BALMFORD, University of Cambridge

Reconciling the conflict between food production and biodiversity conservation is one of greatest challenges we face this century, and the focus of major debate within the conservation community. Central to this debate are comparisons of 'land sharing' (integrating production and conservation on the same land through low-yield farming, requiring a relatively greater area under cultivation) and 'land sparing' (segregating the two aims, using high-yield agriculture to minimise the area needed for production, maximising the area that can be set aside for conservation). To compare these alternatives, we used empirical data from Poland to assess changes in the population densities of individual species of birds, trees and sedges across a gradient of agricultural yield, from natural habitats to high-yielding arable land. Our results indicate that more species will benefit from a land sparing approach, where 'spared' land may be used for both the protection/restoration of natural habitats AND for the conservation of mixed-habitat mosaics that include some extremely low-yielding farmland but contribute very little in terms of overall food production. This research raises many questions about mechanisms for delivering such an approach within the EU, in landscapes with complex systems of land-ownership and multiple objectives underlying land-management decisions. It stresses an urgent need to link EU policy tools that deliver sustainable food production (through the CAP) with those that deliver nature protection (e.g. Natura2000). It also highlights the importance of conserving the extremely low-yielding 'High Nature Value' (HNV) farmland habitats that are rapidly disappearing from many parts of the EU. Alongside our results, I will present a case-study that explores how landscape-scale land-use strategies might be delivered in practice, and the outcomes of a science-policy workshop focussed on the challenge of conserving HNV systems within the wider landscape in Europe.

(147) A GLOBAL INDICATOR FOR AICHI TARGET 15: A CASE STUDY FOR EBV APPLICATION

Miguel Fernandez

IDIV

Laetitia NAVARRO, IDIV ; Alexandra MARQUES, IDIV ; Florian WOLF, IDIV ; Henrique PEREIRA, IDIV

Despite the progress in biodiversity data mobilization and monitoring initiatives there are still no clear indicators that can help us to assess the pulse of biodiversity of the planet. Degraded landscapes around the globe constitute an opportunity for biodiversity restoration and carbon sequestration, which are two key components of Target 15 of the Convention on Biological Diversity. Using remote sensing information we evaluated a couple Essential Biodiversity Variables that address Target 15, over a decade, to provide a global assessment of trends in ecosystem restoration at global scale.

PRIORITIZING BIODIVERSITY MONITORING IN BOLIVIA

Miguel Fernandez

IDIV

Laetitia NAVARRO, IDIV ; Alexandra MARQUES, IDIV ; Amira APAZA-QUEVEDO, Herbario Nacional de Bolivia, Universidad Mayor de San Andrés ; Silvia GALLEGOS, Herbario Nacional de Bolivia, Universidad Mayor de San Andrés ; Florian WOLF, IDIV ; Carlos ZAMBRANA-TORRELIO, EcoHealth Alliance ; Healy HAMILTON, NatureServe ; Henrique PEREIRA, IDIV

Pragmatic methods to assess the status of biodiversity at multiple scales are required to support conservation decision-making. With ~10 million people in an area the size of Texas and California combined, in which almost every South American ecosystem is represented, Bolivia has extraordinary potential to develop a monitoring strategy aligned with the Group on Earth Observations Biodiversity Observation Network' objectives. Fortunately, Bolivia, a GEO Observer since 2005, is already taking small steps towards a national earth observation system with the creation of GEO Bolivia, a portal for standardized geospatial information that can inform policy and management. However biodiversity is still a missing component in this initiative. Bolivia, as a Member State of the Convention on Biological Diversity is currently at a crossroad where it should build upon knowledge and good practices to develop a country level biodiversity monitoring strategy. Here we discuss two aspects of the process: identification of taxonomic, temporal, and spatial data availability to detect both data gaps and opportunities for long term monitoring; and evaluation of issues related to the acquisition, integration and analyses of multi-scale biodiversity datasets. We capitalize this information into recommendations for the implementation of the Bolivian Biodiversity Observation Network consistent with the Essential Biodiversity Variables framework. This network will guide stakeholders to make better-informed decisions regarding urgent issues such as climate change adaptation and mitigation, food and water security, disaster

prevention and public health but will also help ensure that biodiversity is sustained as the country continues on its path of development.

ID 34 USING EARTH OBSERVATIONS TO MANAGE PROTECTED ECOSYSTEMS

Néstor Fernández

Estacion Biologica de Doñana, CSIC

Domingo ALCARAZ-SEGURA, Dep. of Plant Biology, University of Granada

Conservation management of protected ecosystems has traditionally focused on preserving and restoring structural components of biodiversity such as species composition, while paying less attention to ecosystem functioning. This bias has been partly motivated by the “intangible” nature of ecosystem functioning attributes important in conservation such as the matter and energy balance in the land surface, making it difficult to identify specific conservation and monitoring targets. We illustrate the implementation of an Ecosystem Observatory for Protected Areas as a means to provide conservation practitioners with accessible information on changes in ecosystem functioning parameters and their responses to management interventions. The Observatory is based on the continuous monitoring of synoptic indicators of ecosystem functioning calculated from satellite imagery, including vegetation greenness, evapotranspiration and vegetation drought. It builds along three main components: 1) the identification of baseline conditions to evaluate change, 2) the definition of quantitative criteria to diagnose the conservation status of ecosystems, and 3) a monitoring interface informing on trends and anomalies. The Observatory is being implemented in the Doñana Biosphere Reserve and is providing useful information on both short-term and long-term ecosystem responses to perturbations and management interventions, including the effects of flood management on the seasonal dynamics of primary production in marsh; the impact of shrubland restorations on the estimated carbon assimilation; and the differential ecosystem responses to climate anomalies like extreme droughts. Such successful applications point out the importance of remote sensing of ecosystem functioning in conservation. However, much more progress is still needed to broaden applications and to connect functioning-based monitoring to specific management targets required by conservation practitioners.

CAUSE-SPECIFIC MORTALITY OF ATLANTIC COD AND PREDICTED SURVIVAL UNDER ALTERNATIVE MANAGEMENT SCENARIOS

Albert Fernandez-Chacon

Institute of Marine Research

Even Moland, Institute of Marine Research ; Sigurd Heiberg Espeland, Institute of Marine Research ; Esben Moland OLSEN, Institute of Marine Research

Individual deaths in animal populations can be related to multiple causes, either natural or anthropogenic, but the contribution of each of these factors to total mortality has seldom been evaluated, despite cause-specific mortality proportions may help us to understand the demographic impacts of different mortality factors and allow us to derive adequate management actions for the corresponding populations. Here we investigated the mortality dynamics of a heavily exploited species, the Atlantic cod (*Gadus morhua*), with the aim to provide scientifically sound knowledge for the management of existing cod stocks. Our research was based on capture-recapture and recovery records of individually tagged coastal cod collected from 2005 to 2013 in Southern Norway, also including information on the type of gear used by fishers reporting tagged fish. This long-term information-rich database was analysed under a multi-event modelling approach, an extension of classical capture-recapture models that allowed us to link our field observations to multiple underlying “dead states” and thus robustly estimate the proportion of deaths associated to different gear types while controlling for natural mortality and detection errors. Our results revealed that the average annual survival of cod was low (28 %) and that fishing mortality accounted for nearly a 68 % of the total annual mortality in our study area. Model results indicated that the majority of deaths (45 %) were caused by fixed gear types (gill nets and fyke nets) and secondly by hand lines (22 %), with only a 0.9 % caused by other gear types (long lines and trawls), although such estimates varied over time. Using the model outputs, we could estimate annual survival rates for different fishing scenarios and predicted current survival rates to double (60 %) if fixed gear types were banned, thus linking fishing practices to local demographic responses.

ARE LARGE MPA'S EFFECTIVE FOR MARINE MEGAFUNA? A CASE STUDY OF MANTA ALFREDI (FAMILY: MOBULIDAE) IN THE CHAGOS MPA.

Daniel Fernando

Linnaeus University

Joshua STEWART, Scripps Institution of Oceanography, UCSD ; Katherine ADAMS, University of Plymouth ; Andrew BRIERLEY, University of St Andrews, Pelagic Ecology Research Group (PERG) ; Phil HOSEGOOD, University of Plymouth ; Roland PROUD, University of St Andrews, Pelagic Ecology Research Group (PERG) ; Tom LETESSIER, Zoological Society of London

Manta alfredi are cartilaginous, planktivorous filter feeding rays found in tropical and subtropical waters of the Indian and Pacific Oceans. Like other elasmobranchs, *M. alfredi* are characterised by their low fecundity, matrotrophic

reproduction, late maturity, slow growth rates and longevity, making them highly susceptible to fishing pressure and slow to recover from depletion. The driving force behind the global manta fishery is the increasing demand for dried manta gill plates used in Chinese Medicine, which led to their “Vulnerable” status on the IUCN RedList. As part of a precautionary approach, they were listed under Appendix I & II of CMS and Appendix II of CITES. *M. alfredi* are found in Chagos, an island chain in the Indian Ocean which is at the centre of the world’s largest enforced no-take MPA. Little is known about the spatial ecology of manta rays in Chagos, and a key question is whether the MPA can effectively protect the species from fisheries based in nearby countries such as Sri Lanka. We used Wildlife Computers SPOT (GPS) tags to track *M. alfredi* in the Chagos MPA and determine habitat use and spatial ecology. CTD casts were conducted to profile the physical environment, and scientific echo-sounders (EK60; 120 kHz and 38 kHz) to survey the zooplankton prey. These data will provide insights into the spatial arrangement of the manta’s deep prey field and help evaluate the effectiveness of the MPA. Previous telemetry studies have reported daily diurnal migrations of *M. alfredi* seeking deeper water/offshore habitats in the evening hours, which in Chagos could make them vulnerable to IUU fisheries that attempt to enter the MPA under the cover of darkness. Furthermore, their potential to undertake seasonal migrations of several hundred kilometres could take them across unprotected international waters which, combined with their tendency to aggregate at feeding sites, could lead to local population collapses.

BRIDGING THE GAP BETWEEN SMALL-SCALE HIGH-RESOLUTION AND LARGE-SCALE LOW-RESOLUTION MARINE STUDIES

Renata Ferrari

The University of Sydney

Will FIGUEIRA, The University of Sydney ; Stefan B. WILLIAMS, The University of Sydney ; Maria BYRNE, The University of Sydney

Modern marine conservation planning is based on models that predict species distributions, map threats and calculate the most cost effective solution to achieve the highest possible conservation target with the minimum economical investment. These conservation tools rely upon species distribution models, which are often based on data extrapolation obtained through monitoring programs. These models are useless without data that can represent the larger area under management. Nonetheless the assumption that a few transects/quadrats are representative of a larger area is inaccurate. Alternatively, remote sensing can cover large spatial scales, but the resolution of these data is not high enough to understand processes and patterns influencing an ecosystem’s trajectory. Automated Underwater Vehicles (AUV) and computer vision

can cover large areas and collect data that can be used to characterize benthic communities and measure habitat structural complexity with unparalleled accuracy. Here, we present a few study cases that have used imagery to measure habitat complexity and community composition. Some cases have compared the relationship of habitat structural complexity and marine communities inside and outside marine protected areas; while others are investigating the effect of climate change on the community composition and habitat structural complexity of threatened ecosystems. Imagery is also used to reconstruct 3D models of different habitats, which are great tools for outreach and policy. This tool is applied to improving marine conservation around Australia, and is an example of how conservation challenges are best solved by multidisciplinary teams. The accuracy of spatial predictive models is significantly improved by AUV imagery, and the measurement of a key habitat attribute, 3D structural complexity, is now possible.

HISTORIC REVIEW OF PREDATOR CONTROL IN THE IBERIAN PENINSULA

Catarina Ferreira

Trent University, Peterborough, ON, Canada

Carolina MÁRQUEZ, Facultad de Ciencias, Universidad de Málaga ; Rafael VILLAFUERTE, Instituto de Estudios Sociales Avanzados ; J. Mario VARGAS, Facultad de Ciencias, Universidad de Málaga ; Emilia GARRIDO, Universidad Autónoma de Madrid ; Paulo Célio ALVES, CIBIO, Centro de Investigação em Biodiversidade e Recursos Genéticos, InBio Laboratório Associado ; Dennis L. MURRAY, Trent University, Peterborough, ON, Canada ; Pablo FERRERAS, Instituto de Investigación en Recursos Cinegéticos (IREC-CSIC- UCLM-JCCM)

The reconstruction of the historic relationship between Man and wildlife is a recurring topic of the world scientific literature, being the study of the effects of direct and indirect legal persecution over predator species particularly exhaustive. The investigation of the historical human impact in animal populations is essential to understand current patterns of species abundance and distribution, their expansive or regressive trends, as well as the potential causes for extant hotspots of human-wildlife conflict. Moreover, historical information is vital to properly guide management decisions for several species, especially for those facing serious conservation issues or those that are socially conflictive. This study represents the first comprehensive attempt to compile information relative to the persecution of predator species in the Iberian Peninsula throughout the XXth century. Preliminary results show that legal mechanisms operated almost simultaneously in both Portugal and Spain although at different rates and spatially asynchronous. The official extermination campaigns of predator species was overall very effective and their impact in mammal, bird and reptile

populations must have been devastating. Nowadays, the near disappearance of many species of predators and the drastic reduction of their distribution area is a consequence of the direct persecution imposed over this period. The legal protection that these species enjoy currently is not yet warranty of their survival in the long-term in this region.

82-CHALLENGES AND OPPORTUNITIES FACING SUSTAINABLE LAND-USE IN FRONTIER REGIONS OF THE AMAZON

Joice Ferreira
Embrapa

In the last ten years the Brazilian Amazon has received increasing international attention, both for the dramatic fall in deforestation rates and the rising importance of its agricultural sector. The conservation and development trajectory of the region now stands at a crossroads, the future of which will be shaped in great part by landscape management decisions that are made in the coming decade. Here we provide a focus on some of the key issues facing the future of biodiversity conservation in regenerating and degraded forests that dominate much of the remaining private forest estate in frontier and post-frontier regions of eastern Amazonia. We employ both empirical data on the characteristics of more than 500 rural properties in two municipalities, together with an analysis of governance and institutional change in the state of Pará, and personal experience from engagement in state-level science-policy processes. We illustrate that while second-growth and degraded forests are a critical resource for smallholders who depend on fallow-farming systems, they are also of central importance in efforts to achieve compliance of these actors with Brazil's environmental legislation. However, significant uncertainties remain regarding the spatial planning and management of regenerating and degraded forests, including priorities and incentives for on and off-farm restoration, rehabilitation and compensation programs, and opportunities to integrate the management of both forest and production areas at both property and landscape scales. In situating our observations alongside the development a "Green Counties" program for the state, and Brazil's new federal restoration strategy and revised Forest Code, we identify specific opportunities for public policies seeking to foster more sustainable land-management and conservation programs in one of the most dynamic agricultural-forest frontier regions on the planet.

CRYOPRESERVATION FOR LONG-TERM CONSERVATION OF CORAL DIVERSITY: A CASE STUDY WITH POCILLOPORA DAMICORNIS.

Lionel Feuillassier

Université Pierre et Marie Curie, Observatoire Océanologique de Banyuls-sur-mer
Myriam COLLIN, Institut de Recherche pour le Développement ; Nancy TROUILLARD, Université Pierre et Marie Curie, Observatoire Océanologique de Banyuls-sur-mer ; Patrick MASANET, Aquarium de Canet-en-Roussillon ; Pascal ROMANS, Université Pierre et Marie Curie, Observatoire Océanologique de Banyuls-sur-mer ; Isabelle ENGELMANN-SYLVESTRE, Institut de Recherche pour le Développement ; Dominique BARTHELEMY, Océanopolis ; Florent ENGELMANN, Institut de Recherche pour le Développement

For several decades, the decline of coral diversity has been largely relayed by the scientific community. Increasing environmental perturbations and human activities drastically impact coral reef biodiversity. Ocean acidification and global warming constitute the two major threats. Despite the multiplicity of safeguard programs, the danger of extinction is now becoming a reality for a range of coral species. Cryopreservation, i.e. the storage of biological material at ultra-low temperature (liquid nitrogen, -196°C) may provide an alternative for the long-term ex situ conservation of these threatened organisms, which often have medical or pharmaceutical potential. Moreover, the development of cryopreservation protocols for coral may facilitate their establishment for other phyla of marine invertebrates. To date, only coral spermatozoa and dissociated cells have been successfully cryopreserved using a slow cooling protocol, while no such success has been obtained with pluricellular forms such as apexes or planulae. Various biomaterials from other phyla which failed to respond positively to slow cooling techniques have been successfully cryopreserved using the vitrification technique, which is based on the use of highly concentrated cryoprotectant (CPA) solutions and very high cooling and warming rates. With the objective of cryopreserving pluricellular forms from the tropical coral *Pocillopora damicornis* using a vitrification procedure, we tested the tolerance of cellular aggregates termed tissue balls (TBs) to CPA solutions. In addition to survival evaluation, histological observations were performed to study the effect of CPA treatments on TB structure. Our results showed that TBs could withstand exposure to CPA concentrations higher than 4.0 M and that they constituted a suitable material to optimize the various parameters of a cryopreservation protocol.

PRODUCTION VERSUS ENVIRONMENTAL IMPACT: CAN WE HAVE IT ALL ON A CONVENTIONAL ARABLE FARM?

Rob Field
RSPB

Rachel HILL, RSPB ; Matthew CARROLL, RSPB ; Tony MORRIS, RSPB

European farmland biodiversity has undergone declines through the late 20th and early 21st centuries, as a result of increased productivity. Both these trends are likely to continue as the drivers (human population increase, availability and cost of raw materials, policy constraints, price volatility and climatic changes) increase. These are likely to be complicated and exacerbated by the attendant environmental impacts of conventional farming. We assess the effects of different management priorities (production driven cropping versus wildlife friendly farming) at an arable farm in eastern England on crop yield, greenhouse gas emissions and biodiversity between 2000 and 2012. Loss of small areas (up to 10.5%) of productive land coupled with a more diverse rotation (including legumes) resulted in a large increase in breeding birds (177%) and reduction of 9.4% in greenhouse gas emissions at the cost of 9.6% of food energy. Food protein lost was only 2.9%. A smaller increase in bird numbers of 50% could be achieved at a much smaller cost to yield (~1.7% energy or protein) but with correspondingly smaller emissions reductions (1.2%). We demonstrate that it is possible to incorporate wildlife friendly farming techniques into a conventional arable farm, whilst reducing climate forcing emissions and maintaining the majority of food production, but that further improvement of environmental performance may impact production under this system. To become more sustainable, the current system may have to change more fundamentally.

A BUZZWORD LOST IN SPACE? UNDERSTANDING THE NEW RELATIONSHIP BETWEEN RESILIENCE KNOWLEDGE AND PARTICIPATORY CORAL REEF MANAGEMENT

Clare Fieseler

UNC Chapel Hill

Lisa CAMPBELL, Duke University Marine Lab ; Chris BERGH, The Nature Conservancy

Coral reef scientists and managers increasingly discuss adaptive management as a global imperative. In addition to single-actor management and stress abatement, ecosystem resilience and participatory feedback are newly fundamental. Broadly defined, ecosystem resilience is the capacity or an ecosystem to absorb disturbances and reorganize. Although the system may shift, it essentially retains the same function, structure, identity, and feedbacks. Few managers have practically incorporated the concept of ecological resilience in decision-making on coral reefs. However, in 2011, the Florida Keys National Marine Sanctuary adopted a novel guideline; resilient reef areas were identified and prioritized in a multi-year review of the sanctuary's zoning. From 2012 through 2014,

scientists, agency staff, and stakeholders were engaged – via a specially appointed Working Group and long standing Advisory Council – to recommend improvements to the zoning network using this and other conservation guidelines. Drawing from interviews, meeting transcripts, and surveys, this research illuminates the informational (i.e., visual representation) and social contexts in which these two groups translated reef resilience. The interaction of a complex concept – resilience – with stakeholder discourse led to a re-shaping of resilience by sociopolitical narratives. Political ecology provides a lens to reflect on broader, professional implications: can the scientific community effectively inform resilience-based management without considering if and how new management understandings of resilience, in turn, affect the science?

ISLANDS IN THE SKY: SCIENCE, SYMBOLISM, AND THE CONSERVATION IMPACT OF MONTANE EXPEDITIONS ACROSS TROPICAL PACIFIC ISLANDS

Christopher Filardi

American Museum of Natural History

Patrick PIKACHA, Solomon Islands Community Conservation Partnership

Pacific island arcs comprise natural laboratories that have inspired some of the most influential scientific theory of our time. Much of the data underlying this theory were gathered nearly a century ago on world-renowned expeditions. Despite the scientific and social impact of early expeditions, numerous upland areas have never been rigorously sampled. At the same time, as lowland areas have been degraded by poorly regulated resource extraction, montane areas are under increasing threat from direct and indirect impacts of timber extraction and recent upsurge in mining activity. Montane and cloud forest areas are characterized by high endemism and are also primary, often sacred, elements of the customary lands of island peoples, the original custodians of Pacific island biodiversity. On high islands, where customary landholders largely retain subsistence, economic, and spiritual reliance upon biodiversity, both ecological process and human well-being rely on the integrity of upland forests and altitudinal gradients. Contemporary biodiversity expeditions focused on montane endemism can provide scientific, practical, and symbolic opportunity to improve regional conservation efforts for currently under-studied and threatened high-elevation ecosystems. This presentation describes several case studies from the Solomon Islands that highlight how investing in the broader social context of exploring islands in the sky provides a means to advance biodiversity science and conservation. By combining landholder engagement, scientific training, and public outreach with biodiversity discovery and analysis, collaborative expeditions are reviving the local co-creation of protected areas. Beyond Pacific Islands, the examples presented in this talk provide guidelines for well-designed

expeditions that not only revive the potency of basic natural history, but also improve conservation prospects of protected areas strategies.

117-NOVEL ECOSYSTEM THEORY: IS IT USEFUL FOR THE MARKET-ORIENTED MANAGEMENT OF LANDSCAPES FOR BIODIVERSITY AND PEOPLE

Jennifer Finn

Queensland University of Technology

Ecosystems can end up degraded because previous species and environmental conditions were not compatible with the demands of past or present-day land-use. Non-native plants have been introduced globally, with a genuine intention to improve ecosystems and many times with a specific market in mind. Some of these introductions have proven successful, but others have not. The degradation of our natural ecosystems has occurred, despite the best intentions of aiming to improve an ecosystem to fit “present-day” and projected future needs. Both a problem and a benefit with novel ecosystem theory is that it has this same goal—managing ecosystems with current and predicted futures needs in mind, a challenging task to monitor and evaluate. In this talk, I will discuss examples of the benefits of adapting and integrating existing frameworks (i.e. reclamation, rehabilitation and restoration goals with theories such as alternative states) to underpin the design of restoration goals for rangelands and forests where trade-offs between multiple objectives can be clearly defined and progress monitored and evaluated in a systematic manner. Most importantly strategies and maybe even goals changed as knowledge of the system increases.

DOES SEED FATE DETERMINE INVASION SUCCESS OF A HIGHLY COMPETITIVE HERBACEOUS LEGUME IN ARID RANGELANDS?

Christina Fischer

Restoration Ecology, Technische Universität München
Johannes KOLLMANN, Restoration Ecology, Technische Universität München ; Thomas Christian WAGNER, Restoration Ecology, Technische Universität München

Seed predation is an important ecosystem process, which significantly reduces recruitment in many plant species, thereby it can impact the invasion success of non-native but also native plants. In contrast plant invasion can be facilitated by higher seed production and more effective dispersal. Here, we studied pre- and post-dispersal seed predation, as well as primary and secondary seed dispersal of *Crotalaria podocarpa*, an invasive native herbaceous legume, which considerably increased in arid rangelands of Namibia during the past years of elevated rainfall, thereby reducing the density and vitality of economically important fodder grasses. Additionally, we

quantified the impact of different predator groups on post-dispersal seed removal by experimentally excluding (i) birds, (ii) vertebrates (birds and rodents), (iii) vertebrates and large invertebrates, and (iv) neither vertebrates nor invertebrates (control). Seed predation was mainly caused by invertebrates, with 30% pre-dispersal seed predation in pods and up to 90% post-dispersal seed removal for free seeds on the ground which is the most persistent seed stage. The main primary dispersal mode for *C. podocarpa* is explosive dehiscence, with seeds reaching dispersal distances of up to 5 m, while wind or rolling dispersal played a minor role. Subsequent secondary dispersal by animals accounted for dispersal distances up to 19 m. Our study highlights the combined effects of pre- and post-dispersal seed predation to determine the total seed fate. However, for *C. podocarpa* invasion the remaining ca. 370 seeds m⁻² that are constituting its persistent soil seed bank seem more decisive than the species dispersal ability. However, to reliably develop management options against economic loss through *C. podocarpa* spread seed predation, seed dispersal and seed bank dynamics have to be studied in the long-run.

CHALLENGES OF MULTIPLE SPECIES MANAGEMENT: EFFECTS OF CATTLE GRAZING AND RESTING RANGELAND ON SONGBIRD ABUNDANCE AND VEGETATION STRUCTURE IN A MIXED-GRASS PRAIRIE IN SOUTHWESTERN SASKATCHEWAN

Samantha Fischer

University of Manitoba

Nicola KOPER, University of Manitoba

Using livestock grazing to mimic historical disturbances, via the application of variable stocking rates and resting rangeland, has been proposed as a method for addressing the mass declines of grassland songbirds occurring today. Both strategies could provide a means of increasing landscape heterogeneity, thereby increasing the variety of habitats available to songbirds. We collected data on bird abundance at 90 point count locations in 9 experimental pastures, each 300 ha, located in Grasslands National Park, Saskatchewan. After at least 15 years of rest, followed by 2 years of baseline surveys, pastures were grazed from 2008-2011 with stocking rates ranging from low to very high. In 2012 grazing was removed from the experimental pastures. Our goal for this component of the project was to determine if differences in songbird abundances and vegetation structure among pastures, created by applying variable stocking rates for 4 years, persisted following grazing removal. Stocking rate had a negative effect on Savannah Sparrow, Grasshopper Sparrow, and Baird's Sparrow abundances but a positive effect on Chestnut-collared Longspur abundance. Following grazing removal, Grasshopper Sparrow and Savannah Sparrow abundances returned to pre-grazing levels, but the effects of stocking

rate on Baird's Sparrow and Chestnut-collared Longspur abundances persisted for at least two years. Stocking rate had a negative effect on litter depth, litter cover, and vegetation height-density but a positive effect on *Selaginella densa* cover. Vegetation height-density and *S. densa* cover returned to pre-grazing levels following two years of rest, however, stocking rate previously applied continued to affect litter depth and litter cover for the duration of our study. Our analysis suggests that resting rangeland could quickly erase changes in songbird abundance and vegetation structure created by grazing but for certain variables more than three years of rest may be necessary to achieve this.

21 EQUITY AND JUSTICE AS GOALS FOR CONSERVATION: ANALYTICAL TOOLS AND THEIR APPLICATION

Janet Fisher

University of Edinburgh

Ruth MAKOFF, University of East Anglia ; Adrian MARTIN, University of East Anglia ; Helen SCHNEIDER, Fauna and Flora International ; Thomas SIKOR, University of East Anglia

Time-honoured debates about conservation and people are resurfacing in contemporary exchanges about the 'new' conservation. While the debates are not new, new elements do exist regarding who should benefit from ecosystem services (ES). In parallel, much research effort, catalysed by the MEA and funded in part by development agencies, seeks to disentangle the links between ES and poverty alleviation. This paper discusses research asking a fundamental and slightly provocative question: why should ES be used for poverty alleviation? It is a fundamental question because, in the presence of ecological and social trade-offs, ES do not automatically benefit poor people, but have been demonstrated to accrue to wealthy and powerful actors. It is also a timely question, not only because many environmental interventions continue to take place amidst entrenched poverty, but also because demand for ES from non-poor and distant actors is predicted to rise. These matters concern ethics and justice, encompassing questions about the common good, non-human nature and inter-/intra-generational distribution. While research increasingly seeks to disentangle the nexus between ES/poverty, none has considered the ethical foundations of the proposition that ES should be governed for poverty alleviation. Our paper comprises two bodies of work that address this question. The first seeks through qualitative and Q-methodological research, to understand how conservation practitioners rationalise whether and why ES should be governed for poverty alleviation. The second identifies theories in political philosophy and environmental ethics underpinning the same proposition. Through these combined analytical tools, we seek to identify an explicit and defensible case, from theoretical and practitioner perspectives,

of why the poorest should take priority as ES beneficiaries. We also reflect on this unusual combination of disciplinary approaches and methods for examining environmental justice.

EXTENSIVE LANDSCAPE DISTURBANCE EXPLAINS MAMMALIAN DISTRIBUTION IN THE CANADIAN OIL SANDS

Jason Fisher

Alberta Innovates - Technology Futures

Cole BURTON, Alberta Innovates - Technology Futures

Landscape disturbance is often synonymous with habitat loss and fragmentation, and subsequent biodiversity loss. However, the effects of landscape disturbance vary among species and disturbance types, creating ecological "winners and losers" in human-dominated landscapes. In Canada's oil sands, petroleum extraction interacts with logging and road building to create an extensively disturbed landscape with few global analogs. This unique disturbance is implicated in endangered woodland caribou declines. We hypothesized that the effects of oil sands development are not limited to caribou, but manifest across the boreal mammal community. We sampled mammalian occurrence in a 3000 km² area of Alberta's boreal forest at 60 camera-trap stations deployed in a stratified systematic design, sampled between 2011 and 2013. We quantified natural land cover and anthropogenic disturbance from Geographic Information System (GIS) data. We used generalized linear models to relate each species' occurrence to landscape features in an information-theoretic approach. For every species examined, anthropogenic features were a key component of the best-supported model. Some species were positively, and others negatively, associated with landscape disturbance. Overall, anthropogenic features had a greater effect on species than did natural land cover. We contend that these widespread effects signal a change in landscape function, with increasing landscape fragmentation and permeability favoring generalist predators and browsers at the expense of other species. As world leaders contemplate continental-scale pipelines and international climate change agreements, the regional-scale impacts of oil sands development take on global significance. The oil sands' spatial footprint is manifested across the boreal forest mammal community, and the future trajectory of these species may hinge on global decisions.

WHAT LIES BENEATH: DETECTING SUB-CANOPY CHANGES IN SAVANNA WOODLANDS USING A 3D CLASSIFICATION METHOD

Jolene Fisher

University of the Witwatersrand

Ed WITKOWSKI, University of the Witwatersrand ; Barend ERASMUS, University of the Witwatersrand ; Penelope MOGRABI, University of the Witwatersrand ; Gregory ASNER,

Carnegie Airborne Observatory, Department of Global Ecology, Stanford University ; Jan VAN AARDT, Rochester Institute of Technology ; Konrad WESSELS, Council for Scientific and Industrial Research ; Renaud MATHIEU, Council for Scientific and Industrial Research

The co-existence of woody plants and grasses characterise savannas, with the horizontal and vertical spatial arrangement of trees creating a heterogeneous biotic environment. To understand the influence of biogeophysical drivers on the spatial patterns of 3D structure of woody vegetation, these patterns need to be explained over large areas to capture the context. The aim of the study was to produce an ecologically meaningful savanna classification using LiDAR (Light Detection and Ranging). We then applied the classification to detect change in a protected area (PA) and a communal rangeland (CR). Canopy height model (CHM) and volumetric pixel (voxel) data from the Carnegie Airborne Observatory-Alpha system were used to create the structural classification. Vegetation was classified as shrub (1-3 m), low tree (3-6 m), high tree (6-10 m) or tall tree (>10 m). A hierarchical a priori approach was used to develop classification criteria. Metrics were based on the cover and spatial arrangement of the height classes: Canopy Cover, Sub-canopy Cover, Canopy Layers, Simpson's Diversity Index and Cohesion. For change detection four of the metrics were used (Canopy Cover, Canopy Layers, Cohesion and Number of height classes present). Gains, losses and persistence (GLP) of cover at each height class and of the four structural metrics were calculated. Trees >3 m in height showed gains up to 2.2 times higher in the CR where they are likely to be protected for cultural reasons, but losses of up to 3.2 times more in the PA, possibly due to treefall caused by elephant and/or fire. A 3D classification approach was successful in detecting fine scale, short term changes between land uses, and can thus be used as a monitoring tool for savanna woody vegetation structure.

ROCKY OUTCROPS: A HARD ROAD IN THE CONSERVATION OF CRITICAL HABITATS

James Fitzsimons

The Nature Conservancy

Damian MICHAEL, Australian National University

Rocky outcrops form important landscape and geological features, and important wildlife habitats. Rocky habitats come in many varieties including escarpments, overhangs, cliffs, tors and boulder-heaps, and large rock domes (inselbergs). Being hard and inorganic, they provide long-lasting landscape features that provide stable micro-climates, habitat and shelter for thousands of years. They provide breeding sites for many top order mammalian and avian predators, as well as colonial nesting species such as bats and swifts. They are also home to rare or endemic plant and reptile species. Due to their relatively stable position in the landscape, and general inaccessibility,

they are considered ecological refugia and can contain high species diversity. In addition, rock overhangs and caves can provide important insights into our ecological past where they contain the remains of species which have long since disappeared. As rocky environments are generally less fertile and less accessible than the surrounding landscape, they are typically less prone to vegetation removal. Nonetheless, they face a variety of threats including compaction of soil (from stock), leading to increased runoff and nutrient enrichment which can encourage weeds; recreational activity causing physical damage and disturbance to nesting birds by walkers and climbers; and potentially climate change. Rocky outcrops also provide refuge for economically- and ecologically-damaging feral animals, and invasive weeds. In fragmented landscapes various approaches have been taken to conserve rocky outcrops, including land acquisition for conservation, fencing from stock and private land conservation agreements with landholders. Where rocky outcrops occur in more intact landscapes, targeted responses for faunal species have included limiting human access around key breeding sites, baiting to reduce pressure from introduced predators, restoring rock habitat and translocation of key species (particularly mammals).

COMMUNITY COMPOSITION OF ENDOPHYTIC FUNGI IN NATIVE VANILLA SPECIES IN THE CHOCÓ BIODIVERSITY HOTSPOT IN COLOMBIA ASSESSED USING NGS: BASELINE DATA FOR MONITORING OF ECOSYSTEM FUNCTIONING.

Nicola S. Flanagan

Pontificia Universidad Javeriana

Andrew DETHERIDGE, Institute of Biological, Environmental and Rural Sciences, Aberystwyth University ; Gareth W.

GRIFFITH, Institute of Biological, Environmental and Rural Sciences, Aberystwyth University

Fungi are rarely considered in conservation biology despite their key role as providers of ecosystem services. In an integrative ecosystem-based approach to forest conservation, documentation of the diversity and functional roles of fungal communities is imperative. Endophytic fungi represent a hyperdiverse group globally, and are a source of both unknown species and undiscovered bioactive compounds. The tropical lowland forest of the Chocó biogeographic region in western Colombia is a neglected biodiversity hotspot. The approximately 50% of the original ecosystem remaining is under increasing pressure, and novel solutions for enhancing livelihoods are essential. Within this ecosystem the native species of *Vanilla* are understudied and underexploited as potential non-timber forest products. In order to determine the phylogenetic diversity of the endophyte community of terrestrial and aerial roots, and leaf tissue of five native

Vanilla species, we used Ion Torrent sequencing of 200bp of the D1 variable region of the Large Sub Unit rDNA. In total, more than 6,000 fungal Operational Taxonomic Units (OTUs) were found. 70% of fungal sequences were identified to family, and 59% to genus. Dominant genera were *Veronaea*, *Trechispora* and *Tulasnella*. The community composition was tested using Permanova. No significant differences were seen between tissue types within the same species, but differences were seen between species. *Vanilla bicolor* showed the greatest dissimilarity to other species, reflecting the distinct ecology of this species. This study attests to the utility of NGS to characterize hidden fungal diversity. Our results greatly extend a previous culture-dependent study of terrestrial root endophytes of native *Vanilla* species, enhancing our understanding of the phylogenetic diversity and distributions of these cryptic microorganisms. It is essential that conservation actions begin to consider both the function and potential of fungal endophytic biodiversity.

EFFECTS OF QUARRYING ON LANDSCAPE CONNECTIVITY: A RESISTANCE CALIBRATION APPROACH ACROSS SPECIES, LANDSCAPES AND TIME

Théo Flavenot

CESCO, MNHN

Virginie STEVENS, SEEM, CNRS ; Pierre JOLY, LEHNA, Université Lyon 1 ; Louise KESZLER, CESCO, MNHN ; Michel BAGUETTE, ISYEB, MNHN[INSTITUTE]SEEM, CNRS ; Aurélie COULON, CESCO, MNHN[INSTITUTE]CEFE

Landscape connectivity is a key element to biodiversity. Its conservation is threatened by anthropogenic land conversion, which triggers (among other things) an isolation of populations. As other industrial activities, quarrying has a deep effect on landscapes, and may disturb local dispersal processes. However, newly created habitats can be favourable for some specialist species. To assess the global effect of quarrying on connectivity, we estimated its resistance to gene flow relative to that of surrounding land cover classes. We focused on two amphibians with opposed habitat preferences: the common toad (*Bufo bufo*), a species favouring vegetated environments; and the natterjack toad (*Bufo calamita*), a pioneer species. Resistances were inferred with an innovative calibration procedure that integrates mixed modelling and circuit theory. The study was conducted in six contrasted areas to account for the influence of landscape context; and at three points in time to control for time lags between landscape modifications and changes in genetic structure. Results show that time lags between genetic and landscape processes vary among sites and species, and are driven by the type of changes that happened in the landscapes. The calibration procedure failed for areas showing high rates of land conversion. For the others,

the estimated resistances of the surrounding land cover classes were consistent with the biology of our species, but were influenced by the landscape context. Active quarry sites were shown to support connectivity for *B. calamita*, whereas the effect on *B. bufo* was closely linked to landscape context.

(117) NATURE, CAPITAL, AND SOCIAL JUSTICE: DEBATING THE ROLE OF ECONOMICS IN CONSERVATION

Robert Fletcher

Utrecht University

Whether economic interests – either those of resident populations or of outside investors – should be included within conservation policy has been a contentious issue since the advent of the ICDP movement - coalescing into the so-called ‘people vs. parks’ debate that has polarized conservationists for decades. Recently, this debate has become more complicated with advancement of a call for a(nother) ‘new’ conservation paradigm appropriate for the advent of the ‘Anthropocene’, which builds on the growing popularity of market environmentalism to advocate an explicitly anthropogenic approach to conservation in which the capacity to harness the economic value of in situ natural resources is foregrounded. This approach, however, has been called into question by two opposing positions: one demanding a return to strict nature preservation; the other foregrounding concerns for social justice in conservation programming. At the same time, each of these critical positions has questioned the other - for minimizing consideration of the rights of humans and nonhumans, respectively. The result is (at least) a three-pronged debate concerning the relative importance of people, capital, and nonhuman nature in conservation planning. This presentation seeks to dissect this debate, highlighting the terms of debate among these different positions in order to ask whether there exists any possibility to finding common ground among them that might serve as the basis for a new consensus on appropriate conservation futures.

THE EU HABITATS DIRECTIVE AND THE RESTORATION OF VANISHED WILDLIFE POPULATIONS: THE CASE OF LARGE CARNIVORES

Floor Fleurke

Tilburg University

Arie TROUWBORST, Tilburg University

The EU Habitats Directive (HD) instructs EU member states ‘to maintain or restore, at favourable conservation status, natural habitats and species’ covered by the Directive (Article 2(2)), and sets out further duties to achieve this. Much has been published on what is required to fulfill these duties in respect of currently existing wildlife. Far less attention has

been paid to the question what the obligations are once a wildlife population has disappeared, and in particular to what extent the HD requires the restoration of such vanished populations. We address this question using standard EU law research methodology, i.e., identifying and interpreting relevant HD provisions, case law of the EU Court of Justice, overarching treaties, and EU guidance documents, while also using relevant legal and biological literature. We conduct our analysis with particular reference to the large carnivore species brown bear (*Ursus arctos*), wolf (*Canis lupus*) and Eurasian lynx (*Lynx lynx*). These are associated with an array of restoration scenarios and HD regimes, i.e., Annex II (habitat protection), Annex IV (strict protection) and Annex V (flexible protection). Our analysis indicates that the extent of member states' duties regarding the restoration of vanished populations is context-dependent and influenced by a range of variables including (a) the applicable HD regime(s); (b) whether extinction occurred prior or subsequent to the HD's entry into force; (c) whether the population was original or reintroduced; (d) the causes of extinction (natural/anthropogenic); and (e) the prospect of natural recolonization. For each combination of variables we identify and discuss the corresponding obligations. To illustrate, different duties apply regarding each of the following extinct populations: lynx in the UK; wolves in the Netherlands; bears in central Austria; and (assuming they are extinct) wolves in southern Spain.

SUPPLEMENTARY FEEDING STATIONS TO SUSTAIN GRIFFON VULTURE POPULATIONS: A RISK OF ECOLOGICAL TRAP ?

Julie Fluhr

Centre d'Ecologie Fonctionnelle et Evolutive (CEFE)
Olivier DURIEZ, Centre d'Ecologie Fonctionnelle et Evolutive (CEFE) ; Simon BENHAMOU, Centre d'Ecologie Fonctionnelle et Evolutive (CEFE) ; Louise RIOTTE-LAMBERT, Centre d'Ecologie Fonctionnelle et Evolutive (CEFE)

As a conservation tool, supplementary feeding programs are widely applied on scavengers, likely to bring positive benefits but also negative ones. While scavengers have supposedly evolved to search for unpredictable resources, gathering food at feeding stations are likely to promote non-natural behaviours. Birds may face a risk of "ecological trap" since their behavioural responses inherited from their evolutionary history may be inappropriate in a context of predictable food resources in space even time. As part of a reintroduction program of Griffon vultures (*Gyps fulvus*) in the Grands Causses (France), managers established two types of feeding stations, providing a quasi-experimental framework to address the impact of food predictability on foraging behaviour. While "heavy feeding stations" – concentrating carcasses at a few sites – can be considered as highly spatially and temporally predictable, the network of hundred "light feeding stations"

– diluting the concentration of carrions in space and time – is only spatially predictable, and "open grasslands" – where carcasses are randomly distributed – are, in essence, unpredictable. Using high resolution GPS tracks for 15 vultures, we investigated both spatial and temporal components of foraging movement patterns. We first studied the sequences of visited sites to assess the extent to which vultures rely on routine rather than random behaviour to find ephemeral food resources. In a second step, we focused on the periodicities of movement recursions, likely to reflect and inform about the adaptation of behaviour to periodic constraints.

WHICH METHOD IS BEST? THE IUCN SSC'S NEW GUIDELINES FOR ASSESSING CLIMATE CHANGE VULNERABILITY OF SPECIES

Wendy Foden

IUCN Species Survival Commission

Conservation practitioners wishing to carry out assessments of species' vulnerability to climate change face a burgeoning literature describing a wide variety of methods, each with its own strengths and limitations. Similarly those wishing to use existing assessments increasingly encounter conflicting results from multiple sources. Based on a broad literature review and input from a wide range of experts, the IUCN SSC Climate Change Specialist Group has developed guidance for selecting methods for assessing species' climate change vulnerability and interpreting their results. We outline commonly used approaches for assessing species' climate change vulnerability namely correlative (niche-based), mechanistic and trait-based approaches. We then guide users through clearly defining the scope and objectives of their assessment, as well as to identify and evaluate their available data, technical, expertise, time and financial resources. Using a decision framework, we help users to identify the approaches and methods that meet their objectives and/or are possible given their available resources. The guidelines also include sections on selection and appropriate use of climate and biological data, selecting temporal and spatial scales, and working with uncertainty, knowledge gaps and indirect climate change impacts. We also present ideas for communicating assessment results for practical conservation use. Lastly, we provide examples of how the guidelines can be applied, including for IUCN Red Listing. This presentation will provide an overview of the new IUCN SSC guidelines on assessing species' climate change vulnerability, and familiarize attendees with steps for making sound and defensible decisions on method choice. Through these guidelines we hope to make climate change vulnerability assessment more accessible to conservation practitioners, thereby providing the best possible foundation for climate change adaptation planning.

MITIGATING EXTINCTION RISK FROM FORECAST CLIMATE CHANGE USING MODELS, FOSSILS AND MOLECULAR LOG BOOKS

Damien Fordham

University of Adelaide

Disregarding or misinterpreting biotic responses to past environmental changes could impede our understanding of future ecological dynamics under global change and make accurate predictions and effective solutions difficult to formulate. Current forecasts indicate that anthropogenic climate change will cause widespread biodiversity loss. However, the accuracy of these ecological predictions remains largely untested. I will discuss how biotic responses to past climate change, imprinted in species' genes and observed in fossils, can be used to establish if forecasts of extensive biodiversity loss from future climate change are a likely reality; and to identify traits that make some species more prone to extinction from climate change. A tighter integration of genetic and fossil data into ecological models will generate more robust and validated predictions of the response of demographic and evolutionary processes to large-scale environmental change. These multidisciplinary methods will help conservation scientists to better connect theory to the on-ground design and implementation of effective measures to protect biodiversity.

INCORPORATING ENVIRONMENTAL AND SOCIAL CO-BENEFITS INTO REDD+ SPATIAL PLANNING

Adam Formica

University of Oxford

Forests do more than store carbon. They offer co-benefits such as habitat for species, regulation of water flow and quality, and support for livelihoods. REDD+ countries must balance international incentives for global climate change mitigation with national interests in maintaining local co-benefits. Exploring spatial tradeoffs among carbon, biodiversity, ecosystem services, and poverty alleviation reveals where there may be opportunities for gains in co-benefits without large sacrifices in carbon. Countries may find that the value of the gains in some co-benefits outweighs that of the carbon lost. Such findings could encourage countries to pursue strategies that emphasize these co-benefits rather than maximize carbon. Not all forests, however, are eligible for REDD+ because they may not be at risk of deforestation or the value of their carbon and non-carbon benefits does not exceed foregone development costs. Modeling deforestation and calculating the financial viability of forest protection define the extent of forests that qualify for REDD+. This study puts forward a spatially explicit method for incorporating co-benefits into

REDD+ planning. It applies the method in Kenya, a country in the REDD+ readiness stage which has pledged to focus on co-benefits, in hopes that it will provide a template for countries elsewhere.

MANAGING CO-OCCURRING DISTURBANCES FOR THE CONSERVATION OF FOREST VEGETATION AND SMALL VERTEBRATE FAUNA

Claire Foster

ANU

Philip BARTON, ANU ; Chloe SATO, ANU ; Jeff WOOD, ANU ; Christopher MACGREGOR, ANU ; David LINDENMAYER, ANU

Reinstating natural disturbance regimes in ecosystems where they have been disrupted is a priority of many biodiversity conservation programs. As different kinds of disturbances often co-occur, understanding their interactive effects is essential to avoid unintended management outcomes. Fire and herbivory are two disturbances which often co-occur, but studies of their interactive effects are rare in forest ecosystems. We experimentally tested the interactive effects of prescribed fire and browsing by macropod herbivores on understory vegetation and its vertebrate fauna. Fire and herbivory interacted synergistically to affect the forest understory, with palatable plants showing poor post-fire recovery in browsed compared with un-browsed sites. Despite these strong interactive effects on vegetation, the effects of fire and herbivory on the small vertebrate fauna were additive rather than interactive. The native insectivorous mammal *Antechinus stuartii* was more frequently encountered on large herbivore exclusion sites, as was the introduced European rabbit. In contrast, the small skink *Lampropholis delicata* was more common on sites with high densities of large herbivores. Skinks, snakes and European rabbits were also more active on burnt than unburnt sites. Our results suggest that it may be necessary to manage the macropod herbivore population after fire to prevent the decline of palatable plants, and maintain the dense habitat required by some small mammals. However, as the invasive rabbit was most active in macropod-free sites after fire, any management must include both types of herbivores. Our study demonstrates that interactive effects of disturbance on vegetation communities may not lead to predictable effects on animals, and highlights the importance of considering both multiple stressors, and multiple species, in the management of disturbance regimes.

WHAT IS THE REAL COST OF CONSERVATION INVESTMENTS?: CALCULATING THE CONSERVATION OPPORTUNITY COST OF FINANCING LAND PROTECTION

Rachel Fovargue

University of Tennessee Knoxville

Paul ARMSWORTH, *University of Tennessee Knoxville* ; Joe FARGIONE, *The Nature Conservancy*

Evaluating costs of large conservation land deals is a vital but complicated component of conservation planning. For the most expensive land deals, simple acquisition costs are often confounded by loans, cost sharing and sale of easements, after which the realized cost of the deal may be significantly different than the estimated purchase price. The practice of financing is rarely considered when evaluating the cost of conservation in the conservation planning literature, even though about half of land trusts use loan financing strategies for land acquisition. We used a case study of historical land deals conducted by The Nature Conservancy, the world's largest land trust, and financed through internal loans to calculate the 'conservation opportunity cost' of financed conservation deals. This conservation opportunity cost reflects dollars that are unavailable through time for other projects, because of outstanding loans. These conservation opportunity costs of potential deals are uncertain because they are affected by the time required to repay the loans. We conclude that conservation opportunity costs do not simply reflect purchase prices, and thus may be important to consider separately to other cost estimates. We developed a regression model to show how financial characteristics of a deal, such as percent of purchase price in hand, and deal structure characteristics, such as number of conservation partners, affect the opportunity cost. Our results will help conservation planners to consider the likely conservation opportunity costs when comparing the return on investment across new conservation projects.

SPATIAL VARIATION AND THE ROLE OF WILDLIFE IN SEASONAL WATER QUALITY DECLINES IN THE CHOBE RIVER, BOTSWANA

J. Tyler Fox

Virginia Tech

Kathleen A ALEXANDER, *Virginia Tech*[INSTITUTE]CARACAL: *Centre for Conservation of African Resources*

In water-stressed regions of southern Africa, freshwater resources are under increasing extractive pressures. Sustainable management of dryland river systems is often complicated by extreme variability of rainfall in time and space, especially across large catchment areas. The Chobe River is the only permanent surface water source in the remote Chobe District of northern Botswana, and its floodplain and associated wetlands ecosystem are among the most biodiverse in the world. Seasonal rainfall and floods in the Chobe River system exert a significant impact on the timing of human activities, as well as the movement and ecology of native wildlife. Further, significant temporal relationships have been identified between hydrological dynamics in this system and diarrheal disease outbreaks in the local community. Because

of the extensive provision of ecosystem services and high subsistence value of the Chobe River, and other southern African dryland rivers and their wetlands, there is a critical need to better understand the interdependent drivers of water quality changes in the region. Using field-transect data, GIS, remote sensing, geospatial analysis, and a spatiotemporal modeling framework, we examined seasonal variation of the fecal indicator bacteria, *Escherichia coli*, and total suspended solids (TSS) in the Chobe River in relation to land use and hydrology. Distinct seasonal variations in *E. coli* and TSS concentrations coincided with a transition period between wet and dry seasons. Areas of protected land use (national park) and presence of river floodplain were significantly associated with higher *E. coli* concentrations. *E. coli* levels within the national park were also greater in locations where high-density wildlife populations occur. The results suggest seasonal wildlife presence, floodplain distribution, rainfall, and annual flood pulses influence the timing of water quality declines in this dryland river system.

CONTRASTING TRENDS IN THE BIRD POPULATIONS OF NORTH EUROPEAN PEATLANDS

Sara Fraixedas

University of Helsinki

Aleksi LEHIKOINEN, *University of Helsinki* ; Andreas LINDÉN, *Novia University of Applied Sciences*

Climate change is posing a threat to biodiversity, forcing it to adapt through shifts in species' distributions and thus altering their abundances. Given the prediction of greater temperature increases at high compared to low latitudes, species with restricted range, habitat or climatic niche may face problems. As a further complication, degradation, destruction and fragmentation of natural habitats are clearly increasing the vulnerability of species worldwide. In this context, the relevance of North European (hereinafter NE) peatlands lies not only in the role they play in the carbon cycle, but also because they act as biodiversity reservoirs. In this work we investigate the status of NE peatland birds based on data collected in breeding bird monitoring schemes. Using geometric means of common species' population indices, we analyse the state of the NE peatland bird populations in three different areas: Finland, Scandinavia (Sweden and Norway) and the Baltic region (Estonia and Latvia). While the Finnish populations have declined ca 30% over three decades, the Scandinavian ones have remained stable during the last 20 years. On the other hand, the Baltic populations show moderate increases, providing a contrast with the Finnish populations. We relate these results with the country-specific historical management of these particular ecosystems, therefore gaining insight into the target habitats that are more conducive to biodiversity. Additionally, as a follow-up of the analysis, we explore the effects of climate change by means of community climatic

indices. Our findings call for more effective conservation actions in NE peatland habitats and a deep reconsideration of the current management schemes, particularly in Finland, where the studied populations show the poorest conservation status.

ARE WE UNDERESTIMATING BIODIVERSITY LOSS USING SPACE-FOR-TIME APPROACHES?

Filipe França

Federal University of Lavras[INSTITUTE]Lancaster Environment Centre

Jos BARLOW, Lancaster Environment Centre[INSTITUTE]Museu Paraense Emilio Goeldi ; Vanesca KORASAKI, Universidade Estadual de Minas Gerais ; Juliana SILVEIRA, Federal University of Lavras ; Hannah GRIFFITHS, Lancaster Environment Centre[INSTITUTE]Federal University of Lavras ; Julio LOUZADA, Federal University of Lavras[INSTITUTE]Lancaster Environment Centre

A key challenge for conservation is assess how forest conversion and degradation reduces the biodiversity. However, are we really assessing the true impacts of human disturbances on biodiversity loss? Most of studies in literature use space-for-time substitution, implying that average changes over space are representative of changes through time. A less common approach is the temporal change approach, here considered as before-and-after, whereas the biodiversity is assessed prior and after a disturbance. We compared both approaches to evaluate if space-for-time approach may lead to underestimate the biodiversity loss of dung beetles in Amazon forest selectively logged. We detected a positive relationship between the dung beetles species richness before selective logging and the number of trees that would be removed by selective logging later, revealing that areas with greater potential for selective logging may be those which display greater biodiversity. Both approaches showed significant negative effects of selective logging intensity, but space-for-time approach showed weaker explanation, effect size and significance. Therefore, before-and-after approach had some logistical implications, such higher costs and longer time spent for data sampling. We highlight that future studies using meta-analysis to assess human disturbances impacts should be aware of underestimation of the disturbance effects on biodiversity loss when including space-for-time studies in their analysis.

SURROUNDING AGRICULTURE PRACTICES MAY IMPACT POND BIODIVERSITY: THE EXAMPLE BLACK-HEADED GULLS COLONIES

Charlotte Francesiaz

CEFE UMR 5175

Emy GUILBAULT, CEFE UMR 5175 ; Jean-Dominique LEBRETON, CEFE UMR 5175 ; Aurélien BESNARD, CEFE UMR 5175

The Forez agricultural plain (central France) comprises 343 ponds, managed for fishing and hunting purposes. These ponds present various sizes and vegetation covers and the surrounding landscape can either be openfield or wood. These man-made wetlands welcome high biodiversity, especially of waterbirds. However, there are currently suffering of significant changes due to the piscicultural crisis that might affect species at different speed and intensities. Moreover agricultural practices can as well have important consequences on the biodiversity that the ponds hosted, because they affect pond functioning or because some species use both ecosystems. Every spring, black-headed gulls, *Chroicocephalus ridibundus*, settle in ponds to breed, at the same time they feed in the surrounding ploughed fields. In this plain, the population size decreases over the last 30 years and presents a high spatio-temporal dynamics. We took advantage of the 37 years monitoring of the black-headed gull population to explore the potential relative impact of ponds and land use modifications on this decrease. We demonstrated that both agriculture practices and pond vegetation sharply change over the past 30 years, with an intensification of the former and mainly decreases of the latter. We proved that even today several ponds seem favorable to colony settlement. The cultivated lands surrounding the ponds, and the cover of bulrushes favour long occupation of the ponds by gulls, probably by allowing a better reproductive success. The decrease of helophytes and the alteration of agricultural practices, notably the reduction in the duration of tilling, have probably caused the decrease in the number of gulls observed over the past 30 years because it might have reduced their ability to construct their nests on proper vegetation and decrease the food availability needed on this crucial period of reproduction. This study shows the impact environmental conditions can have on wetlands biodiversity.

THE ROLE OF EGG PREDATION IN HERRING POPULATION DYNAMICS IN PACIFIC HERRING, PUGET SOUND, USA

Tessa B. Francis

University of Washington Tacoma

Andrew O. SHELTON, NOAA ; Gregory D. WILLIAMS, NOAA ; Phillip S. LEVIN, NOAA ; Shannon HENNESSEY, NOAA

Forage fish such as Pacific herring (*Clupea pallasii*) are ecological foundation species in many marine and estuarine ecosystems. In the Puget Sound estuary, USA, Pacific herring are an indicator species, owing to their critical position in the marine foodweb, and the regional management agency has set recovery targets to guide herring management. Puget Sound herring are spatially and temporally segregated into individual

subpopulations by their spawning behavior, and these individual subpopulations show asynchronous abundance trends over the past several decades. While the Puget Sound herring stock as a whole shows variable but largely stable biomass through time, some local spawning subpopulations have significantly declining trends. Efforts are underway to identify leading potential limitations on herring populations to inform recovery targets and potential management strategies for reaching them. Here we focus on the embryonic stage as a potential limiting stage for herring, assessing the relative importance of predation in determining herring egg hatch success, and the implications of predation rates for observed local trends in herring biomass. Using a combination of in situ incubations and predation exclusion devices, we estimated herring egg loss rates both in the presence and absence of large predators, across multiple spawning subpopulations in Puget Sound. We found that predation accounted for approximately 50% of egg loss across all spawning populations. We link predation rates to 40+ years of herring biomass estimates for each spawning population and trends in major egg predators (diving ducks) to develop hypotheses about leading pressures on herring populations in Puget Sound.

118 INTEGRATED CONSERVATION AND DEVELOPMENT PROJECTS, POVERTY AND EQUITY

Phil Franks

International Institute for Environment and Development
Helen SCHNEIDER, Fauna and Flora International

Integrated conservation and development projects (ICDPs) began in the 1980's with a narrow focus on providing alternatives to income and resources obtained from a protected area (PA). In some cases such projects evolved into a broader effort that combined interventions to decouple livelihoods from PA resources, interventions to enhance the contribution of PAs to livelihoods, and, in some cases, interventions to promote stronger community participation in PA governance. With both the narrower and broader strategies there was very often an underlying assumption that threats to conservation were essentially driven by poverty within PA-adjacent communities, and thus the "D" in ICDP was framed in terms of poverty reduction. Recent research from PAs in Uganda and Kenya suggests that the ability (or otherwise) of PA management and associated development activities to enable more equitable distribution of the benefits and costs of conservation may be as important in addressing drivers of biodiversity loss as attempts to reduce poverty (or more important). The presentation will discuss an analytical framework for understanding equity in PA management based on research in related fields, and the extent to which different notions of equity may (or may not) contribute to poverty reduction. Clearly there is a need for further research in this area. At this stage we suggest that many of the ICDPs of the

past, and much of current practice in the social dimension of conservation, might be more successful in terms of both conservation and social objectives if framed in terms of addressing (in)equity in stakeholder participation and in distribution of the costs and benefits arising from conservation and development interventions. Such a framing would utilise a broader conceptualisation of human well-being beyond a focus on addressing poverty in a purely economic sense. Some implications for policy and practice will also be explored.

CONSERVATION NEEDS FOR THE VERMETID REEFS IN THE MEDITERRANEAN SEA

Giulio Franzitta

University of Palermo

Emanuela Claudia LA MARCA, University of Palermo ; Emma CAPRUZZI, University of Palermo ; Marco MILAZZO, University of Palermo ; Renato CHEMELLO, University of Palermo

Vermetid reefs are intertidal bioconstructions typical of many subtropical and temperate coastal areas worldwide. Distributed in the warmest waters of the Mediterranean Sea, the reefs are built by the vermetid gastropod *Dendropoma petraeum* and the coralline alga *Neogoniolithon brassica-florida*, two species included in the annexes of the Berna Convention. Vermetid reefs provide a wide set of ecosystem services, such as coastal protection from erosion, regulation of sediment transport and accumulation, serving as carbon deposit and increasing biodiversity at the intertidal level. Despite its vulnerability to several threats, such as pollution, spread of invasive species, ocean acidification and anthropic use of rocky shores, the vermetid reef is only generically protected under the European Habitat Directive (92/43/EEC, code 1170), but not explicitly taken into account in many conservation management plans. On 112 censused reefs, the percentage of protected sites varies among countries. About 50 % of the reefs are officially protected in Italy, Malta, Spain, Morocco and Syria, but less than 20 % is protected in Lebanon, Tunisia and Turkey, and no protection is ensured in Algeria, Cyprus and Libya. In Israel, where protection regards more than 50 % of the reefs, *Dendropoma petraeum* got recently extinct. Up to date, less than 30 % of vermetid reefs in the Mediterranean are apparently protected by means of MPAs or coastal reserves, but a lack of information on the reef conservation status for the coastal areas of northern Africa and the eastern basin is clear. These data marks the need to extend action plans to protect the vermetid reefs and to improve its management in the Mediterranean. Developing a conservation strategy at basin scale and implementing monitoring of protected and not protected reefs are essential to guarantee an effective and sufficient protection of this neglected but relevant coastal key habitat.

133 “WHOSE FAITH, WHOSE BIODIVERSITY?” MULTISCALE ISSUES IN THE CONTRIBUTION OF FAITH TO BIOCULTURAL CONSERVATION: CENTRAL ITALY AS A CASE STUDY

Fabrizio Frascaroli

University of Zurich[INSTITUTE]University of Florida

There are increasing expectations about the role that the world's faiths can play in the conservation of biological diversity. This understanding, however, is often based on a theoretic examination of the 'values' associated with different spiritual traditions rather than on empirical evidence. In particular, it is seldom recognized that faiths are dynamic manifestations in which contrasting values and multiple levels of spatial and social organization frequently coexist. In this paper, I illustrate this multilayered character with case studies drawn from years of socio-ecological research in Central Italy. Based on spatial, ecological and ethnographic data, I show that even within the same faith tradition, Roman Catholicism, there are multiple ways to conceive and realize the relationship with the environment. I show that divergent views and tensions around the spiritual meaning and management of biodiversity-rich sacred sites are frequent. I review some of the practical and ethical implications that this has for faith-based conservation and suggest that faith-based initiatives should ideally be conceived in a framework equally attentive to both biological and cultural diversity. I conclude by calling for more systematic research in the future: without a thorough understanding of and engagement with each local context, faith-based conservation will hardly be able to deliver its expected bounty.

THE ROLE OF BUFFER ZONES IN THE CONSERVATION OF BIRDS IN PROTECTED AREAS: A CASE STUDY OF SAPO NATIONAL PARK, LIBERIA

Benedictus Freeman

Fauna & Flora International[INSTITUTE]A.P. Leventis Ornithological Research Institute (APLORI), University of Jos
Mary N MOLOKWU, Fauna & Flora International ; Filibus DAMI, A.P. Leventis Ornithological Research Institute (APLORI), University of Jos ; Kathryn SHUTT, Fauna & Flora International ; Matthew VARNEY, Fauna & Flora International

The inclusion of buffer zones in the establishment of protected areas has become a common practice in conservation. However, little is known about the efficiency of these buffer zones around national parks in Liberia and most parts of Africa. Sapo National Park (SNP) is the only national park in Liberia and contains the second-largest area of primary rainforest in West Africa. This study assessed the role of the buffer zone in the conservation of birds of SNP. Birds were surveyed using Distance Sampling with line transects. A total

of 183 bird species belonging to 55 families were recorded. Sixteen species of global conservation concern were recorded in both SNP and the buffer zone including the 'Endangered' Gola Malimbe Malimbus ballmanni and 'Vulnerable' Yellow-bearded Greenbul Criniger Olivaceous. Overall mean density of species and Pielou's evenness index were significantly higher in the Park than the buffer zone, while species richness and diversity were higher in the buffer zone compared to the Park. The high density and evenness of birds in the Park maybe attributed to the intactness and homogeneity of the forest inside the Park. On the other hand, the high species richness and slightly higher diversity in the buffer could be attributed to the heterogeneity in the buffer habitats and the observed availability of food resources (several fruiting trees and farmlands) in the buffer zone as compared to the Park during the time of this study. The presence of 16 bird species of global conservation concern and other birds in both SNP and its buffer zone suggest the conservation importance of not only the Park but also the buffer zone in the conservation of these species. Thus, to effectively conserve biodiversity in SNP, conservation planning and active management efforts should explicitly include a well-defined buffer zone around the Park.

INCORPORATING FUNCTIONAL DIVERSITY IN ECOLOGICAL INDICATORS OF CONSERVATION IN BRAZILIAN SAVANNA

Juliana Freitas

Universidade de São Paulo (USP)

Waldir MANTOVANI, Universidade de São Paulo (USP)

Developing effective ecological indicators is a great challenge of conservation. Surrogates of biodiversity are frequently used as indicator of ecosystems performance and most of times they are based on taxonomic criteria. Nevertheless, the maintenance of ecosystems functioning are more related to the role of each species in the ecosystem than to species per se. Surrogates that incorporate functional component of biodiversity are related to the niche model and may be more effective indicators. Functional diversity seeks to measure the extent of the functional differences among the species of an assembly, using functional traits diversity. Traits are defined as individual's measurable characteristics that potentially affect the species performance. The cerrado (Brazilian savanna) is one of the world's conservation hotspots and lacks of indicators for management and monitoring. We aimed to construct biodiversity surrogates for cerrado including both taxonomic and functional components of biodiversity using plants. We collected data in 2 areas covered by cerrado, in São Paulo State (Brasil). In each area we established randomly 10 plots (10m x 10m), where we identified all individuals of the tree layer to the species level. We raffle 5 individuals from each species to collect functional traits based on measure (plant height, basal area, life form) and literature (leaf phenology, reproductive

phenology, frutification, dispersal syndrome.) We calculate two taxonomic indices (Simpson and Shannon) and three widely accepted functional diversity indices (Functional Divergence, Functional Evenness and Functional Dispersion). In order to find the indicator we are applying two step analysis: TITAN (Baker and King 2010) and INDVAL (Duf rene and Legendre 1997). The preliminary results suggests that it is possible to use functional diversity to find surrogates for biodiversity and thus incorporate functional approach in conservation strategies.

FARMLAND BIRDS IN CENTRAL GERMANY: ABUNDANCE AND RICHNESS TRENDS LINKED TO SPECIES TRAITS AND LAND USE

Mark Frenzel

Helmholtz Centre for Environmental Research - UFZ
Jeroen Everaars, Helmholtz Centre for Environmental Research - UFZ; Oliver SCHWEIGER, Helmholtz Centre for Environmental Research - UFZ

Farmland bird communities have been in decline in agricultural landscapes for several decades now and we were interested in the situation in a regional agricultural area (50 x 90 km) area in Saxony-Anhalt in Germany, and how this relates to regional land use and species traits. Birds were observed in six landscapes of 4 x 4 km following the point-stop count method (20 points per site) in the years 2001, 2009, 2012, 2013 and 2014. The observations are part of ongoing work within the long term monitoring initiative TERENO (TERrestrial ENvironmental Observatoria) which aims to catalogue the long term ecological, social and economic impact of global change at the regional level. We combine bird abundance and richness data with species traits, land use and landscape configuration to explain changes in bird communities of different ecological groups.

UPDATE ON THE STATUS OF THE ENDANGERED SHORT-BEAKED COMMON DOLPHIN (DELPHINUS DELPHIS) IN THE CENTRAL MEDITERRANEAN SEA

Sylvia Frey

OceanCare
Bruno CLARO, KAI Marine; Natacha AGUILAR, University of La Laguna; Ana TEJEDOR, KAI Marine; Salvator SANCHEZ, University of La Laguna; Lorenzo BRAMANTI, Observatoire Océanologique Banyuls sur mer; Ricardo SAGARMINAGA, KAI Marine

Once considered abundant, the short-beaked common dolphin (*Delphinus delphis*) in the Mediterranean Sea has been subject to a large-scale decline during the last few decades. Despite considerable efforts in the conservation of this species, to date, only a few conservation measures have been implemented. Furthermore, although Malta is recognized

as one of the few areas of conservation importance for *D. delphis* in the Central Mediterranean Sea, the most recent studies on the species distribution in Maltese waters dates back more than one decade (Bearzi et al. 2004, Vella 2005). Here we present the results from a recent survey in Maltese waters that update the information on the species' status. A transect survey was conducted from August to October 2013 and July to September 2014. During a total visual effort of 3123 nm, 11 sightings of *D. delphis* have been recorded (4 in 2013 and 7 in 2014). Average group size was 20 individuals (SD=14), with a maximum group size of 45 dolphins. On two occasions dolphin movements were tracked for 5 h 40 min, and 1 h 20 min respectively. Our study confirms the regular presence of *D. delphis* in the waters of Malta during summer and early fall and underlines the importance of this area for this species which subpopulation in the Mediterranean Sea is listed as endangered (Bearzi 2003). However, differently from previous findings by Vella (2005), our data do not confirm the presence of large groups (150-250 animals). Despite the methodological differences which do not allow direct comparisons between the two studies, our data point to a need for further investigation on the ecology and population dynamics of *D. delphis* in Maltese waters in order to ground conservation measures for this endangered species on sound and updated data.

USE OF LIDAR DATA TO PLAN FOREST MANAGEMENT MEASURES FOR BAT CONSERVATION

Jeremy Serge Pascal Froidevaux

University of Bristol
Florian ZELLWEGER, Swiss Federal Institute for Forest, Snow and Landscape Research WSL; Kurt BOLLMANN, Swiss Federal Institute for Forest, Snow and Landscape Research WSL; Gareth JONES, University of Bristol; Martin Karl OBRIST, Swiss Federal Institute for Forest, Snow and Landscape Research WSL

Recent technological advancements in remote sensing such as Light detection and ranging (LiDAR) now allow detailed quantification of the three-dimensional structure of forest components across a hierarchy of scales. LiDAR data have rapidly become a popular tool in forest sciences, and ecologists have explored potential applications to ecology. In faunal studies, LiDAR technology was mainly applied to investigate bird response to the 3D ecosystem structure. Although bats are known to be sensitive to the vegetation structure according to their eco-morphologic traits, few studies have related bat activity and occurrence to structural components of the forest based on LiDAR. In this study, we aimed to identify key structural forest variables that affect bat guild activity and species occurrence at different scales. We collected bat acoustic data from canopy, ground and gap microhabitats at four stands within eight 1 km² landscape cells in Swiss temperate forests. Airborne LiDAR data were extracted at both forest stand and landscape scales. The relationships between forest structural

variables and bat guild activity were assessed using General Mixed Effects Models (GLMMs) and we used sites-occupancy models to relate bat species occurrence to forest variables. The main results of the study will be presented with a focus on bat conservation in harvested forests.

SYMPOSIUM 88 - BEHAVIORAL AND ENVIRONMENTAL FACTORS INFLUENCING THE VIABILITY OF TRANSLOCATED ELK IN ONTARIO

John Fryxell

University of Guelph

Luca BORGHER, University of Guelph

Elk reintroduction has been repeated several times and in several places in Ontario over the past decade. Using these aggregate data, we evaluated longer-term survival probability based on Cox proportional hazard. Specifically, we used boosted regression trees to model individual differences in survival time as a function of differences between dispersal distance, settlement time, habitat use, presence of conspecifics, or age at release. 41 elk died out of 142 radio-collared elk that were tracked on average for four years post-release. 15 of these individuals had been killed by wolves, 5 drowned, 7 were hit by a car or a train or shot incidentally by hunters, 5 died of infections or starvation, and 9 death causes were unknown. Both the timing and distance of dispersal markedly affected female elk survival, with marginal mortality risk generally increasing with distance dispersed from the release site. Interestingly, mortality risk also increased steeply for individuals who had remained close to the release site. The timing of dispersal affected the probability of survival: mortality risk was lowest for individuals who dispersed soon after release months after release. Compared to the other predictors the relative contribution of the timing and distance of dispersal was 12% and 19%, respectively. The relative influence of age was 26%, with increasing risk with age. The relative influence of differences between study areas was 15%. Use of forest habitat had a relative influence of 19%, compared to 7% for use of pastures. Conspecific presence accounted for an additional relative influence of 3%, with higher mortality risk for solitary individuals.

TARUKA IN CHILE: ENDANGERED, UNKNOWN AND UNLOVED

Nicolas Fuentes

Imperial College London

Cristina MATA, Universidad Autonoma de Madrid ; Giorgio CASTELLARO, Universidad de Chile ; Julie DONOSO, Universidad Arcis ; Denise DONOSO, Flora & Fauna Chile Ltda ; Andre

VIELMA, Universidad de Chile ; Benito GONZALEZ, Universidad de Chile

Taruka (*Hippocamelus antisensis*) is a Neotropical deer, which lives in the Central Andes of South America between 2,000 and 4,000 m.a.s.l., a desert biome dominated by rocks and cliffs interspersed among agricultural areas. In Chile, taruka are listed as "Critically Endangered" due to conflicts with local people, small population size (about 500 individuals), and insufficient information to develop conservation strategies. We conducted a survey between 2012 and 2014 to study habitat availability in Chile and understand the human-wildlife conflict. To assess habitat availability, we built a distribution model using data from taruka sightings and indirect signs of presence. To characterize the conflict we assessed if tarukas prefer areas close to crops using preference-availability analysis, and we studied the diet of individuals around villages conducting microhistological analysis to faeces collected during the dry and wet seasons. Finally, we assessed people's perceptions of tarukas through surveys and workshops. The distribution model estimated a total of 22,000 [ha] as suitable habitat for tarukas in Chile, 89% of which (19,579[ha]) is unprotected. We found that tarukas prefer areas close to crops (60±15.2 %) in spite of their availability (26%). In the diet assessment, we found that groups living close to villages eat alfalfa crops (*Medicago sativa*) increasing their intake during the dry season (51.3±10.6 % during dry season; 12.1±3.6 % during wet season). Through 43 surveys, we found 44% of people do not tolerate tarukas because of crop damage and cultural beliefs. They believe the best solution to this conflict is fencing their crops (75%) and killing tarukas (38%). Considering the limited information available, the high proportion of unprotected habitat, and its conflict with local communities, we conclude that it is necessary to focus management actions on understanding and reducing the human-deer conflict in order to promote their recovery in Chile.

ASSESSING THE RELATIVE IMPORTANCE OF LOCAL VS. LANDSCAPE LEVEL ACTIONS TO DEVELOP ECOLOGICAL NETWORKS

Elisa Fuentes-Montemayor

University of Stirling

Kevin WATTS, Forest Research ; Nicholas MACGREGOR, Natural England ; Kirsty PARK, University of Stirling

Current actions to reconnect fragmented landscapes include creating new habitat patches and restoring, expanding and connecting existing patches to develop functional 'ecological networks' (a suite of core habitat areas connected by buffer zones, corridors and 'stepping stones' that allow movement of species or their propagules). However, there is much uncertainty on the relative importance of alternative actions (e.g. increasing habitat area vs. connectivity) to develop

ecological networks. As part of an ongoing collaborative research project (Woodland creation & Ecological Networks; WrEN) between academics, policy makers and conservation practitioners, we surveyed 100 secondary woodland patches in the UK to study how different taxa were influenced by local- and landscape-level woodland attributes related to the ecological network concept. Our surveys focused on a range of species with different life-history traits (e.g. habitat specificity and dispersal abilities), including ground beetles, small mammals and bats. Preliminary analyses indicate that taxa differ in their response to local- and landscape-level woodland attributes, depending partly on their dispersal abilities. The abundance of ground beetles (limited dispersal) was negatively related to woodland size and age, and positively to proximity to nearest woodland and amount of woodland in the landscape (< 3 km). The abundance of small terrestrial mammals (e.g. *Myodes glareolus*, intermediate dispersal) was related (positively) to woodland size, and (negatively) to woodland age and the amount of woodland in the landscape. Bat (e.g. *Pipistrellus pygmaeus*, higher dispersal) activity levels were mainly related (positively) to the amount of woodland in the landscape, and marginally to woodland age (positively). Our results suggest that local-level conservation activities are particularly important for lower-mobility species. For higher-mobility species, both local- and landscape-level actions are required.

197-LIFE IN EUROPEAN RIVERS: LEGISLATIVE FRAMEWORK AND FRESHWATER BIODIVERSITY

Leopold Füreder

Institute of Ecology, University of Innsbruck

European freshwaters, although on the continental range abundant and variable, are under intense pressure from multiple use, pollution and habitat degradation. Freshwater integrity but also freshwater ecosystem services to society have been reduced significantly. Ecosystem structure and function including the biota are strongly affected, with several aquatic species disappearing from entire ecoregions. Climate change will also play a significant role. In Europe, the principal legal instrument to halt the deterioration of aquatic ecosystems is the Water Framework Directive, which aims at restoring aquatic ecosystems back to good status. Together with other legislative frameworks, primarily the Fauna Flora Habitat Directive and the Wild Birds Directive, it should improve, restore and conserve freshwater biodiversity. These two directives form the basis of the so-called Natura 2000 network, which has been set up in order to protect the most seriously threatened habitats and species across Europe. The LIFE programme, an EU funding instrument for the environment, began in 1992 to co-finance best practice or demonstration projects that contribute to the implementation of the Birds and Habitats directives and the

Natura 2000 network. Here it is demonstrated and critically discussed, i) how LIFE projects do consider aquatic habitats and associated endangered species, ii) how river restoration and species conservation interact to improve freshwater biodiversity, and, finally, iii) how connectivity analyses could be used within this context to assess and improve freshwater biodiversity and integrity.

MONITORING FISHER (*PEKANIA PENNANTI*) AND OTHER FOREST CARNIVORES ACROSS A LARGE GEOGRAPHIC AREA USING CAMERA TRAPS AND HIERARCHICAL MODELS OF DETECTION/NON-DETECTION DATA

Brett Furnas

California Department of Fish and Wildlife

Russ LANDERS, California Department of Fish and Wildlife ;

Heather BARRETT, California Department of Fish and Wildlife ;

Richard CALLAS, California Department of Fish and Wildlife

The fisher (*Pekania pennanti*) is a forest carnivore proposed for listing as "threatened" in California and other Pacific States under the US Endangered Species Act. From 2011 to 2013 a total of 292 baited camera stations was surveyed for fisher and other carnivores across a 2.8 million ha area in northwestern California. We used hierarchical models of the detection/non-detection data to estimate occupancy at 2 survey scales (stations and pairs of stations 1.6 km apart) and abundance at the station-scale. We estimated an average occupancy of 0.418 [90%CI: 0.345, 0.492] for stations and 0.608 [90% CI: 0.515, 0.702] for pairs of stations, and an average abundance of 0.825 [90%CI: 0.581, 1.068] fishers per station. Of stations at which fisher occurred, we estimated 65% had 1 fisher, 25% had 2 fishers, and 10% had >2 fishers. Simulations calibrated from these estimates suggest that continuation of annual surveys at a rate of 100 new stations each year would provide 80% power for observing declines in occupancy as small as 1.5% per year over 20 years or 4% per year over 10 years. We also found that occupancy and abundance were associated with the percentage of the 10-km-radius area surrounding each station that had burned over the preceding 50 years. Both metrics were maximized when approximately 36% of the surrounding area had burned, which is greater than the average frequency (25%) of fire across the study area for these spatial and temporal scales. Besides furnishing a wealth of data on a single species of conservation concern, we are using the same surveys to concurrently monitor a variety of other mammals for little additional cost. In particular, by combining data from fisher and 8 other forest carnivores in a multi-species occupancy model, we estimated that 6 of these 9 species had an average detection probability > 80% after 30 days.

CASCADE EFFECT OF INSECTIVOROUS BIRDS ON ARTHROPOD ABUNDANCE AND HERBIVORY

Bruna Leone Gagetti

Universidade Federal de São Carlos

Suelen Barbosa MORAES RODRIGUES, Universidade Federal de São Carlos ; Augusto João PIRATELLI, Universidade Federal de São Carlos

Birds are important predators of arthropods and may influence their abundance and diversity, which in turn can affect leaf herbivory and the adaptive value of plants. Here we tested the top-down effect of insectivorous birds in the abundance of foliage arthropods and levels of leaf herbivory in an Atlantic Forest area of southeastern Brazil, assessing the spatial effects. The study was carried out from October 2013 to March 2014 in three sites having different successional stages. We sampled abundance and diversity of birds through 12 fixed-point counts. We restrict the access to the branches by birds using exclosures in 48 trees of Melastomataceae species for four months, and to control for exclusion effects, we added an open-net treatment. The abundance and diversity of arthropods were estimated by the branch clipping methodology, and herbivory was evaluated by measuring the area of 384 leaves. Results were compared by linear multiple regression analysis. We sampled 136 arthropod-eating birds, and the exclusion of birds has resulted in a higher amount of arthropods in the branches ($p=0.0018$) as well as an increased richness of arthropod orders ($p=0$) in all studied sites. However, other factors as successional stages and abundance and diversity of birds did not significantly affect these results. The herbivory was not influenced by any of the studied parameters. Thus the exclusion of birds has affected abundance of arthropods, but not herbivory, which may be driven by other factors not evaluated here, as an increase in arthropod predators.

HIGH PARASITOID DIVERSITY IN REMNANT VEGETATION, BUT LIMITED SPILLOVER INTO THE AGRICULTURAL MATRIX IN SOUTH AFRICAN VINEYARD LANDSCAPES

René Gaigher

Stellenbosch University

James PRYKE, Stellenbosch University ; Michael SAMWAYS, Stellenbosch University

The maintenance of remnant natural vegetation in agricultural landscapes is an important component of conservation programmes that promote farmland sustainability. Demonstrating the biodiversity value of remnant vegetation can support conservation initiatives in production landscapes. We assessed the diversity and assemblage structure of hymenopteran parasitoids in fragments of native scrubland

(fynbos) within vineyard landscapes in the Cape Floristic Region of South Africa. We also aimed to detect positive effects of adjacent fynbos on vineyard parasitoids, such as elevated diversity at vineyard edges adjoining fynbos or evidence of parasitoid spillover into vineyards. Fynbos remnants had significantly higher parasitoid abundance and richness than neighbouring vineyards, and supported assemblages distinct from those within vineyards. However, proximity to fynbos had no effect on vineyard parasitoid diversity, and evidence for spillover was limited, as there were abrupt changes in assemblage structure at fynbos/vineyard boundaries. Surrounding vineyards seem to have a fragmenting effect on parasitoids in remnants, emphasising the need to increase the permeability of the vineyard matrix. Yet, our results show that remnants are important for retaining parasitoid diversity and may provide refugia for certain species within the disturbed agricultural environment. Approaches that combine natural remnant conservation with arthropod-friendly activities in vineyards may be the most effective way to support diverse and functional parasitoid assemblages at the landscape scale. Conservation of this diversity will be crucial for maintaining long-term ecological resilience in agricultural landscapes.

WHEN COMMON BIRDS BECAME RARE: HISTORICAL RECORDS SHED LIGHT ON LONG-TERM RESPONSES OF BIRD COMMUNITY TO GLOBAL CHANGES IN THE LARGEST FRENCH WETLAND

Thomas Galewski

Tour du Valat

Vincent DEVICTOR, Institut des Sciences de l'Evolution

We propose a new method to reconstruct the past structure of a species community in a given area, based on historical naturalist literature. We think that providing that major bias are identified, details and information on the status of species provided by checklists and various reports can be relevant to identify species constitutive of a community, characterize their relative abundance, and highlight major changes in status over time. We reviewed ornithological literature dedicated to the Camargue, the largest wetland in France. It was possible to reconstruct the entire breeding bird community from 1830 to present day. Qualitative information depicting the abundance of species was translated into semi-quantitative data, allowing the calculation of a Community Commonness Index, measuring the average level of commonness of species in a community. Two other multi-species indices were used to evaluate the potential past impact of land-use and climate change on the composition of the bird community. Community Commonness and Community Specialisation Indices simultaneously dropped between 1950 and 1980, suggesting that change in land-use negatively impacted the structure and composition of the local bird community by reducing the number of individuals per species and decreasing the

representation of habitat-specialised birds. Indeed, land-cover data show a major loss in natural habitats in the Camargue at that time due to conversion to cultivated and industrial areas. This general and unsuspected decline contrasts with long-term increases shown locally by well-monitored colonial waterbirds. Our results plead for a more regular use of historical naturalist data when assessing the conservation status of a population or a species community as they allow the establishment of an older baseline and encompass more species than data issued from monitoring schemes.

33-THE IMPORTANCE OF SOCIAL NETWORKS IN EFFECTING BEHAVIOR CHANGE THROUGH POLICY

Sarah Gale

Michigan State University

This study explicates an innovative theoretical framework that combines the Advocacy Coalition Framework (ACF) with Social Network Analysis (SNA) to understand policy processes in environmental sectors. This approach draws on scholarship from policy and social network literatures on the management of knowledge, resource sharing, information flow and exchange, and group formation. Taken together, this literature demonstrates that both the macro-level policy context and the micro-level local social relations facilitate and limit policymaking and implementation processes in environmental policy sectors. I discuss how policy-oriented social networks, which can be observed empirically using SNA techniques, influence the exchange and acquisition of a wide breadth of policy-related information and resources, such as new innovations and reform-related political and technical knowledge. Moreover, network structures and the network location of individual actors play an important role in effecting the implementation of new policies and reforms through bridging and brokering activities. Finally, I consider the potential of SNA visualizations for designing strategies for change within and between environmental policy organizations for more effective advocacy, policymaking and policy implementation behaviors.

ASSESSING CAUSES OF THE DECLINE OF LITORIA AMPHIBIANS IN AUSTRALIA USING SPECIES DISTRIBUTION MODELS.

Catharina Gallacher

National University of Singapore

David BICKFORD, National University of Singapore ; Ryan CHISHOLM, National University of Singapore

Amphibians display a wide array of physiological adaptations and have colonised a diversity of terrestrial and aquatic environments. They rely on multiple habitats, generally exhibit low vagility and have permeable skin that makes them

sensitive to changes in their direct environment. Currently, the IUCN estimates that globally around 41% of amphibians are threatened with extinction. For example the Australia genus *Litoria* has 26% of its species listed in one of the threatened categories. Amphibians are often exposed to many threats simultaneously, such as disease outbreaks, habitat destruction, invasive species, pesticides and impacts from climate change. The simultaneous nature of these threats makes it particularly difficult for species to adapt and increases the chance of extinction. Devising effective strategies to assess the impacts of various threats on populations of amphibian species is therefore imperative. Species Distribution Modelling (SDM) can be used to assess current amphibian species distributions and explore different future scenarios. SDM has the advantage of being able to overlay multiple environmental factors that might affect a species distribution and can potentially help to identify areas that are in need of conservation efforts as well as to quantify what factors have the biggest impact on a species' distribution. In this study we used presence-background SDMs with bioclimatic, disease, land use and vegetation layers to explore the changes in distribution of Australian *Litoria* amphibians. By comparing historical distributions with current distributions and projecting future distributions, we explore which environmental variables have the overall biggest impact, and assess whether impacts differ across species within the *Litoria* genus.

SINGLE-SPECIES MANAGEMENT HAS LONG-TERM CONSEQUENCES FOR NON-TARGET WILDLIFE

Travis Gallo

Colorado State University

Lani STINSON, Colorado State University ; Liba PEJCHAR, Colorado State University

Habitat alterations intended to benefit a single species or suite of species are widespread, yet their effects on non-target wildlife are poorly addressed. Given the broad and increasing impact of anthropogenic activities on biodiversity, advancing our understanding of the costs and co-benefits of single-species management for other species of conservation concern is warranted. We investigated the long-term effects of mechanical forest reduction designed to benefit mule deer (*Odocoileus hemionus*), an economically important game species, on non-target bird and mammal communities in Colorado, USA. We conducted bird point counts and established wildlife cameras in sites where trees were mechanically removed forty years ago, and in undisturbed reference sites. We compared bird and mammal habitat use among these treatment and control sites using dynamic occupancy modeling, and determined the ecological parameters (e.g. vegetation structure and composition) that had the greatest influence on the probability of use. Our results suggest that forest reduction catalyzes a long-term

change-of-state from dense pinyon-juniper forest to sagebrush scrub, consequently changing the wildlife communities that use these areas. We also found that particular wildlife guilds were influenced by specific vegetative characteristics that could be factored into management decisions. For example, bark-gleaning birds were 53% more likely to use reference sites over historically disturbed sites and mean tree diameter had the greatest positive influence on the probability of their presence. Therefore, using forest-clearing techniques that retain some large standing trees may reduce the long-term impacts of mechanical disturbance on bark gleaning birds. By understanding both the short and long-term consequences of single-species management on non-target species, we can enhance our ability to protect and restore the biodiversity of natural communities.

HUNTING OF MIGRATORY SHOREBIRDS IN THE EAST ASIAN-AUSTRALASIAN FLYWAY: A REVIEW OF THE EVIDENCE

Eduardo Gallo-Cajiao

The University of Queensland

Richard A. FULLER, The University of Queensland

Migratory shorebirds have declined in the East Asian-Australasian Flyway (EAAF) due to multiple threats. Evidence is accumulating that habitat loss is a key driver, though hunting may also account for the decline of particular species. However, the evidence of this activity in this flyway seems patchy both temporally and spatially. This is inadequate to inform policy, as effects of hunting can only be appraised at a flyway scale. We reviewed all the available evidence on hunting of migratory shorebirds across the flyway to (i) characterise the evidence base, (ii) assess the magnitude and spatial patterns of hunting, and 3) identify the socio-economic contexts of hunting. We searched thoroughly for relevant references and obtained 125 of the 155 located. Most references presented anecdotal evidence and corresponded to grey literature. Hunting of migratory shorebirds has been detected in 77% of the countries in the EAAF. Of all its migratory shorebird species, 73% have been hunted, including threatened and least concern species. When all figures per species are pooled, 12 species have had minimum annual harvest levels of over 1,000 individuals. This harvest has not been even, as there are differences in target species and magnitude of hunting between localities. Hunting has been practiced for sport, subsistence, and commercial purposes, with geographic variations. Migratory shorebirds have been subject to hunting at some localities for extended periods of time, warranting further research at those places with no current data. Unfortunately, the full magnitude of hunting remains unknown across the EAAF, because the evidence is largely anecdotal and not robust. This pitfall precludes any assessment of potential impacts of hunting on population dynamics, though they may

be considerable. Modelling studies and a monitoring scheme are urgently required, especially at a time when other stressors are at play on these birds in this flyway.

THE STUDY OF BEHAVIORAL ECONOMICS OF LIONFISH FISHERIES TO IMPROVE CORAL REEF MANAGEMENT EFFECTIVENESS

Nohora Galvis

Fundación ICRI Colombia en Pro de los Arrecifes Coralinos
Rosa Helena GALVIS, Fundación ICRI Colombia en Pro de los Arrecifes Coralinos

The red lionfish native from the Indo Pacific is in the Caribbean Sea as an invasive species (*Pterois volitans*). Its population has been attempted to be controlled in the Colombian Caribbean by developing an artisanal fishery. This activity resulted to be an economic alternative to the overfishing that faced the native commercial species. It represents a win-win-win policy since it provides ecological, social and economic solutions to improve coral reef management effectiveness. A detailed study has identified the behavior of the community of fishermen (SWOT Analysis and CPEU Database), media, scientists and managers since the appearance of lionfishes in the coral reef areas of Colombia until the development of a national market. This publication facilitates public action.

EXTINCTION RISK IN MIGRATORY BIRDS

Veronica Gama

The University of Queensland

Morena MILLS, The University of Queensland ; Richard FULLER, The University of Queensland ; Simon BLOMBERG, The University of Queensland ; Judit SZABO, Charles Darwin University ; Cagan SEKERCIOGLU, University of Utah ; Hugh POSSINGHAM, The University of Queensland

Extinction does not occur randomly and is often correlated with traits such as large body size, high specialization, small population and small geographic range size, among others. Most species extinction risk assessments are based on measures of abundance and range but both of these traits are usually problematic to obtain and evaluate for migratory species. The distribution of migrants is highly dynamic in space and time, thus monitoring their range and abundance is more difficult than it is for their sedentary counterparts. Failure to properly account for these traits in the extinction risk assessments could result in misleading threat classification and consequently leave species without the protection they need. In this study we untangle the drivers of extinction risk for migratory bird species considering a large array of correlates of extinction and phylogenetic comparative methods at two different scales: globally and in Australia. We determine whether migratory birds are more threatened than non-migrants and also discover whether different forms of

migration (full, altitudinal and nomadic) are associated with different levels of extinction risk.

IS BIGGER BETTER? UNDERSTANDING THE EFFICIENCY OF EXPANDING PROTECTED AREAS

Edward T Game

The Nature Conservancy

Laurel B FINK, University of Queensland

Protected areas remain the backbone of global conservation effort. In 2011, signatories to the Convention on Biological Diversity (CBD) agreed to increase the protected areas target from 10% to 17% for terrestrial ecosystems (Aichi Target 11). Although few countries had previously met the 10% target, many had completed conservation assessments that identified critical areas to meet this target. We investigated whether the increased CBD target would mean that plans based on 10% targets were now inefficient. We used MARXAN develop conservation plans for five countries with both 10% and 17% targets. In an ideal situation all of the priority locations in the 10% scenario would also be present in the 17% scenario. This would indicate that conservation assessments done with 10% targets remained efficient despite the target increase. Unfortunately, the average percent overlap between priority areas for the 10% scenario and the 17% scenario was only 33%, meaning that conservation plans based on 10% targets represent inefficient priorities for the revised 17% targets. This inefficiency has major implications for national protected area planning.

WITHIN AND AMONG-INDIVIDUAL VARIATION MAY DETERMINE TIGER OCCUPANCY AND CONNECTIVITY IN HUMAN-DOMINATED LANDSCAPES

Aditya Gangadharan

University of Alberta

Srinivas VAIDYANATHAN, Foundation for Ecological Research Advocacy & Learning ; Colleen ST. CLAIR, University of Alberta

The conservation of flagship carnivores (e.g., tigers *Panthera tigris*) often catalyzes the designation and funding of reserves, co-incidentally also protecting numerous other threatened species. Hence, the persistence of these co-occurring species may be tied to large carnivore persistence. In turn, carnivores may need to use and move through mixed-use zones outside reserves to survive. Yet, the habitat and behavioral traits determining large carnivore presence in multiple-use areas are poorly studied. We evaluated four hypotheses to explain tiger presence in a human-dominated 302 km² linkage between two reserves in the Western Ghats biodiversity hotspot, India: (a) spatial habitat characteristics (b) temporal segregation of space with humans; (c) individual tiger variation in prey associations and human tolerance; and, (d) the influence of body state on prey associations and human tolerance.

We tested these hypotheses using mixed-effects logistic regression, based on 36,855 trap-days at 445 camera-trap locations from 2011 to 2013. Tiger presence was positively correlated with detection rates of the large, human-sensitive gaur (*Bos gaurus*), and distance to human infrastructure. Tigers were less active by day, regardless of distance to human infrastructure. One individual ventured significantly closer to settlements than others. When this individual was in a poor body state, it also avoided gaur-rich areas (i.e., it used more human-dominated areas), bringing it closer to crossing critical connectivity gaps than other tigers. Thus, behavioral variation among and within individual carnivores may influence use of fragmented landscapes, resulting in higher occupancy and greater functional connectivity than would be expected from studies conducted within protected areas. Greater attention to individual-level characteristics in landscape-scale monitoring programmes could help managers enhance connectivity, while also anticipating potential conflict with people.

PERCEPTIONS AND INFORMATION ON ELEPHANT IVORY TRADE IN CHINA: APPRAISAL AND RECOMMENDATIONS

Yufang Gao

Yale School of Forestry & Environmental Studies

Susan CLARK, Yale School of Forestry & Environmental Studies

African elephant poaching has escalated to an untenable level. Western NGOs and media generally attributes the problem to China's internal ivory market. Chinese authorities often accuse international community of using inaccurate information and exaggerating Chinese demand for ivory. A solution to the poaching problem remains elusive. We contextualized the claims and counter-claims to find a new basis for effective conservation. Data came from analysis of Chinese news articles in 2003-2013, interviews and participant observation in China and Africa in 2013-2015. Our findings showed that international community and diverse interests inside China held different narratives about the ivory trade. Most NGOs and media blamed the Chinese demand for ivory's high price. Chinese, in contrast, insisted the limited supply was the price driver. Most NGOs and media considered the Chinese middle class as major ivory buyers; Chinese suggested it was the Baofahu (the "suddenly wealthy"). Most NGOs and media aimed at addressing ivory's symbolic social status value; Chinese media hyped up ivory artworks' economic value as investment alternatives. We also evaluated adequacy of the information activity (i.e., the gathering, processing, and dissemination of information) in the global dialogue about the ivory trade issue. We found that the information function at place only partially met widely accepted standards of dependability, comprehensiveness, selectivity, creativity, and availability. We suggested how to integrate reliable knowledge and improve the information activity to help all parties achieve a shared understanding of

the problem. Our recommendations encourage integration and harmony among the contending perspectives, which will potentially rehabilitate elephant conservation at both strategic and tactical levels and expand opportunities for significant international cooperation on the ivory trade issue as well as other urgent conservation matters.

VEGETATION SHIFTS AND COMMUNITY CONSERVATION ISSUES DUE TO CLIMATE CHANGE IN THE HOLARCTIC

Ágnes Garamvölgyi

Corvinus University of Budapest

Levente HUFNAGEL, Szent István University

Climate change is one of the most significant global challenges nowadays. Changes in temperature and precipitation pattern and increases in greenhouse gas concentration will alter numerous site factors and biochemical processes such as nutrient and water availability, fire regime, biotic interactions and invasion. As a consequence, climate change is expected to alter distribution ranges of many communities as well as boundaries of biomes. Objective of my research is to overview observed and predicted changes of vegetation distribution in the Holarctic and discuss need and possibilities of ex situ community conservation. Available literature on possible vegetation shifts in Europe, Siberia and North America was reviewed, main conclusions were summarized and potential area changes were estimated. Current and potential distribution changes are described according to geographical regions including the Alps, Scandinavia, Western Europe, Southern Europe, Central Europe, Siberia, Canada, Alaska, California, Southwestern, Eastern and Southeastern USA, the Great Lakes region, the Great Plains, intermontane basins and plateaus, the Rocky Mountains and the Cascades. Main trends are similar in Eurasia and North America: northward shift of several biomes and the tree line and upward shift of mountain communities; shrub expansion in the Arctic; reduction of boreal forests with increasing number of broadleaved species; drought tolerant species and communities becoming dominant in temperate forests; emergence of invasive species; reduction of alpine communities; structure and composition change in grasslands as well as reduction of wetland areas and marshes. Changes of vegetation patterns emphasise the need for ex situ conservation of communities besides current in situ efforts. In order to be able to help communities to migrate and adapt, different methods and tools of ecological engineering and landscape architecture are analysed and evaluated.

CURBING 'INEVITABLE' ILLEGALITY IN PROTECTED AREAS: A COLLABORATIVE APPROACH

Ch Garcia

Ya'axche Conservation Trust

Kamille PENNELL, Ya'axche Conservation Trust ; Bartholomew TEUL, Ya'axche Conservation Trust ; Lee MCLOUGHLIN, Ya'axche Conservation Trust ; Jaume RUSCALLEDA ALVAREZ, Ya'axche Conservation Trust ; Maarten P G HOFMAN, Dept. of Wildlife Sciences, Georg-August University of Göttingen[INSTITUTE] Ya'axche Conservation Trust[INSTITUTE]School of Environment, Natural Resources and Geography, Bangor University

Protected areas (PAs) worldwide are under increased pressure due to encroachment from unsustainable, often illegal, human activities. In developing countries, this frequently originates from a lack of economic opportunities for the people in the surrounding area and an increased need for resources and land by growing human populations. At the same time, governments can't afford to put adequate funds towards PA management, or do not regard it as an economic or political priority. These factors can result in uncontrolled habitat destruction inside PAs. In Belize, a country just south of Mexico, a local environmental NGO has collaborated with communities, the government and the private sector to curb ongoing illegal clearcutting, farming and settlement inside PAs. By providing the opportunity to the trespassers to remain in the area under set conditions, the conflict between the goals of the PA and the communities' needs is minimized. Organized farmer's collectives can apply for a cacao-based agroforestry concession stipulating strict guidelines to minimize impact on natural systems inside the PAs, while still providing income for the farmers. Cacao is rising as a major cash crop for small-scale farmers in southern Belize, with a promising global market and a supporting local private sector. It has been grown by local populations for centuries and plays an important role in local cultures. Due to its need for sufficient canopy cover to grow, the crop is ideally suited for less disturbing farming practices, while farmers can harvest products such as timber, fruits and non-timber forest products from the farm set up. The NGO provides the training and support for efficient operation of the concession, while the private sector provides product processing and marketing. This Belizean case study is an example of how fruitful collaboration between communities, private sector, NGOs and government can successfully mediate inevitable destructive impacts on natural systems.

A NATIONAL ASSESSMENT OF THE SUCCESSIONAL STATE AND ANTHROPOGENIC PRESSURES OF TROPICAL DRY FORESTS IN COLOMBIA.

Hernando Garcia

Instituto de Investigación de Recursos Biológicos Alexander von Humboldt

Camila Pizano, Instituto de Investigación de Recursos Biológicos Alexander von Humboldt ; Roy GONZALEZ,

Instituto de Investigación de Recursos Biológicos Alexander

von Humboldt ; Paola ISAACS, Instituto de Investigación de Recursos Biológicos Alexander von Humboldt

Tropical dry forests (TDF) have been heavily fragmented in Colombia, where 8% of the original TDF remain, and only 5% of what is left is under protection. Moreover, more than 90% of the remaining dry forests remain in private areas, making it urgent to find incentives for landowners to preserve the little TDF left. Our objective was to quantify the successional state and anthropogenic pressures of TDF at the national level. To do this, we assessed TDF structure (early, intermediate and late succession) and anthropogenic pressures (cattle, agriculture, fire, human infrastructure, mining, wood harvesting) in 800 geographic points across the six regions where TDF occurs: the Caribbean, the Cauca valley, the Magdalena valley, the Patía Valley, Northeastern Andes, and the Llanos. We found that the most fragmented dry forests are found in the Cauca Valley, where only 20% of the geographic records contained late successional forests. In contrast, 88-90% of the records from the Caribbean and Llanos regions contained late successional forests. In the Caribbean, 77% of records also contained early successional forests, while in the Llanos no records contained early successional forests. At all points we detected at least one anthropogenic disturbance, with agriculture, cattle ranching and human infrastructure being the most pressing disturbances throughout the country. Based on these data, we present conservation and management priorities for TDF in both natural and productive lands. In particular, we discuss management alternative models for private lands where the majority of TDF are found in Colombia, and conservation incentives are mostly needed.

INTEGRATING BIRD TAXONOMIC, FUNCTIONAL AND PHYLOGENETIC DIVERSITY FOR CONSERVATION MANAGEMENT IN HIGHLY THREATENED ECOSYSTEMS OF THE COLOMBIAN ANDES

Hernando Garcia

Instituto de Recursos Biológicos Alexander von Humboldt
Elkin TENORIO, Instituto de Recursos Biológicos Alexander von Humboldt ; Paola MONTOYA, Instituto de Recursos Biológicos Alexander von Humboldt ; Beatriz SALGADO-NEGRET, Instituto de Recursos Biológicos Alexander von Humboldt ; Maily GONZALEZ, Instituto de Recursos Biológicos Alexander von Humboldt

The Colombian Andes are among the most diverse world's biodiversity hotspots. Highly threatened by human settlement, highland ecosystems in the Andes now face major pressures from gold mining, among other human activities. Paramo a unique highland ecosystem that provides water to all major cities in the country, has been recently excluded from mining by the Colombian law. Accordingly, the Colombian Ministry of Environment requested the characterization and delimitation

of paramos at the national level in 2013. In this study we focused on how bird taxonomic, phylogenetic and functional diversity of Colombian paramos increase our understanding of these highly diverse ecosystems, in addition to provide useful information for their management. Taxonomic diversity was assessed at a 1km² scale based on 800 species distribution models, while indices of functional richness (FD) and dispersion (FDiv) were measured from five traits of 6000 individuals corresponding to 399 species assessed. Phylogenetic diversity was defined as the sum of branch lengths of bird species present in each community, which was assessed using a bird global phylogeny. All indices were corrected by species number with linear regressions and species distribution null models. Our results show that the three components of diversity are decoupled. The highest levels of taxonomic diversity were found in the Eastern Cordillera and North part of the Central Cordillera, while the lowest levels were found in Central Cordillera. Only the Eastern flank of the Eastern Cordillera had higher levels of phylogenetic diversity than expected. In contrast, functional diversity did not show a significant geographic structure. These results suggest that different biodiversity components change within and between paramo complexes. Thus, integrating other components of biodiversity is crucial for future management and conservation planning of these highly diverse areas.

WHY AND HOW MIGHT GENETIC AND PHYLOGENETIC DIVERSITY BE REFLECTED IN THE IDENTIFICATION OF KEY BIODIVERSITY AREAS?

Jaime Garcia Moreno

ESiLi

Thomas BROOKS, IUCN ; Annabelle CUTTELOD, IUCN ; Dan FAITH, Australian Museum ; Penny LANGHAMMER, Arizona State University ; Silvia PEREZ-ESPONA, Anglia Ruskin University

'Key biodiversity areas' (KBAs) are defined as sites contributing significantly to the global persistence of biodiversity. Their identification builds from existing approaches based on measures of species and ecosystem diversity and process. Here, we build from the work of Sgro' et al. (2011 *Evol. Appl.* 4, 326-337) to extend a framework for how components of genetic diversity might be considered in the identification of KBAs. We make three recommendations to inform the ongoing process of consolidating a KBA standard. These include genetic diversity within species, phylogenetic diversity among species and the evolutionary processes which drive and maintain both of these, namely: (i) thresholds for the threatened species criterion currently consider a site's share of a threatened species' population; expand these to include the proportion of the species' genetic diversity unique to a site; (ii) expand criterion for 'threatened species' to consider 'threatened taxa' and (iii) expand the centre of endemism criterion to identify as KBAs those sites holding a threshold proportion of the

compositional or phylogenetic diversity of species (within a taxonomic group) whose restricted ranges collectively define a centre of endemism. We also recommend consideration of occurrence of EDGE species (i.e. threatened phylogenetic diversity) in KBAs to prioritize species-specific conservation actions among sites. Our recommendations for incorporation of components of biodiversity below the species level into existing KBA criteria span aspects of composition, structure and function of genetic diversity, and also the breadth of mechanisms for putting this into practice. We believe the implementation of these recommendations would allow confidence in the claim that such sites do indeed contribute significantly to the global persistence not just of species and ecosystem components of biodiversity but of genetic components as well.

ID 177 AZTECA CHESS AND AGRODIVERSITY: EDUCATIONAL TOOLS TO EXPLORE THE EMERGENCE OF FUNCTIONAL BIODIVERSITY IN AGROECOSYSTEMS

Luis García-Barrios

El Colegio de la Frontera Sur

John PERFECTO, University of Michigan ; John VANDERMEER, University of Michigan ; Erika SPEELMAN, Wageningen University

The complexity, relevance, challenges, and beauty of many ecological and socio-ecological processes are not easily grasped by social actors collectively involved in their (mis) management. We have developed a number of original stylized board games and interactive agent based models that allow participants coming from the most contrasting social and educational backgrounds to experience and understand the nonlinear processes and the surprising properties, challenges and opportunities that emerge at different scales in biodiverse socio-ecological systems. AZTECA CHESS is a two-player table board strategic game, based on thorough, long term ecological research by Vandermeer, Perfecto and collaborators. It captures in a stylized form some of the cascading interactions that occur among a number of insects and fungi species in the mesoamerican shade coffee agroecosystem, and its practical implication for autonomous pest control. Among the species involved are *Azteca instabilis* – a keystone species ant- and *Hemileia vastatrix* which is currently producing a severe coffee rust epidemics in Latin America. AGRODIVERSITY v.2 is an agent based model in Netlogo language, in which fictional populations of a crop (strawberry), a weed, an herbivorous insect that consumes the crop, and a predator spider that consumes the insect interact in a 2D field. This interactive ABM challenges users to find the biological and management parameters with which functional biodiversity can self-organize to produce ecological and economic sustainability far from equilibrium (i.e. strawberry fields forever). We briefly describe

the tools and present initial results on learning by farmers and students who have interacted with them.

82-TRADE-OFFS AND SYNERGIES IN THE SOCIAL-ECOLOGICAL VALUES ASSOCIATED WITH DIFFERENT LAND-USES IN THE EASTERN AMAZON

Toby Gardner

Stockholm Environment Institute

Achieving more sustainable development trajectories in tropical agricultural frontiers depends partly on our ability to understand the relationships, including potential trade-offs and synergies, between forest conservation and rural development objectives. Here we extend existing work in this area using survey data from 36 landscapes and nearly 500 properties in the eastern Brazilian Amazon, and examine how such relationships are moderated by factors such as the choice of ecological and socio-economic condition measures, spatial scale (farm, catchment, region), land-use, farm-size and actor type. Understanding the suite of interactions, including both potential trade-offs and synergies, for different types of land-users can help reveal a wider range of barriers and opportunities associated with land management options that take into account additional social objectives beyond economic efficiency, such as regional food and labour security and social justice. Our preliminary results are a first step into understanding the enabling conditions at both farm and landscape levels for such a transition to occur. We reveal high levels of heterogeneity in social and ecological condition and actor characteristics within landscapes dominated by farms from both ends of the property size and wealth spectrum. This same heterogeneity suggests some scope for improving conservation and socioeconomic objectives through integrated changes in the management of both agricultural and forested lands, e.g. through conditional credit access and extension work and more inclusive certification standards. However, the highly dynamic nature of land-use, social and institutional change in forest frontier regions underscores the urgent need to consider how this landscape and actor diversity can be explicitly accounted for in fostering new approaches to land-use sustainability, including legal compliance mechanisms, conservation strategies and investments in the agricultural sector.

ON-SITE BIODIVERSITY CONSERVATION IN URBAN AREAS THROUGH BIODIVERSITY SENSITIVE URBAN DESIGN

Georgia Garrard

RMIT University

Sarah BEKESSY, RMIT University

Urban development has a substantial impact on native plants and animals and is considered one of the greatest threats to biodiversity around the world. Urbanization impacts biodiversity in a number of ways; the net effect is a reduction in the ability of native species and ecosystems to persist in urban landscapes. Traditional approaches to conservation in urban areas protect high value remnants and seek off-site compensation for losses incurred in the urban matrix through biodiversity offsets. This type of approach underestimates the role of the urban matrix in conserving biodiversity, as well as the importance of the development process and future inhabitation of the area for minimizing impacts on biodiversity. However, many of the impacts of urbanization can be reduced by improvements to urban design. We propose a new protocol for biodiversity sensitive urban design that focuses on on-site conservation of native biodiversity in urban landscapes. We investigate how biodiversity sensitive urban design can be used to create urban environments that minimize impacts on biodiversity and, in some cases, contribute to the persistence of biodiversity in urban landscapes. Using viability as a currency, we propose a 'star-rating' system in which new urban developments can be rated for their contribution to biodiversity persistence. We demonstrate this protocol using Melbourne as a case study, where sprawling urban growth presents a major threat to the conservation of native grasslands.

15-MANAGING POLLINATION SERVICES FOR SUSTAINABLE CROP PRODUCTION

Michael Garratt

University of Reading

Simon POTTS, University of Reading

Insect pollinators are a fundamental component of global ecosystems but they are also crucially important for food production. Pollinators improve the yield and quality of over 75% of crop species and contribute over \$3.61 Billion to global agriculture. Despite their importance, management of pollination services is not currently a core component of many crop production systems and in the face of changing pollinator populations and distributions this threatens food security. Here we present research identifying which pollinators are most important for crop production and how this varies between crops and regions and we discuss the importance of pollinator diversity for resilient crop production systems. We then outline potential pollinator management strategies for improved crop pollination and how these should be targeted and are often context specific, with different crops in different regions requiring different management approaches. Pollinator management can be effective and should be included as a component of integrated farming systems to maintain resilient production despite ongoing environmental change. But there

is still much to learn about the direct impact of pollinator management strategies on crop production so farmers can make sensible cost effective management decisions that pay-off in the long term. The wider benefits of crop pollinator management for biodiversity and ecosystems as a whole is discussed.

99-CONNECTING PEOPLE WITH NATURE - EXTINCTION OF EXPERIENCE: CAUSES AND CONSEQUENCES

Kevin Gaston

University of Exeter

Concern has long been held about the 'extinction of experience', the progressive loss of human interactions with nature, and its implications for the future of biodiversity. However, the extent and depth of the body of evidence that such a phenomenon is taking place, in what ways, and for whom, has grown markedly. In a similar vein, understanding has much improved of the causes and consequences of the extinction of experience. This presentation will review the state of these advances, with a particular focus on the relations between the extinction of experience and human health, and how new frameworks for understanding the relations between human health and nature bear on the extinction of experience.

CHANGES IN LARGE MAMMAL POPULATION SIZE AND EFFECTS OF VEGETATION STRUCTURE IN AKAGERA NATIONAL PARK, RWANDA

Callixte Gatali

University of Rwanda (UR)

Abstract. Systematic point counts and Distance sampling were used to estimate large herbivore population sizes and densities in the savannah habitats of the Akagera National Park (ANP), Rwanda, between 2009 and 2011. Analyses were based on 229 replicated points. The findings were compared with surveys of the park conducted in 1990, 1997/1998, 2002 and 2010. Results showed that the park currently holds about 20 species of large herbivores, including three species that are protected by CITES (African buffalo *Syncerus caffer*, African elephant *Loxodonta Africana* and Eland *Taurotragus oryx*). Estimates of the total population and density varied greatly from one species to another, reflecting the ecology and behavior of each species. The most abundant were impalas, buffaloes, topis, baboons and zebras. There were also large population sizes and densities of impalas outside the park as well as high-population sizes and densities of Ankolé cattle both inside and outside the park, posing a conservation challenge. Compared to previous population estimates of the park, the data demonstrated that most wildlife declined between 1990 and 2011 as a result of anthropogenic interference through park

reduction in size to meet the local human population needs for agricultural development and livestock grazing following the 1994 genocide in Rwanda. Moreover, the results highlighted the role of habitat structure as an important predictor of distribution and abundance of large mammals in the study area, suggesting that changes in this structure are likely to affect wildlife. The present data demonstrated that ANP, despite its recent important reduction in size, still conserves important populations of large mammals but does not have the large mammal population numbers common in other savannah parks in East Africa. Key words: density estimate, Distance sampling, East Africa, large herbivores, point count, savannah habitat.

LEADERSHIP AND COOPERATION: EXPERIMENTAL EVIDENCE FROM COMMUNITY FORESTS IN ETHIOPIA

Tsegaye Gatiso

German Centre for Integrative Biodiversity Research (iDiv)
Halle-Jena-Leipzig
Björn VOLLAN, Universität Innsbruck

We use dynamic lab-in-the-field common pool resource experiments to investigate the role of leadership on cooperation and rule compliance behavior of group members. We find that leaders elected by the community members are more effective in promoting cooperation among the community members compared to the baseline scenario where there is no leadership and to a situation where leadership is exogenously imposed. The effect of leadership is striking as subjects do not have any information on past experimental behavior to choose the “right” leader for them. All but one leader decided to implement a sanctioning rule. All leaders, irrespective of the voting mechanism, increased their cooperativeness in the second game. The elected leaders tended to be relatively wealthy men. Our results do not support evidence on elite capture but highlight the importance of legitimate procedures for decentralization policies.

DNABUSHMEAT: A REFERENCE FRAMEWORK FOR THE DNA-TYPING OF AFRICAN FOREST BUSHMEAT

Philippe Gaubert

IRD
Remy DERNAT, Université de Montpellier ; Agostinho ANTUNES, CIIMAR

The bushmeat trade in tropical Africa represents illegal, unsustainable off-takes of millions of tons of wild game — mostly mammals— per year. We sequenced four mitochondrial gene fragments (cyt b, COI, 12S, 16S) in >300 bushmeat items representing nine mammalian orders and 59 morphological species from five western and central African countries (Guinea, Ghana, Nigeria, Cameroon and Equatorial Guinea).

Our objectives were to assess the efficiency of cross-species PCR amplification and to evaluate the usefulness of our multi-locus approach for reliable bushmeat species identification. We provide a straightforward amplification protocol using a single ‘universal’ primer pair per gene that generally yielded >90% PCR success rates across orders and was robust to different types of meat pre-processing and DNA extraction protocols. For taxonomic identification, we set up a decision pipeline combining similarity- and tree-based approaches with an assessment of taxonomic expertise and coverage of the GENBANK database. Our multi-locus approach permitted us to: (i) adjust for existing taxonomic gaps in GENBANK databases, (ii) assign to the species level 67% of the morphological species hypotheses, and (iii) successfully identify samples with uncertain taxonomic attribution (pre-processed carcasses and cryptic lineages). High levels of genetic polymorphism across genes and taxa, together with the excellent resolution observed among species-level clusters (neighbor-joining trees and Klee diagrams) advocate the usefulness of our markers for bushmeat DNA-typing. We formalize our DNA-typing decision pipeline through an expert-curated query database — DNAbushmeat— that shall permit the automated identification of African forest bushmeat items.

CAN PROTECTED AREAS MITIGATE CLIMATE CHANGE IMPACTS ON SPECIES AND COMMUNITIES?

Pierre Gaüzère

Université Montpellier, CNRS, IRD
Vincent DEVICTOR, Université Montpellier, CNRS, IRD

Protected areas are the mainstay of our conservation strategies. While they succeed to prevent species and habitat degradation from human disturbances, their ability to mitigate the impacts of climate change on biodiversity is debated. Numerous studies have suggested that climate-driven shifts in species distribution could question the relevance of protected area as a long-term conservation strategy. However testing the true effectiveness of protected area was limited by the absence of robust scheme and data allowing fine scale analysis of population responses to protected areas for many species across large spatial and temporal scales. We here propose one of the first comprehensive frameworks tracking both local changes in community composition and species population related to local climate changes with a particular focus on protected area effect on those dynamics. Using the French breeding bird survey, a long term and large scale standardized monitoring program on birds, we investigated this question by specifically testing two main predictions : (i) the thermal adjustment of community composition to temperature changes in a given area should be positively related to the proportion of protected sites in this area. (ii) the species that benefit most from protected area should be less impacted by temperature change. Our results support our predictions.

First, most protected areas seem to promote community adjustment to temperature changes. Second, the more a species benefits from protected areas, the less it is vulnerable to temperature changes. Moreover, we showed that protected areas were more efficient at mitigating the impact of climate change for habitat specialist and northernmost birds.

Overall, our study pleads for using integrative frameworks through different biological scales to assess the usefulness and relevance of protected areas facing climate change and suggest that protected areas are still key effective conservation strategies in a changing world.

WILDLIFE AND WAR: PATHWAYS THROUGH WHICH ARMED CONFLICT AFFECTS FAUNA

Kaitlyn Gaynor

UC Berkeley

Kathryn FIORELLA, UC Berkeley; Gillian GREGORY, McGill University; David KURZ, UC Berkeley; Katherine SETO, UC Berkeley; Lauren WITHEY, UC Berkeley; Justin S. BRASHARES, UC Berkeley

Recurrent conflict throughout the world's biodiversity hotspots continues to threaten conservation efforts and wildlife persistence. Despite a growing number of case studies documenting the effects of war and armed conflict on wildlife populations and habitats, research and policy more often focus on outcomes for wildlife populations than on understanding, addressing, and mitigating causes. Armed conflict can lead to changes in governance, economies, human livelihoods, movement and migration, and militarization, which in turn have distinct influences on wildlife populations and habitats. Understanding the nuanced interactions between humans and the natural environment in areas of armed conflicts is critical to effective biodiversity conservation during and after conflict. To fill this gap, we summarized over 200 case studies from 5 continents to identify pathways through which armed conflict affects wildlife populations. We categorized 27 distinct pathways described in the literature and classified social, economic, geographic, and biological factors for each case study to understand why armed conflict has such diverse impacts on biodiversity. Many of the pathways occur in conflicts across a range of countries and cultures, and the most common pathways included weakened institutions, an increase in subsistence hunting, and a refuge effect in militarized areas. We also evaluate geographic and taxonomic biases in the literature and conclude by outlining some potential applications of our work to help mitigate the destructive effects of conflict on wildlife conservation.

(ID 94) GOING VIRAL: INSIGHTS FROM THE ADOPTION OF TERRITORIAL USER RIGHTS FOR FISHERIES IN CHILE.

Stefan Gelcich

CAPES, Pontificia Universidad Católica de Chile

Marine social-ecological systems are threatened by multiple and overlapping human pressures resulting in long-term trajectories of environmental degradation and decline. Governance and management responses to deal with these changes have generally been small, fragmented and inadequate. Recent years have seen a call for major transformational changes, but shifting from conventional approaches to new integrated, flexible management and governance approaches has proven to be difficult. The presentation explores the diffusion process and outcomes of a governance transformation, which resulted in a revolutionary national system that has allocated more than 700 exclusive territorial user rights to artisanal fisher (TURFs) associations in Chile. The presentation assesses elements which drove the adoption and diffusion of the TURFs regime and assesses the implications of the high uptake rate of TURFs over social and ecological outcomes, shedding lessons on key considerations associated to going viral. Results show the importance of designing a system which considers resource users' priorities to achieve scalability. However, lack of flexibility associated to desirable governance transformations could eventually trap the resulting social-ecological system into a certain management paradigm, with important implications over the systems' adaptive capacity and overall success. The presentation concludes by applying the lessons from the adoption of TURFs in Chile, which stress the importance of enabling conditions, adaptive capacity and human-centered design approaches, to design a new conservation program within TURFs which can have the necessary support and buy-in to result in landscape-scale biodiversity benefits. This presentation is part of the session "When conservation goes viral: Social science insights for catalyzing conservation".

A GLOBAL ANALYSIS OF THE CORRELATION BETWEEN MANAGEMENT EFFECTIVENESS AND THE BIOLOGICAL PERFORMANCE OF TERRESTRIAL PROTECTED AREAS

Jonas Geldmann

University of Copenhagen

Lauren COAD, University of Oxford; Ian CRAIGIE, James Cook University; Megan BARNES, University of Queensland; Marc HOCKINGS, University of Queensland; Stephen WOODLEY,

IUCN ; Neil BURGESS, UNEP World Conservation Monitoring Centre

Protected areas are amongst the most important conservation tools and today cover more than 15.4% of the terrestrial surface of the earth. Our knowledge on protected area performance primarily comes from understanding their location relative to biodiversity values. However, such analyses of coverage do not inform on whether protection improves the state of biodiversity compared to if the protected areas had not been established. Thus, while we are on track towards Aichi target 11, calling for 17% of the terrestrial surface to be protected by 2020 we have little knowledge on how this helps us reach the ultimate goal to halt the loss of biodiversity. We collated a database on management effectiveness with information on staffing, budgets, adequacy of management plans, and a suite of other variables from over 2,000 protected areas. We overlaid this site-specific information with the World Database on Protected Areas and the Living Planet Database containing more than 12,000 population time-series. This unique dataset allowed us to investigate the correlation between management quality and changes in biodiversity. Socio-economic factors at the national level, such as the Human Development Index played a positive role in shaping protected area performance while the role of management was more equivocal. Despite an extremely large sample of population time-series and management information we found only a small spatial overlap between these datasets. Thus while great efforts have gone into collating existing information on both management and changes in population abundance too little attention has been given to the coordination and collection of primary data on both input and outcomes in the field. This study, thus highlight the importance of national level governance structures as well as the paucity in relevant data to assess one of the key questions in conservation science and policy: to what extent do protected areas help us halt the loss of biodiversity?

MAPPING CHANGE IN HUMAN PRESSURE GLOBALLY ON LAND AND WITHIN PROTECTED AREAS

Jonas Geldmann

University of Copenhagen

Lucas JOPPA, Microsoft Research ; Neil BURGESS, UNEP World Conservation Monitoring Centre

It is widely accepted that the main driver of the observed decline in biological diversity is increasing human pressure on Earth's ecosystems. However, the spatial patterns of change in human pressure and their relation to conservation efforts are less well known. We developed a spatially and temporally explicit map of global change in human pressure over 2 decades between 1990 and 2010 at a resolution of 10 km². We evaluated 22 spatial data sets representing different components of human pressure and used them to compile a

temporal human pressure index (THPI) based on 3 data sets: human population density, land transformation, and electrical power infrastructure. We investigated how the THPI within protected areas was correlated to International Union for Conservation of Nature (IUCN) management categories and the human development index (HDI) and how the THPI was correlated to cumulative pressure on the basis of the original human footprint index. Since the early 1990s, human pressure increased in 64% of the terrestrial areas; the largest increases were in Southeast Asia. Protected areas also exhibited overall increases in human pressure, the degree of which varied with location and IUCN management category. Only wilderness areas and natural monuments (management categories Ib and III) exhibited decreases in pressure. Protected areas not assigned any category exhibited the greatest increases. High HDI values correlated with greater reductions in pressure across protected areas, while increasing age of the protected area correlated with increases in pressure. Our analysis is an initial step toward mapping changes in human pressure on the natural world over time. That only 3 data sets could be included in our spatio-temporal global pressure map highlights the challenge to measuring pressure changes over time.

CONSERVATION IMPLICATIONS OF COMPLEX SOCIAL STRUCTURE IN ADRIATIC BOTTLENOSE DOLPHINS

Tilen Genov

Morigenos - Slovenian Marine Mammal Society Institute for Biodiversity Studies, Science and Research Centre, University of Primorska Sea Mammal Research Unit, Scottish Oceans Institute, University of St Andrews

Tina CENTRIH, Morigenos - Slovenian Marine Mammal Society; Polona KOTNJEK, Morigenos - Slovenian Marine Mammal Society ; Ana HACE, Morigenos - Slovenian Marine Mammal Society

Complex social structure is a prominent feature in several species of mammals, and plays an important role in population dynamics and behavioural patterns. But understanding social structure is not only interesting biologically – it may also help conservation and management efforts. This is important because although conservation actions usually target populations, not all segments of a population necessarily interact with human activities in same way, or at the same time. Social network analysis allows groups of social animals to be studied as a network of nodes and ties. When coupled with information on behaviour and interactions with human activities, it can be a powerful tool in the study and conservation of social animals. In this study, we examined the social structure of common bottlenose dolphins (*Tursiops truncatus*) in the northern Adriatic Sea, using social network metrics and association indices. We used nine years of photo-

identification data (2003 – 2011) of 38 individuals sighted ≥ 4 times and in ≥ 2 different years. We calculated association patterns and standard lagged association rates, using the half-weight index of associations and permutation tests within the program SOCPROG 2.4. Network analyses and visualisations were done in program NetDraw 2.123. We show that 1) the local bottlenose dolphin population is structured into distinct social clusters or communities; 2) that the two largest clusters overlap spatially, but not temporally (segregation being based on time of day rather than season); and 3) that the two clusters differ in ways they interact with fisheries (“trawler” vs. “non-trawler” dolphins). This study demonstrates how different segments of animal populations can have different effects on human activities and in turn respond differently to anthropogenic impacts.

HABITAT PREFERENCE MODELLING REVEALS POTENTIAL CONFLICT FOR SPACE BETWEEN AQUACULTURE AND ENDEMIC CHILEAN DOLPHINS

Tilen Genov

Sea Mammal Research Unit, Scottish Oceans Institute, University of St Andrews

Philip S. HAMMOND, Sea Mammal Research Unit, Scottish Oceans Institute, University of St Andrews ; Marjorie FUENTES RIQUELME, Yaqu Pacha Chile ; Sonja HEINRICH, Sea Mammal Research Unit, Scottish Oceans Institute, University of St Andrews

Aquaculture represents an expanding anthropogenic activity with numerous environmental impacts. Mussel farming is generally considered less problematic than fish farming, but this may not hold true for all circumstances, species or ecosystems. Few studies have investigated impacts of aquaculture on marine top predators. The Chilean dolphin (*Cephalorhynchus eutropia*) is a poorly known endemic species in southern South America. Due to paucity of information it is listed as ‘Near Threatened’ by IUCN, but likely qualifies as ‘Vulnerable’. We used a long-term dataset (2001–2012) and a scale-independent modelling approach to investigate fine scale habitat preferences of Chilean dolphins. Sighting data were collected during systematic boat-based surveys in the Chiloé archipelago, one of the most aquaculture-intensive sites in southern South America. Dolphin occurrence was related to environmental and anthropogenic variables using binomial Generalized Additive Models. Chilean dolphins were strongly dependent on restricted areas and particular ecological conditions. Spatial predictions showed that this prime dolphin habitat substantially overlapped with areas intensively used for aquaculture, particularly mussel farming. This overlap likely resulted from Chilean dolphins selecting areas prized for mussel farming rather than operational interactions with the farms. The potential conflict for space may lead to habitat exclusion and consequently habitat

loss. The continuing expansion of aquaculture into relatively pristine southern Chilean fjords and archipelagos is therefore worrisome. The identification of important cetacean habitats should be incorporated into aquaculture management and impact assessments to ensure minimal impact on species and ecosystems. The demonstrated habitat selection could help explain the patchy distribution of Chilean dolphins making them vulnerable to anthropogenic disturbance.

POLLINATOR-FRIENDLY PRACTICES TO ENHANCE SUSTAINABILITY AND CROP PRODUCTION IN APPLES AND PEARS

Benoît Geslin

Sede Andina, Universidad Nacional de Río Negro (UNRN) and Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET)

Marcello A. AIZEN, Laboratorio Ecotono, INIBIOMA, Universidad Nacional del Comahue and Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET) ; Nancy GARCIA, Centro PYME, Agencia de Desarrollo Económico Del Neuquén ; Ana-Jullia PEREIRA, Instituto Nacional de Tecnología Agropecuaria (INTA), Alto Valle ; Bernard E. GARIBALDI, Sede Andina, Universidad Nacional de Río Negro (UNRN) and Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET)

Facing the global challenge of agricultural sustainability, an ecological intensification of agriculture through optimization of ecosystem services has been proposed. Yet, little is known about the practices to enhance crop yield through pollination. A widely management procedure is to supply crops with honey bee colonies, but the contribution of pollination quantity (amount of pollen deposited) and quality (percentage of pollen tubes per pollen grains) to crop yield remains widely unknown. In the main fruit producing area of Argentina, we studied apple and pear pollination and analyzed the pollinator friendly practices that might make it more sustainable. Concretely, we studied the effects of crop and colony management on the a) pollinator visitation rate, b) pollinator behavior, c) stigmatic pollen load, d) ratio of pollen tube/pollen grain, e) quantity of fruits, and f) quality of fruits. Surprisingly, we did not observe any wild pollinators during the 45 days of survey. The whole pollination process relied solely on introduced honey bees, of which we observed 1300 visits on the two crops. We found that visitation rate and fruit set were positively influenced by hives quality through bee abundance and organic farming. High bee abundance also affected bee behavior with higher effectiveness of single visits. Since this pollination system rests totally on just one introduced species, developing management practices that could sustain bee populations appears crucial. We suggest management practices to improve

colony performance in regards to their development and health. This work has important general applications because it depicts a situation that might regrettably be widespread in the future, if wild bee populations continue to decline, with the service of pollination relying only on honey bees. We will discuss these results with regards to the economic costs and benefits of pollinators friendly practices for apple and pear farmers in Argentina.

ASSESSMENT OF HUMAN IMPACT ON BIODIVERSITY OF FUNGI, PLANTS AND ANIMALS AT ARMENIAN SOUTHERN REGIONS

Astghik Ghazaryan

Yerevan State University

Siranush NANAGYULYAN, Yerevan State University ; Marine ARAKELYAN, Yerevan State University ; Felix DANIELYAN, Yerevan State University ; Lusine MARGARYAN, Yerevan State University

The Southern Armenia has rich biodiversity which undergo strong anthropogenic press. The use of bioindicators is an innovative approach for assessing various types of human impact on environment. The aim of this work is to compile multifaceted databases for assessing the current status of fungi, plants, and animals from populations of different ecological intensity: zones of pollution in vicinity of industrial cities Kapan and Kajaran and comparatively clean sites in "Shikahogh" State Reserve. During researches bioindicator species of fungi and animals were highlighted which can be used for assessment in polluted areas. This work was made possible by research grant 13-1F183 funded by State committee of science of Ministry of Education and Science of Armenia.

BIODIVERSITY AND VALORISATION OF ETHNOBOTANY IN ALGERIA: COMPARISON BETWEEN TLEMEN'S MODEL FOREST AND BIOSPHERE RESERVE OF DJURDJURA.

Ghenima Ghemouri

UNIVERSITY OF PADOVA

Rachid MEDDOUR, UNIVERSITY MOULOUD MEMMERRI - FACULTY OF BIOLOGICAL SCIENCES AND AGRONOMIC SCIENCE

Algeria is characterized by high biodiversity. Ancestral generation has a close relationship with nature, using medicinal plants (PAMs) for health purposes and others and transmitted it orally for other generations. However, Currently, only the old rural population kept it this know-How but without rational use. In fact, the biodiversity is decreasing also a disappearance of our Mediterranean phytotherapy culture. To assess biodiversity lost, was conducted a direct ethnobotanical survey (154 samples) to 68 rural people living in 14 villages localized near or inside of tow protected areas

(North and West of Algeria). The majority of questioners were illiterate women, aged between 61 and 70 years. 72 healing plants were identified and classified in 36 families. 65 plants are common and spontaneous. 160 therapies were prepared in 12 different ways for cure 50 diseases at least. Green leaf infusion is the most used, although in Tlemcen, the root part is most estimated. Additionally, those plants were found useful for food, animal feed, craft and veterinary. The study confirms the richness and close relationship between rural population particularly indigenous people and forest, but also shows the high risk of losing plant biodiversity by damage plant's root system, use of rare and endangered plants and unawareness of regulatory policies by rural people. This model showed not being effective and needs urgent development and collaboration among national institutions regarding biodiversity protection and natural resources management. Drawing guidelines and methodologies for conservation and management of NWFPs - traditional medicine for rural economy and modern phyto-pharmacy - must allow integration of this know-how in national green economy under international standards. Keywords: biodiversity, Algeria, medicinal plant, rural population, sustainable development.

PHYTODEPURATION AND GRAZING MANAGEMENT: A TWOFOLD STRATEGY TO CONSERVE BIODIVERSITY IN MOUNTAIN ECOSYSTEMS

Silvia Ghidotti

Department of Environmental Sciences and Territory, University of Milano Bicocca

Cristiana CERRATO, Institute of Atmospheric Sciences and Climate, National Research Council ; Alessandro GIRODO, Department of Life Sciences and System Biology, Turin University ; Beniamino BARENGHI, Blu Progetti srl ; Bruno BASSANO, Gran Paradiso National Park ; Ramona VITERBI, Gran Paradiso National Park

The European Alps have a long history of human presence and exploitation: during the last millennium, agropastoral activities determined a lowering of the treeline ecotone and shaped community composition of plants and animals, creating peculiar semi-natural habitats, on which high level of biodiversity depend on. Currently, two contrasting phenomena are occurring in the Alps: the abandonment of the traditional farming systems in most of the areas and the overexploitation of some remaining pastures. One of the principal objectives of the alpine protected areas should be the conservation of their biodiversity, also through the cooperation with the local stakeholders. In this framework, in 2013, the Gran Paradiso National Park (NW Italian Alps), started a project in an overgrazed alpine pasture (2000 m a.s.l.), located on a steep stony slope, which was historically grazed but now improperly managed, also due to the terrain harshness. A phytodepuration

system, a natural purification technique by biological treatments, has been created to reduce accumulation of organic waste and the eutrophication of nearby grasslands and creeks. At the same time, a lists of “good practices”, mainly determined by rotational grazing, have been adopted by the herder. To assess the concrete effect of such management activities on biodiversity conservation, a monitoring protocol has been developed to evaluate macro-invertebrates composition before and after the operation. Seven taxa were monitored (Coleoptera Scarabeidae, Coleoptera Carabidae, Coleoptera Staphylinidae, Araneae, Orthoptera, Lepidoptera Rhopalocera, Hemiptera) with semi-quantitative sampling techniques. The vulnerability and the responses of the different taxa to grazing pressure is evaluated at a local scale and the indicator (functional) groups most suitable for early detection of grazing impact/recovery have been identified.

PREVALENCE OF INTESTINAL PARASITIC INFECTIONS IN FREE-RANGING RED PANDA *AILURUS FULGENS*, CUVIER 1825 (CARNIVORA: AILURIDAE: AILURINAE) IN NEPAL

Tirth Ghimire

Global Primate Network

Sonam LAMA, Red Panda Network ; Rinzin LAMA, Global Primate Network ; Ganga REGMI, Global Primate Network

The red panda (*Ailurus fulgens*) is a small carnivore that is adapted to a mainly herbivorous diet. The current study was conducted to find out the prevalence of parasitic infection in a free-ranging red panda population in a community forest, Gaam Village Development Committee, Rolpa District, Mid-Western Nepal. A total of 23 stool samples were collected and examined by direct light microscopy (X100 and X400) using a 2.5% (w/v) potassium dichromate solution and stool smear stained with modified acid fast stain and bisporulation assay. The parasitic prevalence rate was found to be 100% with the highest percentage being protozoa infection and the lowest being cestode infection, suggesting a significant problem for red panda health in the study area. Molecular methods should be used to further investigate the taxonomic position of the parasites and their roles in threatening the resilience of red panda populations in Nepal so that appropriate conservation approaches can be devised.

LEOPARD AND PREY DISTRIBUTION IN THE IRANIAN STEPPES SUGGESTS RESPONSE TO POACHING INTENSITY

Arash Ghoddousi

Georg-August-University Göttingen

Amirhossein KH. HAMIDI, Persian Wildlife Heritage Foundation ; Mahmood SOOFI, Georg-August-University Göttingen ; Igor KHOROZYAN, Georg-August-University Göttingen ; Bahram

H. KIABI, Shahid Beheshti University, G.C. ; Matthias WALTERT, Georg-August-University Göttingen

Large carnivores that depend on ungulates are significantly influenced by anthropogenic pressures such as direct persecution or depletion of their prey at reserve scale. As a conservation response, law enforcement in protected areas is the most common practice to battle excessive poaching. Because of financial constraints in conservation, the effectiveness of law enforcement in shaping wildlife abundance and population structure needs evaluation. We investigated abundance and distribution of urial sheep (*Ovis vignei*) and Persian leopard (*Panthera pardus saxicolor*) using a combination of participatory line transect sampling and camera trapping, in steppes of Golestan National Park, Iran. Spatial data from both species in relation to anthropogenic (distances to ranger stations, villages and park border) and environmental variables (distance to water resources, average slope and normalized difference vegetation index) were analyzed using a multivariate approach. Leopard abundance was additionally tested against the urial density, which constitutes its main prey in the steppe area. Group density and group size of urial sheep were negatively affected by distance to ranger stations, thus highlighting the effect of law enforcement on ungulate distribution and demography. However, leopard abundance was positively associated with the urial density. Our analyses suggest the importance of law enforcement initiated from ranger stations for ungulate distribution and the influence of prey densities on predator abundance at landscape level. These results have important implications for the spatial distribution of ranger stations in reserves, where poaching pressure is high. The results of monitoring efforts in this study also suggest that the use of ungulate population metrics such as density and group size may be beneficial in assessing conservation effectiveness under financial and technical limitations commonly faced by protected areas.

MISMATCHES BETWEEN ELEMENTS OF “SUCCESS” AND “FAILURE” OF MARINE PROTECTED AREAS

Sylvaine Giakoumi

University of Queensland [INSTITUTE] Hellenic Centre for Marine Research

Marine Protected Areas (MPAs) are the cornerstone of marine conservation strategies. Currently, more than 7,300 MPAs cover about 3% of the world's marine environment. While the biological benefits of enforced MPAs have been widely documented, best practices for effective MPA design, implementation, and management are still debatable. Comparative studies that assess factors contributing to effective MPA functioning have enabled us to explore common elements of success across marine regions. Cross-regional assessments of "failures" are less common, whereas the question of whether "failure" translates into lack of "success" has not received attention before. Twenty conservationists experienced in MPA planning and management assessed the elements attributed to MPA success and failure using a total of 28 case studies from around the world. A modified Delphi technique was applied to elicit information from experts. Our results show that the principal drivers of success and failure of MPA effectiveness were more related to socioeconomic characteristics rather than MPA design features. In accordance to a large body of literature, stakeholder engagement and its absence were identified as key factors in MPA success and failure respectively. Interestingly, all other elements considered the most important for MPA success and failure did not match. For example, the lack of surveillance was identified as a key factor for failure but the presence of effective surveillance was rarely selected as important for success. Assessment of common failures across MPAs as well as mismatches between factors attributed to MPA "success" and "failure" can provide valuable insights that can inform the development of MPA policy.

POPULATION GENETICS OF PALLAS'S CATS (OTOCLOBUS MANUL) IN MONGOLIA

Melina Giakoumis

American Museum of Natural History
Anthony CARAGIULO, American Museum of Natural History ; Salisa RABINOWITZ, American Museum of Natural History ; George AMATO, American Museum of Natural History

Pallas's cat (*Otocolobus manul*) is a felid species endemic to the grasslands and montane steppe of Central Asia. *Otocolobus manul* is a habitat and feeding specialist particularly sensitive to anthropogenic landscape changes. These ecological characteristics, coupled with declining populations due to direct hunting, depletion of prey base and habitat

degradation, have led to a "near threatened" classification by the IUCN. This project is the first to use non-invasive genetic techniques to study the genetic diversity of *O. manul*, and used 134 scat samples collected from three sites within their Mongolian range. Genotyping at ten microsatellite loci revealed the presence of sixty individuals, with an average heterozygosity of 0.623. A sex ratio was also procured and a haplotype network created using DNA sequences from several mitochondrial genes. Additionally, individual genotypes were used to estimate relatedness and landscape genetic tools were utilized to further examine population dynamics. Individuals within the three sites were panmictic, with no discernible genetic clustering, likely due to Pallas's cats' large home ranges and high dispersal ability. While this signifies a healthy Mongolian Pallas's cat population, the Mongolian steppe is beginning to undergo land use changes that will greatly affect this species. Due to low population densities, *O. manul* requires its high propensity for dispersal to maintain its current heterozygosity level. Dispersal ability is dependent on the availability of contiguous suitable habitat space with large amounts of protective cover and high accessibility to Pallas's cats preferred prey, the pika (*Ochotona deurica*). Efforts must be undertaken to prevent habitat fragmentation as well as to reduce rodent eradication efforts to preserve the health of this population. This study utilized non-invasive methods to investigate the health of a wild population of an understudied felid species to inform future conservation decisions.

CAN FOREST CERTIFICATION SAVE PERICOPSIS ELATA (HARMS) VAN MEEUWEN IN CAMEROON?

Shu Gideon Neba

CIFOR

Denis Jean SONWA, CIFOR ; Richard EBA'A ATYI, CIFOR

Pericopsis elata is an important commercial tree species in Cameroon, but this tree species is very restricted in its geographical distribution; mostly limited to the South Eastern part of the country. *Pericopsis elata* also appeared on Appendix II of CITES in 1992 and was equally listed on the endangered species category in the IUCN Red list of globally threatened species in 2003. Because of its global status, the government of Cameroon raised the minimum exploitable diameter for this species from 80 cm to 100 cm. Also, the forest management policy of Cameroon demands that all trees species that have a density of less 0.05 stems per hectare in a forest concession must be excluded from the list of species solicited for logging in that concession. The introduction of forest certification is expected to reinforce these existing management measures; thus improves the conservation status of *Pericopsis elata* in Cameroon. A considerable number of forest concessions in South Eastern Cameroon are under FSC certification since 2008. However, no information currently exist on the extent to which forest certification and the nationally designed measures

have influenced the exploitation of *Pericopsis elata*. The focus of this study is to investigate whether forest certification has an impact on the exploitation intensity of *Pericopsis elata* in Cameroon. The study will analyse the production statistics of *Pericopsis elata* in certified and uncertified concessions for the period 2008-2013. The rationale is that a downward trend in the production statistics of this species in the certified concessions compared to the uncertified concessions signifies that forest certification has a positive impact on the species by enhancing its conservation.

91-ASSESSING THE USE OF SCIENTIFIC EVIDENCE IN THE MANAGEMENT OF BRAZILIAN PROTECTED AREAS

Eduardo L. H. Giehl

UFSC

Marcela MORETTI, Federal University of São Carlos ; Jessica WALSH, Cambridge University ; Marco BATALHA, Federal University of São Carlos ; Carly COOK, Monash University

Protected areas are crucial to maintain global diversity. Yet, management of protected areas has to match available resources with effective conservation actions. Effective management depends on the application of knowledge, coming from both scientific evidence and the manager's own experience. However, it is still unknown how much scientific evidence is used during management of protected areas, especially developing, highly diverse countries such as Brazil. We sent a questionnaire to Brazilian protected area managers to assess the extent to which they relied on scientific information or self-acquired experience for their management decisions. The set of selected managers were employed by the national government and worked mostly at the local-level. We scored each practitioner's overall use of scientific evidence (a combination of the frequency of use and the scientific content of distinct sources) to identify characteristics of the managers, their protected area, or of the evidence that restrict the use of scientific evidence to guide the management of protected areas. The 267 managers who responded our questionnaire used experience and information sources with intermediate levels of scientific evidence, such as management plans, most frequently to guide their management decisions. We found that even though managers use and recognize the importance of scientific evidence (50% use one highly scientific source at least once every month), poor accessibility and lack of technical training were the main limitations to its wider use. In addition, we found no deviation in managers' scores of scientific use across distinct characteristics of protected areas, managers' roles, and the information sources itself. Based on our results, we suggest that both open access to scientific evidence and governmental actions, such as scientific training, are necessary to increase the use of scientific evidence and to improve efficiency in the management of protected areas in Brazil.

GENETIC DIVERSITY AND POPULATION STRUCTURE OF THE ORPHAN LEAFLESS VANILLA HUMBLIOTII RCHB. F. (ORCHIDACEAE, VANILLOIDAE) AT THE SCALE OF THE COMORO ARCHIPELAGO (INDIAN OCEAN)

Laurent Rodolphe Gigant

Université de la Réunion

Tachirifa M'SA, Université de la Réunion ; Alexandre DE BRUYN, Université de la Réunion ; Yahaya IBRAHIM, Centre national de documentation et de recherches scientifiques ; Valérie GUIOT, Conservatoire Botanique National de Mascarin ; Guillaume VISCARDI, Conservatoire Botanique National de Mascarin ; Laurence HUMEAU, Université de la Réunion ; Marie-Hélène CHEVALIER, Centre de coopération internationale en recherche agronomique pour le développement ; Luc GIGORD, Conservatoire Botanique National de Mascarin ; Michel GRISONI, Centre de coopération internationale en recherche agronomique pour le développement ; Pascale BESSE, Université de la Réunion

The rate of deforestation in the Comoro Archipelago is the highest worldwide and nowadays, no in-depth investigation of the genetic diversity distribution of an endemic plant is available at this scale. "Vulnerable" in Mayotte, the endemic orchid *Vanilla humblotii* is only known of few primary forest populations, with an uncertain status at the archipelago scale. Using 11 polymorphic microsatellite markers, we conducted analyses of 290 *V. humblotii* plants distributed throughout the archipelago in 21 discrete populations. After clone exclusion, we evaluated on 175 genotypes, population genetic diversity indices and genetic structure, and studied the influence of physical barriers in population isolation. The expected heterozygosity ($H_e = 0.20-0.45$), reveals a moderate to high level of genetic diversity, even for small populations. All populations comply with Hardy Weinberg expectations, except one in each Mayotte and Moheli islands. Bayesian and discriminant analyses methods identify three clusters at the archipelago scale differentiating Mayotte, Grande Comore islands and a composite cluster of Anjouan and Moheli islands. The low gene flow among those clusters ($N_m \leq 1.073$, estimated following bayesian, F_{st} and private allele methods) and evidences of isolation-by-distance are mainly responsible for this structure of the genetic diversity. Our results highlight the high degree of isolation of *V. humblotii* populations at the archipelago scale structured by geographic distance, although past gene flow or similar events of colonisation seem to unite the two central islands Anjouan and Moheli islands. At the population scale, it seems that some small remnant *V. humblotii* populations are able to maintain a high degree of genetic diversity, but consanguinity and drift can threaten at least two of them. Such a large scale study is going to make

echo with conservationists in helping to design priorities to *V. humblotii* populations in the wild.

ARE WHITE STORKS ADDICTED TO JUNK FOOD? CONSEQUENCES OF LANDFILL CLOSURE FOR WHITE STORK (*CICONIA CICONIA*) BREEDING SUCCESS AND HABITAT USE

Nathalie I Gilbert

University of East Anglia

Ricardo CORREIA, University of East Anglia ; Joao Paulo SILVA, Centro de Ecologia Aplicada Prof. Baeta Neves ; Carlos PACHECO, Centro de Ecologia Aplicada Prof. Baeta Neves ; Ines CATRY, Centro de Ecologia Aplicada Prof. Baeta Neves ; Phil ATKINSON, British TRust for Ornithology ; Jennifer A GILL, University of East Anglia ; Aldina M A FRANCO, University of East Anglia

The White Stork (*Ciconia ciconia*) was a wholly migratory species in Europe. Since the 1980s, guaranteed, year-round food at landfill sites has enabled resident populations to establish in Iberia. Currently 10,000+ individuals winter in Portugal alone. 80% of wintering storks concentrate on landfill and preferentially nest close by. Landfill also influences migratory decisions and has facilitated colonization of new areas. However, due to EU directives, open-air landfills are being replaced by facilities inaccessible to birds, likely causing important consequences for White Stork habitat selection, breeding and migratory decisions. This project uses newly developed, high precision GPS/GSM data loggers to i) understand reliance on landfill versus non-landfill habitats in winter (November-March) and breeding (March-June); ii) to assess the consequences for productivity and iii) to estimate non-landfill habitat foraging preferences. This allowed speculation on the possible impacts of landfill closure for Iberian White Stork population dynamics and distribution. A total of 47 resident adult storks were caught on landfill sites in Portugal in winter 2012 and 2013 and fitted with GPS/GSM loggers programmed to transmit 5 high-precision (3m) GPS locations per day, allowing unprecedented observation of White Stork behaviour and habitat selection. Results include first confirmation of year-round nest use, a recent behaviour that has arisen as a result of residency. Storks make specific, long distance trips of over 58km to visit landfill and concentrate most non-landfill foraging close to the nest throughout the year. Birds were more dependent on landfill during winter than during breeding. In most years colonies close to landfill breed earlier and experience on average 30% fewer nest failures and raise 0.5-1.0 more chicks per successful nest than colonies further away. The consequences of landfill closure on future population dynamics are also assessed.

NOVEL PRESSURES AND THE POPULATION DYNAMICS OF A PIVOTAL GRASS SPECIES IN THE MEDITERRANEAN ECOSYSTEM OF SOUTHERN AUSTRALIA

Katherine Giljohann

The University of Melbourne

Michael MCCARTHY, The University of Melbourne ; Luke KELLY, The University of Melbourne ; Tracey REGAN, The University of Melbourne

Mediterranean-climate ecosystems have among the highest biodiversity of any biome worldwide. Although covering less than 5% of the world's land area they account for 16% of all plant species, many of which are endemic. Yet despite being regions of high conservation concern they are also one of the most imperilled; due to increasing human-induced threats, such as clearing, altered fire regimes, grazing and climate change. To reduce the rate of biodiversity loss and ensure species long-term persistence an understanding of the dominant processes driving ecosystem function will be crucial for guiding effective management. We present a case study using *Triodia scariosa*, a pivotal grass species within the Mediterranean biome of southern Australia. To understand which processes drive the species population dynamics we used long-term monitoring data and modelled key life-history parameters. Results show that although long-lived and capable of resprouting after fire, the species' dynamics are sensitive to the irregular rainfall and to a synergistic effect between introduced herbivores and prescribed fire. Therefore a key aspect for management will be accounting for the interaction between fire recurrence and the environmental conditions post-fire. This will be especially pertinent if rainfall decreases as forecast under climate change scenarios, and herbivore populations increase. Using parameters from the statistical models we develop a stochastic population model to predict long-term impacts of alternative management scenarios on population persistence. Quantifying the effect of key processes and pressures on the population dynamics of *T.scariosa* provides information relevant to the conservation of multiple species in the system and highlights the processes to target for effective management.

SOLVING THE MYSTERY OF MPA PERFORMANCE: LINKING GOVERNANCE TO ECOLOGICAL OUTCOMES

David Gill

National Socio-Environmental Synthesis Center (SESYNC) Helen FOX, RARE ; Michael MASCIA, Conservation International ; Gabby AHMADIA, World Wildlife Fund US ; Megan BARNES, University of Queensland ; Ian CRAIGIE, ARC Centre of Excellence for Coral Reef Studies, James Cook University ; Emily DARLING, University of North Carolina [INSTITUTE]

Wildlife Conservation Society ; Chris FREE, Rutgers University ; Jonas GELDMANN, Center for Macroecology, Evolution, and Climate, Natural History Museum of Denmark, University of Copenhagen ; Louise GLEW, World Wildlife Fund US ; Susie HOLST, NOAA Coral Reef Conservation Program ; Olaf JENSEN, Rutgers University ; Sarah LESTER, University of California, Santa Barbara ; Hannah THOMAS, UNEP- World Conservation Monitoring Centre ; Sarah WHITMEE, CBER - University College London ; Stephen WOODLEY, WCPA-SSC Joint Task Force on Biodiversity and Protected Areas, International Union for the Conservation of Nature (IUCN)

Marine Protected Areas (MPAs) are increasingly being employed as a tool to promote biodiversity conservation and maintain flows of ecosystem goods and services to coastal communities; however, their implementation has had varying levels of success. Results from numerous case studies suggest that protected area governance is a major factor in explaining the variation in ecological outcomes, but few studies have sought to examine the linkages between MPA governance and impacts at a global scale. This research utilized a cross-disciplinary theoretical framework to test our central hypothesis that positive ecological outcomes from MPAs are associated with good governance: inclusive decision making arrangements, active and accountable monitoring and enforcement systems, equitable resource user rights, and accessible conflict resolution mechanisms. Using datasets that were never previously combined, we compiled ecological data from over 14,000 underwater surveys and governance data from over 300 MPAs to explore the relationship between MPA governance and ecological outcomes at a global scale. While controlling for potentially confounding factors, preliminary analyses of over 250 MPAs/MPA zones demonstrate (on average) increases in fish population metrics (e.g. species richness, total biomass) within MPA boundaries. Preliminary analyses also suggest that designating part or all of the MPA as a no-take zone enhances these metric levels even further. Detailed governance data were available in approximately 50 MPAs, and from that sample, the results show a positive relationship between governance attributes such as inclusive and established decision making arrangements and well-defined resource use rights, and fish biomass and species richness. These preliminary results appear to confirm and extend previous research on the relationships between MPA governance and performance, providing novel insights for evidence-based ocean policy.

SYMPOSIUM #20: IDENTIFYING HOTSPOTS FOR ZONOTIC TRANSMISSION: QUANTIFYING FINE-SCALE MOVEMENT OF DOMESTICATED ANIMALS RELATIVE TO CHIMPANZEES AT GOMBE STREAM NATIONAL PARK, TANZANIA

Thomas Gillespie

Emory University & Rollins School of Public Health ; Michele PARSONS, Emory University & Rollins School of Public Health ; Gonzalo VAZQUEZ-PROKOPEC, Emory University & Rollins School of Public Health ; Elizabeth LONSDORF, Franklin and Marshall College ; Dominic TRAVIS, University of Minnesota ; Iddi LIPENDE, The Jane Goodall Institute ; Baraka GILAGIZA, The Jane Goodall Institute ; Lilian PINTEA, The Jane Goodall Institute

Domesticated animals are an important source of pathogens to endangered wildlife populations, especially when anthropogenic activities increase their overlap with humans and wildlife. Recent work in Tanzania reports the introduction of protozoan and bacterial enterics into wild chimpanzee populations and the increased risk of ape mortality associated with SIVcpz-enteric co-infection. Here we describe the application of novel GPS technology to track the mobility of domesticated animals (27 goats, 2 sheep and 8 dogs) with the goal of identifying potential routes for enteric pathogen introduction into Gombe National Park. Goats and sheep were infected with *Cryptosporidium*, *Salmonella*, and enterotoxigenic *Escherichia coli*; and dogs were infected with enterotoxigenic *Escherichia coli*. Analysis of GPS tracks indicated that a crop field frequented by both chimpanzees and domesticated animals was a potential hotspot for enteric transmission. This study demonstrates the applicability of GPS data-loggers in studies of fine-scale mobility of animals and suggests that domesticated animal-wildlife overlap should be considered beyond protected boundaries for long-term conservation strategies.

EVIDENCE OF A FINE-SCALE GENETIC STRUCTURE FOR THE ENDANGERED PYRENEAN DESMAN (GALEMYS PYRENAICUS) IN THE FRENCH PYRÉNÉES

François Gillet

University of Liège - University of Toulouse Paul Sabatier III ; Maria Teresa CABRIA GARRIDO, University of Liège ; Mélanie NÉMOZ, Conservatoire d'Espaces Naturels de Midi-Pyrénées ; Frédéric BLANC, Conservatoire d'Espaces Naturels de Midi-Pyrénées ; Christine FOURNIER-CHAMBRILLON, Groupe de Recherche et d'Etudes pour la Gestion de l'Environnement (GREGE) ; Eric SOURP, Parc National des Pyrénées ; Corinne VIAL-NOVELLA, Laboratoires des Pyrénées et des Landes ; Rafael ZARDOYA, Museo Nacional de Ciencias Naturales ; Stéphane

AULAGNIER, *Comportement et Ecologie de la Faune Sauvage (CEFS)*; Johan MICHAUX, *University of Liège*

The Pyrenean desman (*Galemys pyrenaicus*) is a small semi-aquatic mammal endemic to the Pyrenean Mountains and the northern half of the Iberian Peninsula where it lives in mountain streams of cold and well-oxygenated flowing waters. This species is currently considered as vulnerable in the IUCN Red List and has been suffering from habitat loss and fragmentation for decades, inevitably impacting its distribution. The ecology and biology of this species are poorly known, notably because of its elusive behavior and its primarily nocturnal activity. Its distribution area is even not definitively established. Furthermore, a recent genetic study, based on mitochondrial and intronic sequences, showed that the genetic variability of the Pyrenean desman is very low in the Pyrenees. In this study we investigated the potential existence of a genetic structure and gene flow at a smaller scale using 24 polymorphic microsatellites loci. As the Pyrenean desman is a very elusive species, we completed our sample collection of tissues with faeces samples coming from the French distribution area of this species. Doing so, we successfully identify 70 individuals out of 355 faeces samples. Bayesian analyses revealed a cryptic genetic structure in our data set. Three clusters were evidenced (one western, one central and one eastern) and gene flow appears to be limited between these clusters (min. *F_{st}* value of 0.2).

SYMPOSIUM 65 - MAKING SENSE OF CITIZEN SCIENCE DATA: A REVIEW OF METHODS

Olivier Gimenez
CNRS

Data collected through citizen science programs allow addressing many important questions in conservation biology related, e.g., to the shift in species range, the ecology of infectious disease or the effects of habitat loss and fragmentation on biodiversity. However, citizen science data are subject to serious statistical challenges when it comes to their analysis and the reliable extraction of the information they contain, mainly due to sampling biases generated by variation in the observation process. Numerous methods have been proposed to address this issue that can be split into two main strategies: either a new approach is developed to deal with a specific problem or an existing approach is used pending some pre-treatment of the data or post-processing of the results. I review these various methods, trying to make the links between them and emphasizing their advantages and drawbacks with respect to the question. I illustrate my talk with two case studies drawn for the research conducted in our group, one on the mapping of the distribution of brown bear in Greece and the other on the assessment of the recolonization

dynamics of wolves in France. Based on this review, I end up this contribution by recommendations on the use of existing methods and by suggesting perspectives on future developments.

SPACE USE PATTERN OF THE ASIATIC WILD ASS (EQUUS HEMIONUS): COMPLEMENTARY INSIGHTS OF RECURSION IN MOVEMENT PATTERN AND HABITAT SELECTION ANALYSES.

Nina Giotto

Jacob Blaustein Institutes for Desert Research
Jean-François GERARD, *Institut National de la Recherche Agronomique*; Shirli BAR-DAVID, *Jacob Blaustein Institutes for Desert Research*; Amos BOUSKILA, *Ben-Gurion University of the Negev*

The way in which animal moves and use the landscape is influenced by the spatial distribution of resources, and is of outmost importance when considering the conservation of a species. Movement patterns and habitat selection of the endangered Asiatic wild asses were studied in the Negev Highlands, Israel, using GPS monitoring technique. We developed a new approach for characterizing animals' temporal space use dynamics, based on the analysis of individuals' recursive movement patterns (i.e. return to previously visited areas). Mean distance performed per hours was higher in summer than in winter (440.13 ± 6.85 mvs 323.31 ± 4.44 m) due to summer greater twilight peaks of displacement and night performed distances. During summer days, activity was reduced and individuals selected high-altitude and north-exposed area, that are windier and receive less sun radiation. At night they selected areas with a high NDVI score, favourable for feeding. In winter, no NDVI selection was observed. Summer home ranges were aggregated around the water point and smaller than in winter (mean \pm SE, 95% Movement Biased Kernel Estimation: 24.02 ± 5.47 km² vs 42.26 ± 7.24 km²). Recursion rate was higher in summer than in winter. Most of recursions occurred on high NDVI areas (during night in summer and day in winter) and on favorable resting sites. Habitat selection, displacement and recursion movement pattern analyses suggest thermoregulation purpose and water dependence as factors affecting wild ass space use and movement patterns. Characterizing recursion areas provided complementary insights suggesting that movements are driven by environmental factors (such as food availability and resting sites), but also by psychosocial factors (such as site fidelity - territorial males returning regularly on their summer home range during winter). The information gained in this study will assist in the development of management strategies to protect the Asiatic wild ass population.

IMPLEMENTING REDD+: POLICY AND PRACTICAL ISSUES FROM THE LOCAL TO NATIONAL LEVELS

Mwangi Githiru

Wildlife Works

REDD+ is an idea mooted from the 2007 Bali UNFCCC meeting (COP-13), where an agreement was reached on “the urgent need to take further meaningful action to reduce emissions from deforestation and forest degradation”. In practice, a REDD mechanism would seek to provide incentives for developing countries to make those reductions where, in many situations, forest are considered worth more when harvested than standing. At its core therefore, REDD aims to change incentive structures in favour of protecting forests so as to reduce greenhouse gas emissions, but also deliver “co-benefits” including biodiversity conservation and social improvement. But how does it work on the ground? How do you deal with the intractable drivers of deforestation while retaining local community support and enhancing their livelihoods? Does this essentially render the social and biodiversity co-benefits, core benefits? What are the some of the key issues, opportunities and challenges involved in actual implementation, and how do they scale from the local (project) level to national or jurisdictional scales? This talk will broach some of these issues besides the general logic around REDD+ in practice, then illustrate how market-driven REDD+ projects actually function, using an example from the first dual (VCS and CCB) validated REDD+ project in the world: the Kasigau Corridor REDD+ Project that is administered by Wildlife Works. This project has been running for four years and has accumulated cutting-edge and vital lessons that can be interesting and useful for other players in the REDD+ fraternity, and conservation practitioners in general.

99. A SOCIAL-ECOLOGICAL APPROACH TO RECONNECT URBAN PEOPLE WITH THE REST OF THE BIOSPHERE

Matteo Giusti

Stockholm University

Stephan BARTHEL, Stockholm University

In postindustrial societies urban design has to face the challenges imposed by unprecedented rates of urbanization in combination with local and global sustainability requirements. So far, the political agenda has adopted quite unanimously urban densification as the strategy to cope with such extraordinary events. Such approach uses a socio-technical lens that seems indeed to appropriately limit energy consumption and mitigate green house gases, but is increasingly questioned (Neuman 2005), especially when a social-ecological lens is used to understand the urban system. A social-ecological approach to urban design sees the urban system inclusive of its

required ecological resources (Folke et al., 1997). This approach has shown how urban densification erodes some ecological dynamics (Seto et al., 2012), and we now use it to understand how dense urbanization patterns remove perceived and experienced links to ecosystem dependence. The “extinction of experience” is embedded attribute of most modern human habitat and produces over time routines characterized by missing or altered natural interactions. Nature-poor routines negatively impact both personal (Giusti et al., 2014) and social (Bendt et al., 2013) fundamentals of sustainable behavior and ecological stewardship. In these regards the presence of Urban Green Commons (UGCs), that are green spaces collectively managed, allow “the mental processes of human perception, memory and reasoning that people acquire from interacting frequently with local ecosystems, shaping peoples’ experiences, world views, and values towards local ecosystems and ultimately towards the biosphere” (Colding and Barthel, 2013). We discuss how the results of Giusti (2014) and Bendt (2013) intertwine connecting practices that consider a more heterogeneous ground for the emergence of sustainable lifestyles. In light of these findings, urban densification is once more a limiting assumption for the creation of sustainable urbanities.

CROSS-SITE COMPARISONS OF WILDLIFE IN EXURBIA: DOES GEOGRAPHY MITIGATE DEVELOPMENT IMPACTS?

Michale Glennon

Wildlife Conservation Society

Heidi KRETSEK, Wildlife Conservation Society; Sarah REED, Wildlife Conservation Society

Exurban residential development is characterized by low housing densities and large lot sizes that fragment natural landscapes. Expanding globally in areas of high amenity value, exurban development is impacting habitats within and near protected areas worldwide. We compared the relative impact of exurban development on bird communities in two contrasting geographies – the Adirondack Park in northern New York State and the Greater Yellowstone Ecosystem in Montana, USA – to determine how land-use decisions shape human impacts on biological communities. We examined bird communities in 7 exurban subdivisions and 7 control sites in each landscape in order to determine (1) the relative roles of human disturbance versus habitat alteration in controlling avian community structure and reproductive success in exurban subdivisions, and (2) the extent to which the magnitude of the effects of exurban development on avian communities across diverse landscapes can be explained by the large-scale connectivity and resilience of the encompassing regions. We found that response to development was similar in the East and West, with Neotropical migrants, low-nesters, and area sensitive species being negatively impacted and edge specialists

benefitting. The direction and magnitude of change in the avian communities between subdivisions and controls was similar in both regions for all guilds but one. Our findings suggest that human behaviors may play an underappreciated role in structuring wildlife communities in exurban areas, with strong similarities across varying geographies. We believe an improved understanding of this relationship can lead to better land management and ecologically healthier landscapes.

BEYOND ECOSYSTEM SERVICES: MECHANISMS LINKING BIODIVERSITY CONSERVATION AND HUMAN WELL-BEING.

Louise Glew

World Wildlife Fund (US)

Daniel, C. MILLER, World Bank ; Michael, B. MASCIA, Conservation International

Recent conservation policy and practice has emphasized the central role of ecosystem services in shaping human well-being. But ecosystem services do not represent the only pathway linking biodiversity conservation and human well-being. Scholars have long recognized the potential for impacts to emerge from the restructuring of resource rights and the infrastructure linked to conservation interventions, as alternative pathways by which conservation efforts may affect local communities. Despite these efforts, no holistic framework exists for examining how these various pathways operate, independently or in concert, to affect human well-being or for analyzing how they interact with contextual factors to generate household and community impacts. This paper examines the multiple pathways that link conservation interventions to human well-being, drawing on empirical examples from Indonesia, Kenya and Niger. We find evidence for multiple pathways that generate complex impact arrays that vary across space, time, and social domains. We examine the synergies and trade-offs among pathways, exploring how the relative importance of individual pathways may vary. In so doing, we shed new light on incentives, opportunities, and constraints to the long-term sustainability of conservation interventions, highlighting the need for a more nuanced understanding of the conservation-poverty relationships as the basis for more effective conservation policy and practice. This presentation is part of a set of contributed papers organized by L. Glew, M. Mascia, and D. Miller. If accepted, please include this presentation in the ICCB scientific program immediately before the presentation by Daniel Miller. If you have any questions, please contact me directly. Thanks.

ESTIMATED IVORY STOCKPILE ACCUMULATION IN AFRICAN ELEPHANT RANGE STATES

Kathleen Gobush

Vulcan Philanthropy

Iain DOUGLAS-HAMILTON, Save The Elephants

Since the international ban on the sale of ivory went into effect in 1990, the governments of many African elephant range states have maintained ivory stockpiles originating from illegally-traded tusks seized by authorities and tusks collected from elephants dying as a result of natural mortality, as problem control animals or other management activities. We report current probable ivory stock volume of 38 range states by assessing available stockpile data since 1990 to 2013 from CITES reports and sales proposals along with estimates of possible accumulation on the basis of an annualized accumulation model. Empirical research informed parameter assignment for mortality rate (low: 1.0% and high: 4.71%), average tusk mass (5.0 kg), average number of tusks per elephant (1.88); a "pick up" rate" of 20% and IUCN African Elephant Database population estimates were applied. The estimated ivory stock accumulation from 17 range states was 449 to 605 tons, using low and high natural mortality rates respectively; only 12 states are likely adding to ivory stockpiles annually, totaling 9.5 to 44.5 tons each year. The remaining 21 range states are likely not accumulating ivory stocks because of low national herd size, small volume of ivory seized, stockpile leakage or other apparent stockpile management deficiency. These results are useful for realistically tempering expectations related to sustainable use scenarios.

116: A WILDLIFE COMEBACK IN EUROPE?

Laurent Godet

LETG-Nantes Géolittomer, CNRS

Conservation is desperately looking for good news. Large herbivores and carnivores, as well a few set of other iconic species and habitats have been recognized as recovering throughout Europe during the last decade. This tendency is such that the beginning of a "wildlife comeback" has been proposed. The extent, meaning and consequences of this trend remain however to be investigated. Here, we performed an extensive literature review to clarify what is actually taken as a sign of wildlife comeback. In other words, what are we talking about, how this comeback is quantified and mapped, and at what spatial and temporal scale is it studied? Through various examples in Europe, we demonstrate that working on wildlife dynamics raises the difficulty to define wildlife, wilderness and other related concepts. We highlight why the spatial and temporal references are also crucial and yet often arbitrarily defined issues to identify a potential comeback or recovery of wildlife. Our review also raises important debates on the future of conservation in Europe: where, when and how should we let nature go; do we have to assist wildlife recovery; does European biodiversity is experiencing a real turning point that should or must be encouraged to meet conservation targets?

SIGNS OF EROSION IN THE IBERIAN LYNX GENOME

José A. Godoy

Estación Biológica de Doñana, CSIC
Federico ABASCAL, Structural Computational Biology Group, CNIO ; Fernando CRUZ, Centre Nacional d'Anàlisi Genòmica ; Begoña MARTÍNEZ-CRUZ, Estación Biológica de Doñana, CSIC ; Miriam RUBIO-CAMARILLO, Structural Computational Biology Group, CNIO ; Sophia DERDAK, Centre Nacional d'Anàlisi Genòmica ; Tyler ALLIOTO, Centre Nacional d'Anàlisi Genòmica ; Alfonso VALENCIA, Structural Computational Biology Group, CNIO

The Iberian lynx (*Lynx pardinus*) is the only felid classified as “critically endangered” by the IUCN. A first annotated draft of the Iberian lynx genome has been recently produced, along with re-sequencing data for 11 Iberian and one Eurasian lynx. The analysis of SNP variation based on this dataset has uncovered extensive signatures of genetic erosion in the Iberian lynx genome. The species shows the lowest heterozygous SNP rate reported to date in mammals. Low diversity extends to coding variation with extremely low synonymous diversity and high ratios of non-synonymous to synonymous diversity (π_N/π_S) and substitution rates (dN/dS), indicating the accumulation of potentially deleterious variants. Loss of genetic diversity has been more intense in the X chromosomes (X) than in autosomes (A), resulting in X/A diversity ratios of 0.35 in intergenic sequences, well below the neutral expectation of 0.75. Regions of the genome with maximal or minimal difference in heterozygosity between Eurasian and Iberian lynx are enriched for genes related to olfactory perception, while regions of smallest difference tend to concentrate in telomeres. The distribution of long runs of homozygosity (ROHs) reflects the higher incidence of recent inbreeding and small effective population size in Doñana, and a history of ancient bottlenecks shared by both remnant populations. Indeed, the reconstructed demographic history comprises a series of three bottlenecks that predate the documented decline in the 20th century. Extreme levels of genetic erosion in Iberian lynx might thus be the consequence of the latest decline acting on an already genetically eroded species. The Iberian lynx is one of the first endangered genomes to be analysed and its study may yield novel insights on the evolutionary processes acting on declining populations and their consequences for fitness and population persistence, an information that may help to optimize current conservation efforts.

THE ECTOPARASITE PISCICOLA GEOMETRA (HIRUDINEA: RHYNCHOBDELLIDA) REPORTED IN THE PRUSIAN CARP (CARASSIUS GIBELIO) (CYPRINIDAE) IN THE SMALL RESERVOIRS LOCATED WITHIN THE LOWER BASIN OF THE JIU RIVER (ROMANIA)

Ionelia Claudia Goga

The Oltenia Museum

Piscicola geometra (Linnaeus, 1761) is the most common fish leech affecting a wide range of host fish in case of both natural and bred populations. In March 2014, we made a field trip as a result of monitoring fish populations in the small reservoirs located within the catchment basin of the Preajba Valley, a small tributary of the Jiu River, where there were caught 47 fish specimens belonging to the species: *Scardinius erythrophthalmus*, *Lepomis gibbosus*, *Abramis brama*, *Carassius gibelio*, *Perca fluviatilis*. The collected fish samples were subjected to ichthyopathological examination, namely clinical examination and parasitological examination, in the parasitology laboratory of the Sanitary Veterinary Directorate of Dolj County. The ectoparasite was detected only at *Carassius gibelio* on the gills and the ventral side of the body as parasitic sites, causing bleeding and ulcerations due to the suction cups. An important factor in causing this parasitosis is water temperature; the invasion decreases when the water temperature increases. The destruction of the macrophyte vegetation and the prevention of fish species ingress from one basin to another, given that they communicate through rubble surge tanks, are some prophylactic measures meant to prevent piscicolosis.

HAS SUSTAINABILITY PELAGIC FISHERIES IN THE BLACK SEA TURKISH COAST EVER BEEN ACHIEVED?

Didem Gokturk

Istanbul University

Tomris DENIZ, Istanbul University ; Muammer ORAL, Istanbul University

Of all the inland seas, the Black Sea is almost completely isolated from the world oceans. It is a semi-closed basin with relatively great depths, and high bio-productivity of the shelf zone. In this inland sea, the main fishery was targeted on small and medium pelagic fish for the Black Sea Turkish coast which is an important spawning ground for some migratory pelagic fish species such as bonito, anchovy, bluefish and herring. However, the coastal and marine biodiversity also fish stocks of the Black Sea was already under stress through a combination of heavy fishing, pollution, eutrophication, climatic fluctuations and the invasion of alien species due to the pressures exerted by mankind. Example of the Black Seafish

stock collapse is numerous and the unsustainable harvest of many fish species continuous today. Turkey is the most important country as to realize maximum fish production from the Black Sea. Pelagic fish species dominate marine landings in Turkey. Especially the Black Seacoast is the most important landing area for this species production for Turkey, particularly *Engraulis encrasicolus* (anchovy), *Sarda sarda* (Atlantic bonito), *Trachurus trachurus* (Atlantic horse mackerel), *Pomatomus saltatrix* (bluefish) and *Clupeidea* species (Herrings). Among these commercial pelagic fish species anchovy takes first place with the rates of % 60.85, following this with the rate of % 11.41 herrings, % 9.63 horse mackerel, % 4.46 Atlantic bonito, % 1.77 bluefish respectively. In this work, we aimed to evaluate pelagic fisheries in the Black Sea Turkish coast in terms of sustainable fisheries management by the commercial fish stocks, number of fishing boats and fishing gears.

ID 7: WILDLIFE'S IMPORTANCE TO HEALTH AND LIVELIHOODS IN MADAGASCAR

Christopher Golden

Wildlife Conservation Society/Harvard School of Public Health

Wildlife consumption can be viewed as an ecosystem provisioning service because of wildlife's ability to persist under sustainable levels of harvest. We used the case of wildlife harvest and consumption in northeastern Madagascar to identify the distribution of these services to local households and communities adjacent to protected areas to further our understanding of local reliance on natural resources. We used longitudinal survey methods, micro-economic analytical techniques, and robust epidemiological study designs to determine the health and economic value of subsistence wildlife harvest. Heightened monitoring and enforcement of hunting could increase the costs of harvesting and thus elevate the price and reduce consumption of wildlife. Effective monitoring would incur a 66% reduction in the biomass of wildlife consumed. Increased enforcement would therefore be beneficial to biodiversity conservation but could limit local people's food supply. On average, the value of wildlife provisioning represented 57% of annual household cash income in local communities from the Makira Natural Park and Masoala National Park. In past work, we have demonstrated a nearly 30% increase in the incidence of anemia given loss of access to wildlife resources. In our current work, we will be investigating the value of wildlife to micronutrient status (vitamin A, vitamin B12, iron, zinc and fatty acid profiles). By explicitly estimating the welfare effects of consumed wildlife, our results may inform targeted interventions by public health and development specialists to improve protected area effectiveness as they allocate sparse funds to support regions,

households, or individuals most vulnerable to changes in access to wildlife.

PROTECTED AREA DOWNGRADING, DOWNSIZING, AND DEGAZETEMENT (PADDD) IN THE UNITED STATES, 1900-2014

Rachel Golden

George Mason University

Roopa KRITHIVASAN, Indian School of Business ; Michael MASCIA, Conservation International

Traditionally, protected areas have been considered permanent means to conserve biodiversity and safeguard natural and cultural resources. However, widespread evidence of protected area downgrading, downsizing, and degazettement (PADDD) demonstrates that legal changes affect protected areas worldwide. Legal changes to reduce the status or size of protected areas have been linked to higher levels of deforestation, carbon emissions, and habitat fragmentation. Drawing on the legal, peer-reviewed, and grey literature, we identified patterns, trends, and causes of PADDD in the United States' protected area system that occurred from 1900 to 2014. During this period, the United States enacted 265 PADDD events (242 downgrades and 23 downsizes) affecting an area of 747,456 km² across 145 protected areas. In addition, we identified 1,841 PADDD proposed events, 1,166 of which are currently active. These 1,160 downgrades and 6 downsizes may affect an area of 990,358 km² across 1,118 protected areas. A large proportion of the documented PADDD events were systemic, wherein one legal change affected multiple protected areas simultaneously. The most common proximate causes of these legal changes were infrastructure construction, subsistence-level extraction, and other industrial-scale resource extraction. Events occurred in every decade and across all federal agencies that manage public lands. Evidence of PADDD in the United States demonstrates that protected areas in developed countries are not immune to legal changes. Further, the magnitude of PADDD across space and time suggests that protected areas should not be regarded as permanent conservation interventions, but instead recognized as dynamic systems. Strategic planning for protected areas should considering systematic accounting for PADDD in the future.

AFRICAN ELEPHANT SOCIAL STRUCTURE IS RELATIVELY ROBUST TO POACHING-INDUCED MORTALITY

Shifra Goldenberg

Colorado State University

Iain DOUGLAS-HAMILTON, Save the Elephants ; George WITTEMYER, Colorado State University

Social structure forms in populations as individuals attempt to maximize the benefits or minimize the costs of social

association. Whether social structure is robust to perturbation in wild populations remains an open question, but may provide insight into the evolution of social systems and the function of social structure. Over the last five years, African elephants (*Loxodonta africana*) have experienced severe poaching-induced mortality, often disproportionately directed toward older age cohorts for their larger tusks. As a result of this harvest pressure and resulting demographic alterations, social structure within this complex society may be changing, with the potential for associated loss of structural function. Here we use a sixteen-year dataset on social associations of adult female elephants to compare social structure between periods of low and high levels of illegal killing. We find that the most tightly bonded levels of hierarchical association in elephant society—core and bond groups—are robust to harvest pressure despite a high degree of turnover in the individuals included in the sample over the course of the study and the disproportionate loss of matriarchs. In contrast, clan groups, the coarsest social level, were only discernable in undisrupted periods. Although core and bond groups were present throughout the study, core groups were larger in the disrupted period, potentially related to greater predation pressure during this time. We discuss the role of social strategies in maintaining hierarchical structure in elephant society and the implications of social reconstruction for population persistence. Our study contributes to understanding of the evolution of social systems and provides a unique behavioral approach to the quantification of anthropogenic impacts on wildlife.

AICHI TARGET 11: IT IS NOT ALL ABOUT NUMBERS

Barbara Goncalves

German Centre for Integrative Biodiversity Research (iDiv)
Silvia CEASU, German Centre for Integrative Biodiversity Research (iDiv) ; Laetitia NAVARRO, German Centre for Integrative Biodiversity Research (iDiv) ; Max HOFFMAN, German Centre for Integrative Biodiversity Research (iDiv) ; Rafael LOYOLA, Departamento de Ecologia, Instituto de Ciências Biológicas, Universidade Federal de Goiás ; Henrique Miguel PEREIRA, German Centre for Integrative Biodiversity Research (iDiv)

Target 11 of the Strategic Biodiversity Plan for 2011 – 2020 calls for the expansion of global protected area network, from the current 13% to at least 17%. The target also states that the selection of such land should be ecologically representative, well-connected to the existing systems of protected areas and take into account the wider landscape. Their conservation should be achieved through effective and equitable management. Hence, target 11 holds two very different components: one very specific and quantifiable, related to the amount of area to be protected, and another component, relatively subjective and open to interpretation, related to the type of conservation management implemented

in the Protected area. Adhering to these goals will challenge countries in different ways. We look at Europe 28 and Brazil and try to assess to what extent how these two regions are meeting, on the ground, the management component of target 11. We look at the distribution of IUCN protected area categories as well as at the legislation for protected areas in order to realize the challenges for meeting the management goals of target 11. We assess how current conservation policies and actions respond to biodiversity needs in our two case studies and we discuss how the future policy decisions should consider global environmental change and the international political, economic and environmental contexts. Focusing on quantitative goals for conservation offers a truncated image of conservation progress and we argue here that more attention should be given to the management aspects of conservation.

ECOLOGICAL NICHE MODELING AS A TOOL FOR PREDICTION OF AN EXTINCT MAMMAL: THE CASE OF THYLACINUS CYNOCEPHALUS (TYLACINAE)

Lucas Gonçalves Da Silva

PUCRS Brazil

Kristofer HELGEN, National Museum of Natural History ; Eizirik EDUARDO, PUCRS Brazil

Actually, one of the greatest threat to biodiversity is the increase of extinction rates due to anthropogenic activities. The human is documented as the responsible for the many of mammals extinctions in the last centuries. One of the most emblematic examples is the case of the Tasmanian Tiger (*Thylacinus cynocephalus*, Tylacinae), a carnivorous marsupial that originally occurring in Oceania continent, especially in Australia and Tasmania islands, and not confirmed in nature since 1930. Moreover, the species is currently recognized in the category 'extinct' by IUCN. The main objective of this project was to develop a prediction model for Tasmanian Tiger occurrence, aiming to identify suitable areas for their persistence in nature. Through ecological niche modeling using Maxent software and environmental and bioclimatic predictors, we generate a potential distribution model for the species, comprising 36 geographic occurrence records from museums around the world, with correct origin of each sample. The prediction model has reached great accuracy and showed the expected distribution of the species in Oceania. Additionally, the model predicts a possible occurrence of the species in remote areas of Papua New Guinea, an possible habitat for a Tylacinae to be rediscovered in nature. This work is the first to address niche modeling as a tool to identify habitats of mammals considered extinct by science and can elucidate areas where extinct animals can persist.

COASTAL WILDLIFE RESERVE OF TIBAU DO SUL (REFAUTS): NURSERY OF GUIANA DOLPHIN, SOTALIA GUIANENSIS, IN RIO GRANDE DO NORTE, BRAZIL

Diana Gonçalves Lunardi

Federal Rural University of Semiárid - UFERSA

Vitor DE OLIVEIRA LUNARDI, Federal Rural University of Semiárid - UFERSA

Coastal Wildlife Reserve of Tibau do Sul (REFAUTS), Pipa Bay, Brazil, is a protected area of sustainable use, created in 2006 with the main objective of conserving Guiana dolphins, and other marine species in the region. In this study, we investigated the fidelity of Guiana dolphins photo-identified at Curral and Madeiro Beaches, REFAUTS, and the presence of calves in these beaches. Photo-identification and behavioral records were made from the beach, above 2m sea level, to avoid that our presence modified the behavior of the Guiana dolphin. Sampling occurred between March 2013 and November 2014, during for 13 sampling days. Guiana dolphins were recorded in all sampling days, and the groups, often cohesive (>1m between dolphins), were an average size of approximately 3 individuals (SD=1.4, mode=2, min=1, max=6). We photo-identified 23 adults: 2 dolphins identified (ID) were present in 46% of samplings, 1 ID in 40% of samplings, 1 ID in 31% of samplings, 2 ID in 15% of samplings and 4 ID in 8% of samplings. Two adults (L2 and L3) were recorded accompanying calves or juveniles for more than a year in the two beaches. A recurrent association (n=3) between two adults (L6 and L7) was also recorded. From the behavioral frequency analysis and presence of calves (present in 62% of samplings), Guiana dolphins used the Curral and Madeiro Beaches mainly for feeding and parental care. Dolphin watching at REFAUTS is growing disorderly in recent years and the code of conduct is not being fulfilled. We recorded up to five boats simultaneously under the same dolphin group. The REFAUTS have been used as nursery for Guiana dolphins, and it is necessary to implement a continuous program of monitoring immediately and a control to ensure the protection of these animals in the Reserve.

RECREATIONAL USES SPATIO-TEMPORAL DISTRIBUTION IN A CONTEXT OF DEMOGRAPHIC INCREASE, IMPLICATION FOR MPA MANAGEMENT

Charles Gonson

Ifremer / IRD

Dominique PELLETIER, Ifremer ; Jocelyne FERRARIS, Ird

All around the world, coastal areas are subject to increase and diversification of recreational activities linked to demographic and touristic development (Duedall & Maul 2005, Davenport & Davenport 2006, Chaboud et al. 2004). Thus conservation implies that managers of marine protected areas find a balance

between environmental protection and visitor access (Cole & Daniel 2003). Unfortunately, recreational uses in natural settings have not been much studied (Gray et al. 2010, Sutton 2005) even though management needs to better account for the needs and impact of recreational users as well as the factors structuring their spatio-temporal distributions (Eagles 2002, Christie et al. 2003). Near Nouméa, the main city of New-Caledonia, monitoring of boat count was conducted between 2005 and 2013 per location site, activities, boat type and type of anchorage. The study site comprises islets and intermediate reefs including 5 no-take long-established reserves. Information gathered through this monitoring was used to calculate indicators of user pressures at each location (e.g. number of anchored boats). We analyzed the influence of temporal, weather (i.e. years, season, type of the day, meteorology) and spatial factors (i.e. protection status, distance to the coast) on these indicators. General results indicate an increase of boating pressure at all sites whereas short-term temporal variations depend on indicators. For example, the number of boats observed on week-end trips increased over years irrespective of boat type whereas it remains stable over years for week days. These results in increased peak pressures which might require specific management measures. These could be identified by characterizing practices of users and their impacts. Based on these outcomes, we will discuss management issues and further research needs.

101-RIPARIAN ZONES: HIGHLY DYNAMIC SYSTEMS THAT REQUIRE ACTIVE CONSERVATION

Eduardo Gonzalez

University of Denver

Bruno BOZ, Italian Centre for River Restoration (CIRF) ; María FELIPE-LUCÍA, Instituto Pirenaico de Ecología ; Christer NILSSON, Landscape Ecology Group, Department of Ecology and Environmental Science, Umeå University ; Grant PALMER, Centre for Environmental Management, Faculty of Science and Technology, Federation University Australia ; Anna A SHER, Department of Biological Sciences, University of Denver

Riparian zones (RZ) lay at the ecotone between aquatic and terrestrial systems. They are dendritic linear corridors in the landscape, but their importance greatly exceeds their area. They contribute disproportionately to biodiversity and provide many ecological services such as wildlife habitat, recreation, water purification and water provision for economic activities. With increasing anthropogenic demands and global warming, water availability for riparian biota is not guaranteed. Many RZ have been dramatically reduced in size and their structure changed; most world rivers are also regulated (dammed or flood protected), altering the natural hydrogeomorphic regime to which riparian systems are adapted. Being open systems, the occurrence of invasive species is common. Very altered biotic communities and reduced ecosystem function

follow. Restoring historical flow regimes is the most effective strategy to restore RZ. Dam removal and environmental flows are being implemented in various world regions but usually create political and social conflict. Legislation is more prone to conserve static features such as successional endpoints or physical boundaries rather than promoting the recovery of river dynamism and resilience. Geomorphic processes have received too little attention in the legislation protecting RZ, with a traditional emphasis on water (e.g., European Water Framework Directive). Other legislation affecting RZ may have antagonistic goals (e.g., reducing flood risk) with policies for conservation. Local communities need to be involved in the conservation of RZ, but people may be attracted to high aesthetic value of landscapes with low ecological value if scientific results are not efficiently disseminated. Thus our role as scientists includes communicating effectively with policy makers and the public, while investigating alternatives to historical flow regimes where possible and creating alternative ecosystems where it is not.

INTEGRATING TAXONOMIC, FUNCTIONAL AND PHYLOGENETIC DIVERSITY IN REDD+ INITIATIVES IN THE PACIFIC COAST OF COLOMBIA, A BIODIVERSITY HOTSPOT.

Mailyn Gonzalez

Instituto de Recursos Biológicos Alexander von Humboldt
Beatriz SALGADO-NEGRET, Instituto de Recursos Biológicos Alexander von Humboldt ; Paula CAYCEDO, Instituto de Recursos Biológicos Alexander von Humboldt ; Angélica DÍAZ, Instituto de Recursos Biológicos Alexander von Humboldt ; Roy GONZÁLEZ, Instituto de Recursos Biológicos Alexander von Humboldt ; Hernando GARCÍA, Instituto de Recursos Biológicos Alexander von Humboldt

The Choco region in the Pacific coast of Colombia is considered one of the most diverse world's biodiversity hotspots. This region is covered by a largely unexplored tropical rainforest and faces accelerated habitat degradation mostly driven by illegal logging and mining activities, therefore REDD+ projects may represent sustainable development alternatives for local communities. However, REDD+ projects mostly focus on carbon stocks and plant species diversity, without accounting for the importance of forests as major repositories of animal species and genetic diversity. In this study, we assessed the taxonomic, functional and phylogenetic diversity of trees, and estimated the taxonomic diversity of birds and mammals in four 1ha plots of lowland tropical forest with different levels of disturbance along the Pacific coast of Colombia. Functional diversity was based on wood density, tree height, specific leaf area and matter content, whereas mammals were quantified with camera traps, and birds with sound-meters. Local communities were trained in the use of camera traps, sound registration,

tissue sampling, and functional trait measurements. We found a total of 200 tree species, and increasing values of phylogenetic and functional diversity in less disturbed forests. In addition, we detected 16 species of mammals including emblematic and endangered species such as *Panthera onca* and *Puma concolor*. This study shows the importance preserving forests not only for their role in carbon sequestration, but also for holding unique species and ecological processes. Camera traps and bioacoustics revealed to be a major tool for monitoring the success of REDD+ initiatives in conserving forest biodiversity.

TROPHIC ECOLOGY, NURSERY AREA & FISHERY OF SMOOTH HAMMERHEAD SHARK (*SPHYRNA ZYGAENA*) IN PERU

Adriana Gonzalez Pestana

EcOceanica

Pepe ESPINOZA, Instituto del Mar del Peru

Peru has the highest accumulated historical shark landings in the Pacific Ocean and the smooth hammerhead shark is the third shark specie most captured. Its situation is vulnerable and is included in CITES. However, their fishery lacks management and its biology and fishery is poorly understood. This study aims to know the trophic ecology, identify and characterize their nursery areas and its fishery in northern Peru, through analysis of stomach contents, fishing areas, size composition and sex ratio, umbilical wound status and catch per unit effort, in the years 2013 and 2014. To determine its trophic ecology, 212 stomach contents were sampled; the sharks measured between 56 and 139 cm in total length (TL). Fifteen prey species were identified being the most important commercial species of squid (*Doryteuthis gahi*, *Dosidicus gigas*). The hammerhead shark is a specialized predator with a trophic level of 4.7. They have different diets depending on its size, sex and location. Smaller sharks fed on coastal prey; whereas larger sharks fed on oceanic prey. So, it is posited that sharks change their distribution and habitat according to their ontogeny. To determine their nursery and fishery areas, 897 sharks were sampled. Three nursery and fishery areas were identified in northern Peru located in coastal and oceanic zones. Pregnant females appear in December and January to give birth. Thus, in December the smallest sharks were measured (53-70 cm TL) which showed open umbilical wounds. As months passed their size increased (80-95 cm TL) and the umbilical wounds were healed. In May the sharks leave the nursery areas. In northern Peru the fishery of hammerhead shark is composed by neonates, juveniles and adult females. In Peru sharks are fished without management; thus, this study will contribute to the design and implementation of conservation plans that include an ecosystem-based fishery management.

SENSORY ECOLOGY OF NECTAR-FEEDING BATS: OLFACTION AND ECHOLOCATION

Tania Paulina Gonzalez Terrazas

University of Ulm

Marco TSCHAPKA, University of Ulm

Nectar-feeding bats are among the most important pollinators in dry tropical ecosystems, which belong to the globally most threatened habitats. Chiropterophilous flowers generally provide a combination of strong floral scents and conspicuous acoustic echoes. While floral scents are assumed to attract bats over long distances, acoustic properties of flower structures may provide an echolocating bat with detailed information at closer ranges. Nevertheless, no study has yet focused on the relative importance as well as on the combination of these cues for detection and precise localization of open flowers. To understand better the significance of olfaction and echolocation in the foraging behavior of nectar-feeding bats, we conducted two-choice experiments with *Leptonycteris yerbabuenae* (Phyllostomidae: Glossophaginae). We tested the bats' performance in three scenarios: olfaction vs. echolocation, echolocation vs. echolocation & olfaction, and olfaction vs. echolocation & olfaction. We used the floral scent of a bat-pollinated cactus (*Pachycereus pringlei*) as olfactory and an acrylic paraboloid as acoustic cues. We recorded 1) first reaction; 2) choice and 3) total number of reactions to each cue per bat and trial. When only single cues were offered, bats showed no significant preferences. However, bats reacted first to and chose more often the coupled cues. Our study provides first evidence that nectar-feeding bats integrate over different sensory modalities for detection and precise localization of flowers. We suggest that scent is not only a long-distance indicator for the presence of open flowers but has also an important function on close range. In current anthropogenously modified habitats efficiency of olfaction and echolocation might be increasingly affected by air and noise pollution. Further studies on how these side effects of urbanization affect the foraging efficiency of these bats will contribute to developing robust conservation plans.

IMPALAS ON THE ROAD: ASSESSING UNGULATE BEHAVIORAL RESPONSES TO THE HETEROGENEOUS ROAD-NETWORK OF KRUGER NATIONAL PARK

Manuela González-Suárez

Estacion Biologica de Doñana CSIC

Margarita MULERO-PÀZMÀNÝ, Estacion Biologica de Doñana CSIC ; Marcello D'AMICO, Estacion Biologica de Doñana CSIC

The world is experiencing a fast increase in road development and motorized traffic, which threatens biodiversity. Road impacts can be particularly significant within protected areas, especially when human activities are centered on wildlife sightings from motorized vehicles, as is the case in many African parks and

reserves. Paradoxically road ecology studies have been rarely conducted in these areas. To reduce this knowledge gap we studied the behavioral response and local spatial distribution of impala *Aepyceros melampus* along the heterogeneous (with variation in road substrates and traffic intensity) road-network of Kruger National Park (KNP, South Africa). We observed relatively few flight responses, suggesting impala may be partly habituated to the disturbance caused by passing vehicles. In fact, impala were largely unaffected by the presence of unpaved roads. However, impala did avoid the close proximity of paved roads, especially those with more traffic revealing a negative, albeit small, effect within this protected area that has a long history of tourism. Effective management of protected areas, particularly those where touristic activities are largely based on driving, requires careful assessment and management of road development and use to keep a sustainable balance between protecting biodiversity, satisfying visitors and optimizing the profitability of the park.

SCOPE OF CITIZEN SCIENCE DATA SHARED THROUGH THE GLOBAL BIODIVERSITY INFORMATION FACILITY

Alberto González-Talaván

Global Biodiversity Information Facility (GBIF)

Siro Masinde, Global Biodiversity Information Facility (GBIF)

; Tim HIRSCH, Global Biodiversity Information Facility (GBIF) ;

Dmitry SCHIGEL, Global Biodiversity Information Facility (GBIF)

The Global Biodiversity Information Facility (GBIF) is an international open data infrastructure that currently provides access to more than 500 million records of about 1.5 million species making it the largest online biodiversity database. About one third of GBIF records comprise citizen science data. Citizen science data publishers are able to mobilize large volumes of digital data records and share them rapidly. We analyse the citizen science data types currently shared through GBIF, and also examine their taxonomic, geospatial and temporal scope, as well as the various routines used to validate records. We discuss the changing landscape of biodiversity data publishers and how GBIF and the science community could engage further with citizen science organizations to leverage emerging opportunities to mobilize large-scale, high quality data.

MANAGING BLACK RHINOCEROS POPULATION RECOVERY IN KWAZULU-NATAL, SOUTH AFRICA: AN ASSESSMENT OF POPULATION PERFORMANCE AND PROGRAMME OUTCOMES

Peter Goodman

Wildlife Conservation Soutions

Anthony CONWAY, Ezemvelo KZN Wildlife ; Jacques FLAMAND, WWF

Following the successful recovery of the white rhino population in KwaZulu-Natal (KZN), Ezemvelo KZN Wildlife, in partnership with WWF Netherlands, embarked on a programme to enhance the much smaller black rhinoceros population in the Province. The programme is designed around three components: securing protected areas containing populations of black rhino; range expansion onto suitable communal and private lands; adaptive management supported by rigorous population monitoring. The long term goal of the programme is to secure 740 black rhino on protected lands in the province and a population growth rate of 5 % per annum towards achieving this. At the heart of the programme is the live harvest of rhino from donor populations in protected areas and the relocation of these animals to large, secure properties under private or communal ownership. Under a custodianship agreement, the founder population remains state property for 25 years, but as part of the incentive to manage effectively, the custodial partner assumes ownership of half of the progeny surviving to the age of 5 years. To encourage the appropriate level of monitoring, a monitoring plan was developed along with regular status reporting of every population in the province. Timely and accurate monitoring data allowed managers to respond quickly to unexpected events such as lowered productivity due to drought, increases in poaching deaths or cohort die-offs often experienced in small populations. After 11 years of implementation, seven new populations have been established on private and communal land in KZN and one in Limpopo Province, and 2015 will see the first removals of state-owned progeny from the newly-established populations which will act as founders for an additional population. Despite an increasing poaching mortality rate and an extended drought, the black rhino population has continued to grow from 411 in 2003 to over 500 by December 2014.

RECOVERY OF RESIDENT LARGE MAMMAL POPULATIONS IN THE WESTERN SERENGETI: SPECIES RESPONSES TO INCREASED PROTECTION, HABITAT MANAGEMENT AND COMMUNITY OUTREACH

Peter Goodman

Wildlife Conservation Solutions

Brian HARRIS, Grumeti Fund ; Matt PERRY, Grumeti Fund ; Philemon MNENEY, Grumeti Fund

The Grumeti Fund established in 2003, is a Tanzanian non-profit organisation which works with other Tanzanian institutions to manage and rehabilitate the Grumeti and Ikorongo Game Reserves and the Ikona Wildlife Management Area concession lands. This concession lies adjacent to the western boundary of the Serengeti National Park. Management undertaken by

the Fund focusses on four areas: ensuring that the Tanzanian Wildlife Laws were being upheld, controlling wildfire to meet predetermined management targets, the control of alien and invasive plants and investing in and implementing an extensive community outreach programme in the neighbouring village lands. Since it was important in realising the tourism potential of the concessions, the recovery of the resident large herbivore community was used as an indicator of project success. Fifteen herbivore species were considered largely resident (non-migratory) and their population recovery was monitored through annual population surveys between 2003 and 2014. Three population responses were evident: 1. Continuous exponential growth, 2. Initial exponential growth levelling at 'carrying capacity' and 3. An initial phase of rapid growth followed by decline. Overall the biomass density of the large herbivores increased from 13 kg ha⁻¹ in 2003 to 51.3 kg ha⁻¹ in 2014. This biomass was dominated (> 90%) by the same six species at the beginning and end of the time series namely: buffalo, elephant, eland, giraffe, impala and topi. The monitoring yielded useful data on two large predators namely spotted hyena which showed no trend over time and lion, whose population grew exponentially at 21% per annum. Domestic herbivores on the periphery of the concessions also increased dramatically as did expansion of agriculture. The conservation programme established without doubt that clearly focussed and executed management interventions can yield positive results for ecosystem rehabilitation and maintenance.

124-THE USE OF MODEL-BASED APPROACHES FOR EVALUATING THE EFFECTIVENESS OF NO NET LOSS POLICIES

Ascelin Gordon

RMIT University

Joseph BULL, Imperial College[INSTITUTE]Wildbusiness ; Astrid VAN TEEFFELLEN, VU University

The increasing decline of biodiversity globally has resulted in many governments, banks and corporations developing policies designed to achieve "no net loss" of biodiversity or ecosystem services in the face of development. Evaluating the outcomes of such policies poses significant challenges. This is due to the different time scales involved in the processes generating biodiversity losses and gains, along with a lack of resources to collect evaluation data at appropriate temporal and spatial scales. In these cases the use of ex-ante evaluation—designed to predict the future outcomes of a policy—is the only viable evaluation option, and necessitates the use of modelling and simulation approaches. This is because predictive models are the only way to evaluate future policy impacts on decadal time scales and provide the only hope for capturing some of the complex array of environmental, social, and economic factors which may

determine the success or failure of no net loss policies. Here, we provide an overview of issues arising from the application of model-based ex-ante evaluation approaches to these policies. This includes: (i) the importance of clearly defining modelling objectives and metrics to be used along with the baselines or counterfactuals against which the policy is being evaluated; (ii) the need for integrated modelling approaches; (iii) the types of insights model-based approaches can provide; (iv) the utility of applying strategic foresight techniques in conjunction with model-based evaluation; and (v) the importance of rigorously assessing the robustness of policies to uncertainty. We illustrate these issues using a range of studies from around the world that have utilised model-based evaluations for no net loss or biodiversity offset policies. We discuss the types of modelling techniques applied and the software tools used. Finally we discuss of the outstanding challenges in applying model-based approaches for evaluating no net loss policies.

TREMATODE-ASSOCIATED MORBIDITY AND MORTALITY OF TADPOLES IN ISRAEL

Liron Goren

Tel Aviv University

Jarkko ROUTTU, Tel Aviv University ; Frida BEN-AMI, Tel Aviv University

Amphibians stand at the forefront of a global biodiversity crisis. The causes of their decline are diverse, and include a rise in amphibian malformations due to various factors, especially trematode infection. However, linking amphibian mortality and morbidity with trematode infection has proven to be challenging due to the complex life cycle of the trematodes, and the fact that trematodes are non-fastidious in their choice of definitive hosts. In Israel the decline in local amphibian populations has been mostly attributed to the loss and degradation of wetlands and riparian habitats. Recently, however, there have been several reports of morbidity and mortality of tadpoles with signs of edema and malformations from various localities in Israel. We collected dead and morbid tadpoles and metamorphs of *Hyla savignyi* and *Pelophylax bedriagae*, and we showed that the morbidity and the deformations observed in the field are the result of infection by trematodes. We also isolated an echinostomatid trematode from the malformed and edematous tadpoles, and from the freshwater snail *Bulinus truncatus*, all from the same site. We further succeeded in experimentally infecting *H. savignyi* tadpoles by echinostomatid cercariae that were shed from the snails, and we showed that infection had significantly increased the mortality rates of these tadpoles. The combination of high trematode prevalence and their pathogenic effects suggest that in nature, the effect of echinostome infection on amphibians may be substantial and could become an emerging disease in Israel.

IMPACTS OF DISTURBANCE ON AN ENDANGERED LIZARD OF AUSTRALIAN HIGHLAND SWAMPS

Sarsha Gorissen

The University of Sydney

Matthew GREENLEES, The University of Sydney ; Richard SHINE, The University of Sydney

The Blue Mountains Water Skink (*Eulamprus leuraensis*) is known only from around 40 fragmented sites within the montane region of south-eastern Australia. It is endemic to a highly specific swamp habitat that is federally listed as an Endangered Ecological Community. Genetic studies show very low rates of lizard dispersal and thus gene flow between these swamps. Climate change is expected to cause hotter and drier weather conditions in the area, resulting in increased fire frequency and reduced water availability. Urbanisation and mining practices may cause further disturbance, potentially degrading habitat quality for this endangered reptile. We conducted standardised surveys of lizard distribution and demography in the majority of these swamps, and quantified habitat attributes associated with lizard occurrence at both a macro- and micro-scale. In combination with GIS-based mapping, our results indicate a lower lizard abundance in swamps that are urban-associated, and have experienced major, frequent fires over the last 40 years. Our monitoring of burnt swamps relative to adjacent unburnt swamps, has clarified the nature and rate of post-fire recovery of both vegetation and lizards. Surveying disturbed relative to undisturbed swamps, has revealed lizards are absent from swamps experiencing severe groundwater disturbance. Therefore, to conserve the Blue Mountains Water Skink in the wild, its rare, fragile and distinctive swamp habitat must be protected from the impacts of threatening processes such as frequent fire, groundwater loss, urbanisation and longwall mining.

EFFECTS OF HONEY BEES (*APIS MELLIFERA*) ON LOCAL PLANT AND BEE COMMUNITIES IN THE ISRAELI RIFT VALLEY

Ariella Gotlieb

Dead Sea and Arava Science Center and Tel Aviv University

Yael MANDELIK, The Hebrew University of Jerusalem ; Tamar DAYAN, Tel Aviv University

Bees contribute to the pollination of both wild plants and agricultural crops, and fulfill a fundamental role in the function of many ecosystems. The intensive agriculture in the Israeli Rift Valley is using large amounts of the commercial Honey Bee (HB) for successful crop pollination. However, the HB is not a local species in the desert due to insufficient bloom year round. It is present in the area only due to the agricultural practices. HBs do not limit themselves to the agricultural plots, and go out to forage in the surrounding natural habitat. There are

several known cases globally of HBs disturbing and displacing local wild bee species, and affecting reproduction success of different plant species, which is why we decided to examine its local effects. We found that the HB is the single most abundant bee species in the natural habitat surrounding the Israeli Rift Valley's agriculture. It was found on most plant species visited by bees in the area, and was the most common visitor in many of them. It managed to deplete food resources very early in the day, and failed to pollinate some of the plants it visited while boosting the pollination of others. We also found differences in HB foraging patterns between years, so that better blooming seasons increased its foraging radius and intensity, thereby increasing its effects on local bee and plant species according to its preferences.

94 THE SPREAD OF LOCALLY MANAGED MARINE AREAS IN THE SOUTH PACIFIC

Hugh Govan

LMMA Network

Alifereti TAWAKE, LMMA Network

The South Pacific has experienced a remarkable proliferation of Marine Managed Areas (MMAs) in the last decade. These protected areas, implemented by over 500 communities spanning 15 independent countries and territories represent a unique global achievement. The approaches being developed at national levels are built on a unique feature of the region, customary tenure and resource access, and make use of, in most cases, existing community strengths in traditional knowledge and governance, combined with a local awareness of the need for action, resulting in what have been most aptly termed Locally Managed Marine Areas (LMMAs). The main driver in most cases, is a community desire to maintain or improve livelihoods, often related to perceived threats to food security or local economic revenue. In the South Pacific, conservation and sustainable use are often seen as inseparable as part of the surviving concepts of traditional environmental stewardship. Here we explore the potential drivers and spatial pattern of spread of the LMMAs.

110-WE CHALLENGE YOU TO CREATE: A NEW CITIZEN SCIENCE MODEL (CONTRIBUTORY, COLLABORATIVE, CO-CREATED)

Yogani Govender

Para la Naturaleza

Lee Ann Rodriguez, Para la Naturaleza

The primary goal of the Citizen Science projects (CS) of the Conservation Trust of Puerto Rico (CTPR) was to engage citizens in nature so they can become stewards of nature. While the conventional model for CS is a participant attending a workshop or training session, learn standard methodologies to measure and assess species, habitats and ecosystems from

a scientist and then go off to collect data on their own and share data with the scientist. The CTPR propose an alternative model that includes the scientist with citizens, throughout the spatial and temporal long-term data collection. In this model, the citizens are mentored by the scientist or scientific assistant to pass through the different phase of the Informal Science Education model (contributory, collaborative, co-created). The main goal is to enable the citizens to develop the skills of scientific inquiry as they participate with the scientist so as to develop their own research question and experiment to address STEM concerns within their community. This approach challenges the project team to provide opportunities such as field trips, workshops, dissemination for participants to interact with scientists in more intimate manner to stimulate dialogue about experiments or research that they would be interested in developing through this project. Based on the criteria set by scientists, these vary from the numbers of times participants contributed to data collection, skills on equipment use, ability to do data entry and analysis and confidence to disseminated information about project citizens are able to move through the different phases of the model. Currently of the 900 citizens we have 25 that have passed the contributory phase of the model and have developed a community based science project.

UNEXPECTED CONSEQUENCES OF POPULATION MANAGEMENT: STRONG GENETIC IMPACT OF HISTORIC REINFORCEMENTS ON A POPULATION OF THE ENDANGERED SPUR-THIGHED TORTOISES.

Eva Graciá

Miguel Hernández University

Roberto C. RODRÍGUEZ-CARO, Miguel Hernández University ; Francisco BOTELLA, Miguel Hernández University ; Uwe FRITZ, Museum of Zoology, Senckenberg Dresden ; Ana C. ANDREU, Equipo de Seguimiento de Procesos Naturales - Estación Biológica de Doñana (CSIC) ; Andrés GIMÉNEZ, Miguel Hernández University

The majority of the western Mediterranean distribution of the spur-thighed tortoise (*Testudo graeca*) lies in North Africa, with a few small and isolated western European populations confined to the Iberian Peninsula (Doñana and south-eastern Spain) and a few islands (Mallorca, Sardinia and Sicily). In the Iberian Peninsula, recent studies identified an ancient North African origin for the south-eastern Spanish population, which was dated to an age of 20,000-30,000 years ago. Here we use molecular data to shed light on the origin of the other Iberian population, located in the Doñana National Park. The earliest references of tortoises inhabiting Doñana trace back to the 18th century, but several introductions of Moroccan animals during 20th century are also well-documented. As a consequence, this population could have mixed ancestries

due to its historic management. We sampled 88 tortoises from Doñana to obtain mitochondrial sequences from the cytochrome b gene and genotypes derived from thirteen microsatellite loci. This dataset was analysed together with molecular data from previous works which involved south-eastern Spanish and North African tortoises. We mainly used population genetic descriptors, haplotype networks and Bayesian clusters analyses to assess the differentiation among the tortoises from Doñana, south-eastern Spain and North Africa. Both mitochondrial and microsatellite data confirmed that historic population reinforcements used the subspecies *T. g. marokkensis* from Morocco, which were introduced to an original population of the subspecies *T. g. graeca*. Sixteen individuals were identified as hybrids, all of them males (sex ratio of 2.18 males per female in our sample). Our results indicate that the recent management of the species had strong effect on the initial genetic composition, and could have altered the sex ratio of the population. This is unexpected since the species is considered to have a temperature-dependent sex determination.

EMPIRICAL EVALUATION OF SPATIAL AND NON-SPATIAL CMR METHODS TO ESTIMATE POPULATION SIZE USING NON-INVASIVE GENETIC SAMPLING

Anne-Céline Granjon

Max Planck Institute for Evolutionary Anthropology
Kevin, E LANGERGRABER, Arizona State University; Carolyn ROWNEY, Ngogo Chimpanzee Project; Linda VIGILANT, Max Planck Institute for Evolutionary Anthropology

Application of genetic capture-mark-recapture (CMR) approaches for estimating population size and sex ratio has great potential for aiding effective conservation management of rare or elusive wild animals. To date, no study has explored the reliability of this approach by directly comparing population size estimates obtained via genetic CMR with the known actual size of a population. Here we used a wild community of almost 200 eastern chimpanzees (*Pan troglodytes schweinfurthii*), for which all individuals are known and genotyped, to evaluate the accuracy and precision of population estimates obtained using autosomal microsatellite genotyping of fecal samples. We used samples collected opportunistically over three years within the known territory of the community to explore the impact of lengthened sample periods, which increase sample sizes but also increase chances of deaths or births and consequent violations of population closure assumptions. We compared the effects of using spatial and non-spatial models as well as equal or heterogenous capture probabilities upon estimates. We found that using all of the available data, which represented 79% of the known number of individuals, leads to up to 90% decrease of the relative bias and over 40% improved precision, despite violation of population closure. We found non-spatial

methods estimated community size accurately. However, this community size estimate represented only adult and adolescent individuals, as comparison of genotypes collected for the census with those from known individuals revealed that infants and juveniles are very rarely sampled in a census. In sum, this study suggests that accurate and precise population size estimates may be obtained provided substantial effort is allocated to sample collection and genotyping, that violations of closure assumptions may not be problematic, and emphasizes that not all age categories of individuals will necessarily be sampled or consequently estimated.

ENVIRONMENTAL-ECONOMIC ACCOUNTING AND PROTECTED AREAS: CASE STUDY FROM PERU

Hedley Grantham

Conservation International
Mahbulul ALAM, Conservation International; Fabiano GODOY, Conservation International; Miro HONZAK, Conservation International; Daniel JUHN, Conservation International; Trond LARSEN, Conservation International; Rosimeiry PORTELA, Conservation International; Ana Maria RODRIGUEZ, Conservation International

Protected areas, and the biodiversity and ecosystems within, provide many benefits for people. This includes protecting biodiversity's intrinsic values, but also safeguarding human-use values, such as the provision and regulation of water sources, and the climate benefits of stored carbon. Because of this, protected areas are now acknowledged as an important component of sustainable development. It is imperative to monitor networks of protected areas and their surrounds to ensure sustainable management of our landscapes and seascapes. The System of Environmental and Economic Accounts (SEEA) is based on an internationally agreed standard concepts, definitions, accounting rules and provides internationally comparable statistics on the environment and its relationship with the economy. As part of this approach is recognizing that biodiversity and ecosystems are key assets of a country. The approach encourages the measurement of statistics on landuse, including protected areas, which can indicate how these form a key component of managing these assets. Ecosystem accounts are often based on spatially explicitly data. This allows measurement of the flows of benefits from assets to different economic sectors and communities, providing statistics, such as, how protected areas provide benefits to those in the landscape or seascape around them. Conservation International is currently piloting a set of ecosystem accounts within a subregion of Peru (San Martin) in partnership with the national and state governments. Here we report on the science underpinning the set of ecosystem accounts, and how these accounts link to key policies and decision-making processes, particularly protected areas

monitoring and assessment but also more broadly landuse planning, REDD+ and sustainable development strategies.

TALKING TO THE REST OF THE WORLD: LESSONS FROM THE FULLER SCIENCE FOR NATURE FUND ON COMMUNICATING YOUR SCIENCE TO NON-SCIENTISTS

Kate Graves

WWF-US

Robin ABELL, Freshwater Biologist

Successful dissemination of science to non-scientists requires even the most cutting-edge thought leaders to be strong communicators. In this age of TED Talks, policy makers and other audiences may expect a scientist's presentation skills to be on par with his/her research and expertise. Many scientists recognize that there are barriers to uptake of their work; for instance, a recent AAAS/Pew Research Center public opinion poll found that "only 15% of scientists say they believe policy choices about land use are guided by the best science most of the time or always." Yet, some scientists continue to communicate their work in traditional ways, hoping that it might be taken up and regularly frustrated when it isn't. Others are keen to improve but may be intimidated by more seasoned presenters on the 'talk circuit.' Based on the Kathryn Fuller Science for Nature Fund's seven-year history of researching, evaluating, inviting, and ultimately hosting scientists to talk about their science, we will discuss the skills scientists must demonstrate to receive speaking invitations, and the presentation design and style that make a scientist an effective communicator to non-scientists. We will cover the importance of an online footprint, social media, simplifying, storytelling, images and the pitfalls of slides, use (and overuse) of video, fit to audience, and common sense. We will highlight relatively easy improvements that individuals can make to their oral communications and provide advice for becoming a 'go-to' speaker, so that the results of scientists' hard work are heard by those who make decisions affecting conservation.

DO TERRESTRIAL PROTECTED AREAS MITIGATE HUMAN PRESSURES? A GLOBAL ANALYSIS OF LOCAL BIODIVERSITY WITHIN PROTECTED AREAS USING THE PREDICTS DATABASE

Claudia L. Gray

University of Sussex

Sam L. L. HILL, UNEP World Conservation Monitoring Center ; Tim NEWBOLD, UNEP World Conservation Monitoring Center ; Lawrence H. HUDSON, Department of Life Sciences, Natural History Museum ; Luca BÖRGER, Swansea University ; Andy

PURVIS, Department of Life Sciences, Natural History Museum ; Jörn P. W. SCHARLEMANN, University of Sussex

Protected areas (PAs) are widely seen as central to biodiversity conservation efforts. Their importance is reflected in the Convention of Biological Diversity's Aichi Biodiversity Target 11, which commits nations to protect 17% of the global land area by 2020. However, few studies have quantified the effectiveness of protection for local biodiversity on a global scale. We present a global analysis of whether and how PAs mitigate human impacts on local biodiversity using a new database (PREDICTS - Projecting Responses of Diversity In Changing Terrestrial Systems: www.predicts.org.uk) that provides unprecedented geographic and taxonomic coverage, with over 2 million biodiversity records, representing 35,000 species from nearly 20,000 sites, 88 countries and more than 450 PAs. Analyses accounting for confounding variables (elevation, slope and agricultural suitability) found positive effects of protection on local species richness, abundance and endemism. However, these positive impacts are partially explained by differences among land uses, as the impact of protection was weaker when sites were matched by land use. These results suggest that a major way in which PAs conserve local biodiversity is by preventing land use change. However, additional benefits of protection were also detected within some land use types, in certain geographic regions and/or particular taxonomic groups. We also assessed the impact of PA characteristics, specifically PA size, age and IUCN category. We did not find a strong effect of IUCN category on local biodiversity, but there were small increases in local species richness with increasing PA size. The effect of PA age varied among geographic realms and biodiversity metrics. Our results provide evidence that PAs are an effective conservation tool, but also highlight that the impact of protection is context-specific and varies with PA characteristics and among taxa, geographic regions and land uses.

NEW PATHWAYS FOR CONSERVATION PLANNING: VALIDATING THE IMPORTANCE OF LAND USE IN SPECIES DISTRIBUTION MODELS

Morgan Gray

UC Berkeley

Adina MERENLENDER, UC Berkeley

Species distribution information is often required for strategic conservation planning. Due to limited empirical information about landscape composition and wildlife movement, conservation professionals often rely on modeled distributions. Species distribution models are often constructed using presence-only (PO) collection records from museums. Maxent is one model that predicts species distributions using PO and environmental datasets. Although the built environment can reduce wildlife movement, human land use is rarely included as

input in these models. Few studies have done post-calibration model validation using independently collected presence/absence (P/A) data for mammalian carnivores – informative focal species because of their sensitivity to fragmentation. To test whether including land use improves the predictive ability of a species distribution model derived from PO data for a carnivore, we used Maxent to construct, compare, and verify two gray fox models: an experimental model that included land use variables and a control that did not. We created both models using a single set of gray fox PO museum records (n=68), as well as environmental and animal co-occurrence input. We confirmed each model's predictions with independently collected gray fox P/A data. Including land use resulted in a stronger model, as measured by the area under the receiver operating characteristic curve (AUC); point biserial correlation; and kappa as an index of Type I and II errors. Validation of model predictions revealed limitations of this commonly used modeling approach. This research can provide conservation professionals with a new tool for collaborative conservation planning in an era of habitat fragmentation. Further, as mid-sized carnivores, foxes have an optimal body size and demography for habitat connectivity models. Understanding land use by these charismatic fauna can help the public conceptualize and prioritize landscape pathways for conservation.

MENTAL MODELER: INCORPORATING SCIENTIFIC AND LOCAL EXPERTISE INTO CONSERVATION PLANNING THROUGH A FUZZY-LOGIC COGNITIVE MAPPING SOFTWARE TOOL

Steven Gray

University of Massachusetts

There is a growing interest in, and use of, Fuzzy-logic Cognitive Mapping (FCM) as a methodological tool for participatory conservation planning. In recent years, FCM has been applied to a diverse set of natural resource case studies, ranging from fisheries management to agricultural development, in an effort to generate predictive models that can support environmental decision-making by illuminating the core presumptions of different stakeholders and integrating both scientific and local expertise. This increase in popularity is due in no small part to FCM's "bottom-up" approach and its ability to represent community-level knowledge in a standardized and dynamic way. Although the method has grown in popularity, software tools that facilitate developing FCM with stakeholders in conservation contexts still remain limited. In this presentation I will present the architecture and various uses of a new freely available FCM-based software tool called Mental Modeler (www.mentalmodeler.org). Using case study data developed from community-driven models of the bushmeat trade in Tanzania and community-based land conservation in the USA, this

presentation will outline the usefulness and limitations of the participatory modeling software as a way to engage in scenario planning and to promote learning among stakeholders. I will also discuss using the FCM data collected as a basis to explicitly engage stakeholders in a discussion about managing resource systems toward desirable or undesirable states and evaluating trade-offs in competing conservation policy options.

SYMPOSIUM #156: SEARCHING FOR SAOLA: HOW IDNA SUPPORTS CONSERVATION OF ASIA'S ELUSIVE UNICORN

Thomas Gray

WWF Greater Mekong

Anh Hoa Anh NGUYEN, WWF Vietnam ; Doug YU, Kunming Institute of Zoology ; Andrew TILKER, Saola Working Group

Saola *Pseudoryx nghetinhensis* is one of the most phylogenetically distinctive and threatened mammals in the world. Only discovered in 1992 saola have never been observed in the wild by scientists and have been recorded from camera-traps only once in the 21st century. Understanding the species' distribution is critical for effective conservation action either in-situ or ex-situ through capturing individuals for a captive breeding program. The recent documentation of the effectiveness of extracting mammalian DNA from haemophagous leeches provides a possible opportunity to survey, and thus detect, saola populations. Between January 2012 and December 2014 more than 50,000 leech samples were collected from protected areas in the saola's range in Vietnam and Laos. Mammalian DNA was extracted from these samples using a number of techniques. At least 20 species of mammal were detected including 5 listed by the IUCN as threatened and 3 Annamite endemic species. Saola have not yet been detected from analysed leech samples. Whilst analysis of haemophagous leeches is able to provide data on mammal communities the methodologies effectiveness for detecting rare and elusive species remains unclear. As a result of a combination of extensive delays in receiving genetic results and insufficient representation of Annamite species in GenBank the advantages of this methodology, compared to camera-trapping, for field conservationists in Asia requires further research.

GENDER DIMENSIONS OF CLIMATE CHANGE ADAPTATION IN COASTAL COMMUNITIES OF THE PHILIPPINES

Kathryn Graziano

School of Marine and Environmental Affairs, University of Washington

Richard POLLNAC, Dept. of Marine Affairs and Coastal Resource Center, University of Rhode Island ; Patrick CHRISTIE, School of Marine and Environmental Affairs, University of Washington

Climate change is expected to have a broad range of impacts on social and ecological systems. In developing countries, climate change will affect and engage men and women differently. However, the type, extent and implications of these differences for the most part lack contextual, empirical support. This study examines the gender dimensions of climate change adaptation (CCA) and marine resource dependency in fishing villages of the Philippines. It seeks to 1) Identify and challenge assumptions about women and climate change 2) Examine beliefs, values, perceptions of risks, resource dependency, and awareness associated with climate change and marine resource management, and 3) Evaluate the implications of gendered relationships with fisheries and the environment. Social surveys were administered randomly to marine resource users in 30 coastal villages within three Philippine provinces (Palawan, Occidental Mindoro, and Batangas). Findings indicate that women felt less connected to nature, were more risk tolerant, and were equally inclined to conservation attitudes as men. Women were more aware of climate change and CCA plans, but less likely to attend outreach activities. Men and women were equally likely to participate in mangrove planting restoration activities for CCA. The results offer insights that dispel certain generalizations and present opportunities for improved integration of both men and women in effective and equitable CCA, as well as marine resource management.

PREDICTIVE MODELS OF SEAGRASS CONNECTIVITY TO INFORM CONSERVATION PLANNING

Alana Grech

Macquarie University

Robert COLES, James Cook University ; Michael RASHEED, James Cook University ; Len MCKENZIE, James Cook University ; Jolan WOLTER, Université catholique de Louvain ; Emmanuel HANERT, Université catholique de Louvain

The rate of exchange, or connectivity, among populations affects their ability to recover after disturbance events. However, our understanding of the extent to which populations are connected is poor, especially in coastal and marine ecosystems. Our research exploits the advanced computational power of new hydrodynamic models to predict the connectivity of seagrass habitats in the iconic Great Barrier Reef of Queensland, Australia. We used the 2-dimensional advection-diffusion Second-generation Louvain-la-Neuve Ice-ocean Model (SLIM) to simulate the dispersal of seagrass fragments and propagules. The simulation outputs were used in a network analysis to identify both the location and intensity of connections between discrete seagrass meadows. The network analysis was also used to explore changes to the

structure and functioning of the seagrass network when one or more discrete meadows were removed due to two disturbance events (cyclones and coastal development). The outputs of our analysis enabled the development of quantitative objectives and conservation strategies that are critical to the management of seagrasses in the Great Barrier Reef, including the identification of critical stepping stones and source meadows. In addition, this project enabled an improved understanding of the potential impact of cyclones and existing and proposed coastal developments on the functioning and health of the Great Barrier Reef.

OPTIMIZING ECOLOGICAL BENEFITS AND ECONOMIC COST OF INVASIVE SPECIES CONTROL: THE CASE OF INDO-PACIFIC LIONFISH REMOVAL ON ATLANTIC REEFS

Stephanie Green

Oregon State University

Elizabeth UNDERWOOD, Reef Environmental Education Foundation ; Bernard CASTILLO, University of the Virgin Islands ; Reale-Munro KYNOCH, University of the Virgin Islands ; Ian LUNDGREN, US National Park Service ; Lad AKINS, Reef Environmental Education Foundation

Many invasions occur at a scale and magnitude that outstrips the conservation and management resources available to eradicate them, setting up a long term battle for control. For these invasions, two key questions arise: What level of control is sufficient to mitigate ecological impacts in high-priority management areas? What resources are required to achieve a sufficient control? An ongoing marine invasion for which there is an urgent need to devise efficient control strategies is that of predatory Indo-Pacific lionfish into the Western Atlantic. Lionfish occupy virtually all marine habitat types in the region, and are causing precipitous declines in the biomass of Atlantic coral reef fishes. Using the lionfish invasion as a test case, we develop a general quantitative model for identifying the marginal value of invasive species control activities, in terms of achieving ecological protection of the invaded community. Specifically, we link a predictive ecological model identifying threshold densities at which lionfish overconsume native fish with an economic model of the cost of removal required to suppress lionfish below threshold levels. We parameterize the model with data from a 2 year experiment at 58 invaded coral reefs in South Florida and St. Croix, USVI, in which we tracked the effort and success rate of culling by divers removing lionfish from half of the sites bi-monthly, and the response of native fish communities at the removal and reference non-removal sites over time. Our analysis reveals that the level of lionfish control required (in terms of cost and removal frequency) to achieve maximum ecological benefit (maintenance of native fish biomass) is highly variable across

the system, with some sites requiring far less effort than is allocated under current management regimes, and some far more. Our work provides a predictive method for efficiently allocating resources to invasive species control from estimates of removal cost and ecological response.

THE IMPORTANCE OF ADDRESSING ALLELIC RICHNESS IN CONSERVATION: THE CASE OF FOUNDER EVENTS AND THE 'ONE MIGRANT PER GENERATION' RULE

Gili Greenbaum

Ben-Gurion University

Alan TEMPLETON, Washington University ; Yair ZARMI, Ben-Gurion University ; Shirli BAR-DAVID, Ben-Gurion University

Two main measures are used to assess genetic diversity: heterozygosity and allelic richness. While both measures have ecological and evolutionary significance, they differ in their implications as well as in their mathematical formulation. While heterozygosity is more significant for a population's short-term viability, allelic richness is more indicative of long-term potential for adaptability and persistence. Although allelic richness is of high importance in conservation, it is less commonly used than heterozygosity, partially because it is more mathematically difficult to take into account the stochastic process of genetic drift for allelic richness. Founded populations (e.g., reintroduced populations) are scenarios where the distinction between the two measures is especially important since such populations are vulnerable to loss of genetic diversity. In this work a stochastic model for allelic richness of a newly founded population experiencing genetic drift and gene flow is presented. The model follows the dynamics of alleles lost during the founder event, and simulates the effect of gene flow on maintenance of allelic richness. The applicable method in which the probability of allele presence can be used in combination with a population's allele frequency spectrum to provide predictions for allele recovery is shown. The model's analysis provides insights into the dynamics of allelic richness following a founder event, taking into account gene flow and allele frequency spectrum. Furthermore, the model illustrates that the 'One Migrant per Generation' rule, a commonly used conservation guideline related to heterozygosity, may be inadequate for preserving diversity at the allelic level. Hence, population genetic studies and conservation efforts aimed at preserving genetic diversity should consider both measures, as focusing merely on preserving heterozygosity might not preserve allelic richness, which is crucial for species persistence and evolution.

PREDICTING DISEASE-INDUCED EXTINCTIONS IN AMPHIBIANS USING HOST TRAITS AND EVOLUTIONARY HISTORY.

Dan A. Greenberg

Simon Fraser University

Wendy J. PALEN, Simon Fraser University ; Arne Ø MOOERS, Simon Fraser University

Conservation practitioners require methods to predict species' responses to threat processes even when data are scarce. The global decline of amphibians represents an urgent case in point. In many regions the fungal pathogen *Batrachochytrium dendrobatidis* (Bd), which causes the disease chytridiomycosis, is a major driver of local extinctions. While epidemics of chytridiomycosis result in a great loss of local species diversity, there are many species that manage to survive these events. Why do some species decline while others persist during a disease epidemic? Host traits are likely to influence several facets of a species' disease susceptibility, and therefore may represent a way to predict extinction outcomes during disease epidemics a priori. To examine this possibility we gathered a global dataset on Bd infection prevalence for over 300 species of amphibians from 85 different sites. We examined how different life history and ecological traits may predict susceptibility to infection using phylogenetic comparative methods. Subsequently, we tested whether these traits similarly correlate to patterns of local extinction during disease epidemics with an independent data set. We found that patterns of Bd infection prevalence in amphibians are phylogenetically non-random, with certain clades bearing high levels of infection while others display very low infection prevalence. This strong phylogenetic signal (Pagel's $\lambda = 0.82$, $p < 0.01$) in infection prevalence suggests that phylogeny alone is a significant predictor of Bd susceptibility in amphibians. Using commonly available data on host traits and phylogeny may represent an effective method to prioritize species for conservation management in the event of future disease epidemics.

OIL AND GAS COMPRESSOR NOISE IMPACTS FECUNDITY OF A THREATENED SPECIES OF PRAIRIE-GROUSE

Andrew Gregory

Bowling Green State University

Thomas LIPP, Bowling Green State University ; David HAUROS, Kansas State University

As a result of precipitous population declines over the last 30 years, in April, 2014 the Lesser Prairie-Chicken (*Tympanuchus pallidicinctus*; hereafter LPC) was listed as threatened under provisions of the United States Endangered Species Act. Due to this listing, the Western Association of Wildlife Management

Agencies created the Lesser Prairie-Chicken Range Wide Conservation plan. One aspect of the plan is to understand and mitigate for impacts of oil and gas energy development on LPC populations. For this study, we assessed the influence that oil and gas compressor station noise had on LPC nest placement on a 500km² landscape in west central Kansas, USA. There are two types of gas pumping compressors used on our study landscape, electric and natural gas. To the human ear, electric compressors produce less noise; however, this is due to less noise at higher frequencies (>300Hz). Prairie-grouse communications occur at a frequency of 30-100Hz. We characterized anthropogenic noise associated with electric and gas compressor stations using Larson Davis Lxt-L1 SPL meters and modeled oil and gas sound propagation across the landscape using SPreAD GIS. On average, additive oil and gas compressor station noise (noise significantly >ambient noise) propagates 1,253.4 meters; thus, additive oil and gas compressor noise impacts ~37% of our study landscape. Over the frequency range at which LPC vocalizations occur (~30-80Hz), additive noise from electric compressors was found to be propagates 25% further than does natural gas powered compressor noise ($P=0.03$). We then plotted the location of 186 LPC nests from 56 GPS collared female LPC's on the soundscape. Of 186 LPC nests observed, only 27 (15%) were placed in areas that were impacted by oil and gas compressor noise. These data suggest that the current mitigation recommendation, of electric compressor stations, may actually be worse for LPC's than the standard gas compressors currently in use.

PREDACIOUS ARTHROPOD DIVERSITY OF AGRICULTURAL LANDSCAPES IN GRASSLANDS.

Bianca Greyvenstein

The North - West University (Potchefstroom, South Africa)
Johnnie VAN DEN BERG, The North - West University (Potchefstroom, South Africa) ; Stefan SIEBERT, The North - West University (Potchefstroom, South Africa)

Biodiversity is a resource that has important ecological and evolutionary potential, and is essential to sustain many vital ecosystem services. Biologically diverse ecosystems are threatened by disturbances such as agricultural activities that reduce levels of biodiversity with extensive monoculture crops. Pesticide resistance within cultivated areas threatens global food security. Predator species are becoming increasingly important for pest regulation. However, current knowledge is lacking regarding the diversity and abundance of predators in fields and their movement patterns to and from fields. We selected a set of predaceous arthropods, namely Lacewings (Chrysopidae), Praying mantids (Mantodea), Spiders (Araneae) and Ladybugs (Coccinellidae) to assess the diversity and species assemblages in and around agricultural fields in the extensively cultivated Highveld grasslands of South Africa. We

sampled fields and field margins four times a day to develop an understanding of the movement patterns of these arthropods within the agro-ecosystems. Our results indicated that field margins (30m) are the most diverse and abundant in terms of predaceous arthropod diversity along a maize field-field margin-untransformed grassland gradient. Predators are drawn to edges of cultivated land to improve hunting success. Our results support the Natural Enemies' Hypothesis which states that predators are more effective in such heterogeneous plant environments. Field margins therefore play an important role in the maintenance of predaceous arthropod diversity and have an important role in strategies to achieve food security. Pesticides remain crucial for the control of pest outbreaks and our findings suggest that mornings (7 A.M.) are better for spraying pesticides as this is the time of day when predator populations were almost absent from maize fields.

REVEALED AND STATED PREFERENCE CHOICE EXPERIMENTS TO ASSESS BEACH MANAGEMENT PRIORITIES

Caroline Griffin

University of Stirling

Nils BUNNEFELD, University of Stirling ; Nick HANLEY, University of St. Andrews ; Andre GILBURN, University of Stirling

A major problem with land management can occur due to necessary trade-offs between different ecosystem services. Should the areas be managed for biodiversity or for people? This is a global problem and examples can be found from a variety of different environments and ecosystems, i.e. agriculture, forestry, fisheries and coastal areas. One solution to this problem is to try and place a monetary value on the natural environment and biodiversity. This is incredibly challenging due to the complexities of the natural world, which cannot easily be represented using a linear economic model. This method of valuing nature polarises opinion and poses a number of moral and ethical questions. However, placing a monetary value on nature does, at least, ensure the environment can be accounted for in any decision making processes involved in management. Choice experiments are one method used to try and overcome some of the problems associated with nature valuation. These economic tools can be used to try and discover the value that society places on an environmental good or service. We carried out stated and revealed preference choice experiments to discover the valuation people placed on features found at tourist beaches on the east coast of Scotland. We found that the majority of people chose excellent bathing water quality and high levels of biodiversity over beach awards. This has implications for how coastal regions are managed and suggests there should be an emphasis on an ecosystem services approach rather than spending time and resources attempting to achieve an award status based on aesthetics and poorly valued services.

95 - ROAD IMPACTS: THE HISTORY SO FAR

Clara Grilo

Universidade de Aveiro

Daniel SMITH, University of Central Florida, USA ; Rodney VAN DER REE, Australian Research Centre for Urban Ecology, Royal Botanic Gardens Melbourne and The University of Melbourne, Australia

The global network of roads, railways, trails, artificial waterways and utility easements is extensive in its length and spread worldwide. The global rate of linear infrastructure construction will continue to rise for the foreseeable future, accentuated by accelerated rates in many developing countries – 90% of the expected 25 million lane km to be added by 2050 will be in non-OECD countries. Traffic volume is expected to more than double by 2050 from 870 million vehicles to 1.7 to 2.8 billion. The combined impacts of linear infrastructure and traffic are significant threats to the persistence of species and functioning of healthy ecosystems through wildlife mortality, habitat loss and degradation, as barriers or filters to movement, avoidance, attraction, provision of habitat and/or corridors for movement, affecting individual wildlife, populations, communities and landscapes. However, the nature and severity of these effects vary among species because of their different morphological, ecological and behavioural traits, and depends on the location, density and configuration of the road network. Many governments and communities around the world have developed strategies to avoid, minimise, mitigate and offset many negative effects. However, not all impacts can be fully mitigated and not all mitigation measures are equally effective. The challenge currently facing society is to build a more efficient transportation system that facilitates economic growth and development, reduces environmental impacts and protects biodiversity and ecosystem functions. Supporting good quality research and collaboration between scientists and practitioners can steer the development and management of effective transportation systems toward establishing long-term environmental sustainability. The broad aim of this symposium is to provide the history so far of road impacts and mitigation and to discuss the latest findings on this issue.

EARLIER TIMING, LOWER SUCCESS: DOES THE SPATIAL SCALE OF CLIMATIC CONDITIONS MATTER IN A MIGRATORY PASSERINE BIRD?

Annegret Grimm

Helmholtz-Centre for Environmental Research

Brigitte M. WEIß, University of Leipzig, Institute of Biology, Behavioural Ecology Research Group ; Lars KULIK, University of Leipzig, Institute of Biology, Behavioural Ecology Research Group ; Jean-Baptiste MIHOUB, Helmholtz-Centre for Environmental Research ; Roger MUNDREY, Max-Planck-Institute for Evolutionary Anthropology, Department of Primatology

; Ulrich KOEPPEN, Beringungszentrale Hiddensee ; Tomas BRUECKMANN, Grüne LIGA Kohrener Land ; Ruth THOMSEN, University of Leipzig, Institute of Biology, Behavioural Ecology Research Group ; Anja WIDDIG, University of Leipzig, Institute of Biology, Behavioural Ecology Research Group

Following over 20 years of research on the effects of climate on biodiversity, we now have strong evidence that climate change affects phenology, fitness, and distribution range of different taxa, especially birds. Although scale-related effects are common in ecology, the vast majority of studies analysing effects of climate change were accomplished using climatic information at a single spatial scale. Using data from a migratory passerine, the double-brooded barn swallow (*Hirundo rustica*) from Eastern Germany, we investigated the scale dependent sensitivity to climate change of the breeding phenology and performance. We investigated effects of the local weather (small scale) and the North-Atlantic-Oscillation-index (NAO) (large scale) on the breeding timing and success of both annual broods. In line with previous studies in migratory birds, we found that these barn swallows bred progressively earlier but showed reduced breeding success over time in response to recent climate changes. Responses were observed on both small and large climatic scales, but they differed with respect to the ecological process considered. Specifically, we found that breeding timing was primarily influenced by the large-scale NAO variations and to a lesser extent by local weather on the breeding ground. Conversely, breeding success of both broods was exclusively driven by climatic conditions on the local scale. The temporal decrease of the breeding success is likely a consequence of mismatches between climatic conditions and different breeding phases resulting from diverging scaling processes. Our findings corroborated numerous evidences of previous studies dealing with biodiversity response to climate change. However, by disentangling climatic conditions acting at different scales, we emphasise that responses of ecological processes to climate change need to be studied in the context of scaling in order to better understand the complexity of climate change effects on biodiversity.

ENVIRONMENTAL VARIABLES DETERMINING THE OCCURRENCE OF THE RED-LISTED CARBONICOLA ANTHRACOPHILA AND C. MYRMECINA IN BOREAL FORESTS- RECOMMENDATIONS FOR NATURE CONSERVATION AND FOREST MANAGEMENT

Fiona Grossmann

Swedish University of Agricultural Sciences

Göran THOR, Swedish University of Agricultural Sciences ; Victor JOHANSSON, Swedish University of Agricultural Sciences

In this study the species-substrate relationship of two red-listed forest-fire dependent lichen species *Carbonicola anthracophila*

and *C. myrmecina* is investigated as well as the environmental variables determining their occurrence. 3 dead wood types (snags, stumps, logs) of *Picea abies* as well as “ordinary” and “resin-rich” *Pinus sylvestris* were sampled. 24 forest stands of different forest types (8-19 years old, 20-64 years old, >65 years old, nature reserves & voluntary set-asides) were inventoried in boreal forests in Hälsingland, Sweden. To record the frequency of potential *Carbonicola* harbouring substrates a dead wood inventory was conducted using a 200 x 10 m sample plot. Lichen occurrence probability was modelled based on the explanatory variables using a generalized linear mixed model with a logit link function. The number of suitable dead wood objects in a stand was modelled based on stand categories using a zero-inflated Poisson regression. Substrate characteristics were the most important variables in species occurrence and therefore confirm the strong substrate specificity of *Carbonicola anthracophila* and *C. myrmecina* towards resin rich, hard, charred, dead pine wood without bark. Both lichen species were found within all stand categories, which demonstrates that stand level characteristics such as forest age or management type are not per se important for lichen occurrence. Resin rich pine dead wood was found more often in nature reserves and voluntary set asides than in middle-aged stands. Due to the high substrate specificity of *Carbonicola* effective conservation measures should aim at (i) the preservation of suitable substrates currently existing in managed forests and (ii) the creation of suitable *Carbonicola* harbouring substrates in the future with a focus on protected areas.

SCIENCE FOR NATURE AND PEOPLE INITIATIVE - MULTIDISCIPLINARY TEAMS SOLVING PROBLEMS AT THE NEXUS OF CONSERVATION AND HUMAN WELL-BEING

Craig Groves

The Nature Conservancy

Most of the world’s most serious nature conservation issues require a breadth of disciplinary expertise to solve. In 2013, three major institutions (The Nature Conservancy, Wildlife Conservation Society, and the National Center for Ecological Analysis and Synthesis at the University of California, Santa Barbara) collaborated to launch the Science for Nature and People Initiative or SNAP (www.snap.is). SNAP has an annual call for proposals from which we have approved and funded 19 interdisciplinary working groups spanning a range of global issues but typically focused on both biodiversity and ecosystem services across three major areas of activity – Food and Water Security, Nature and Economics, and Disaster Risk Reduction. Working group members include a diversity of scientists, policy makers, and conservation practitioners across a variety of institutions. Typical working groups collaborate for two

years, synthesize existing data (e.g., global database of nature-based defense projects) and develop products (e.g., Green Investment Guide indicating the top 25 Latin American cities in which natural infrastructure could play a role in improved water quality) that are used in implementing conservation strategies and actions in existing conservation initiatives. Participants in working groups to date represent 38 countries, over 80 universities, 60 non-governmental organizations, 17 US federal government agencies & 10 non-US government agencies, and 19 private sector organizations. In 2015, the total funding for working groups was \$US 2 million with nearly 2/3 of that funding leveraged through matching funds. The results of four working groups will be highlighted – Infrastructure Development and Freshwater Resources in western Amazonia, Managing Data Limited Fisheries, Nature-based Coastal Defenses, and Conserving Nature for Water Security.

PROVIDING MORE PROTECTED SPACE FOR TIGERS PANTHERA TIGRIS: A LANDSCAPE CONSERVATION APPROACH IN THE WESTERN GHATS, SOUTHERN INDIA

Sanjay Gubbi

Nature Conservation Foundation

Kaushik MUKHERJEE, Government of Karnataka ; M. H. SWAMINATH, Indian Forest Service (Retd) ; H. C. POORNESHA, Nature Conservation Foundation

Conservation of large carnivores is challenging as they face various threats, including habitat loss and fragmentation. One of the current challenges to tiger *Panthera tigris* conservation in India is the conversion of habitat to uses that are incompatible with conservation of the species. Bringing more tiger habitat within a protected area system and in the process creating a network of connected protected areas will deliver dual benefits of wildlife conservation and protection of watersheds. Focusing on the southern Indian state of Karnataka, which holds one of the largest contiguous tiger populations, we attempted to address this challenge using a conservation planning technique that considers ecological, social and political factors. This approach yielded several conservation successes, including an expansion of the protected area network by 2,385 km², connection of 23 protected areas, and the creation of three complexes of protected areas, increasing the protected area network in Karnataka from 3.8 to 5.2% of the state’s land area. This represents the largest expansion of protected areas in India since the 1970s. Such productive partnerships between government officials and conservationists highlight the importance of complementary roles in conservation planning and implementation.

95. THE CONSEQUENCES AND OPPORTUNITIES OF RAPID EXPANSION OF LINEAR INFRASTRUCTURE IN THE DEVELOPING WORLD.

Sanjay Gubbi

Nature Conservation Foundation

Wendy COLLINSON, The Endangered Wildlife Trust ; Kylie SOANES, Australian Research Centre for Urban Ecology, The University of Melbourne

Global road-rush is largely related to economic goals and escalating demands for natural resources. This is especially true in the developing world where there is a confluence of economic growth, biodiversity richness and high species endemism. Nine-tenths of the 25 million kilometers of new road development, that are anticipated to be built by 2050, are expected to occur in developing nations. The opening up of relatively pristine and frontier areas for development increases colonization, habitat fragmentation, overexploitation of wildlife and other natural resources. In countries like India and South Africa the challenge comes primarily from the conversion of existing small roads with low-volume traffic into high-speed highways. Coupled with road improvement is the increase in vehicle numbers and their ability to travel at higher speeds due to improved technology resulting in higher wildlife-vehicular-collision mortalities. In many parts of Asia and Africa, new roads have also contributed to overhunting of endangered species as well as fueling bushmeat trade. Many developing nations lack policies to make road-development wildlife compatible. Hence it is important to establish ecologically sound policies and practice to avoid or minimize the negative impacts on wildlife and their habitats. In countries with developed policies, wildlife concerns are often given insufficient attention during the design, planning and construction of roads. There are, however, some examples where science-conservation initiatives have been successfully implemented to reduce impacts on wildlife and the integration of ecological knowledge and engineering into the development of roads is being recognised. To ensure the conservation of species and ecologically sustainable development, it is imperative that multi-lateral lending and development assistance agencies administer the implementation of biodiversity guidelines to mitigate impacts of roads at the design and planning phases.

USING A SOCIO-ECOLOGICAL SYSTEM FRAMEWORK TO ANALYZE THE RESILIENCE OF A PROTECTED AREA

Chloé Guerbois

CNRS/NMMU

Hervé FRITZ, CNRS

Long-term research is the prerequisite to the in-depth study of socio-ecological systems (SES) and their diverse inner processes at various scales. The diversity of ecological and historical contexts often challenges the direct translation of pre-established conceptual models from one SES to another, and in particular for SESs including protected areas. The French Long Term Ecological Research program Zone Atelier Hwange focuses on the functioning of the Hwange SES (Zimbabwe) including Hwange National Park and its periphery. Started over 15 years ago targeting ecological processes, the program has expanded to develop interdisciplinary research. It offers an original study case to analyze the resilience of protected areas and their associated SESs. Since the creation of Wankie Game Reserve in 1928, the Hwange SES has experienced multiple disturbances and transformations. Colonization, interventionism, decolonization, resettlement, political and economic crises, and droughts constitute the main drivers of several regime shifts : e.g. from a wet season wildlife area to a dry season wildlife area through the surface water provisioning, from a culling driven to an elephant driven ecosystem, from a traditional pastoral and cultural area to an international tourism outfit. However, nowadays Hwange remains an emblematic example of semi-arid wooded savannas with high mammal diversity. In this paper we analyzed the properties and processes behind the apparent resilience of the system, elaborating a transferable conceptual framework underlying interdependencies between its social and ecological components. The main contrasts with existing conceptual approaches are the explicit links between biodiversity and well-being, through the notions of values and attitudes. Illustrative and prospective narratives, one on elephant management and the other on the extension of mining, describe how this model can help thinking the resilience of a SES including a protected area.

DIVERSITY OF WATERBIRDS AT CHOTT EL-HODNA (ALGERIA)

El-Yamine Guergueb

University of Sidi Bel Abbes

Ettayib BENSACI, University of M'sila ; Yacine NOUIDJEM, University of M'sila ; Asma ZOUBIRI, University of M'sila ; Ahmed KERFOUF, University of Sidi Bel Abbes ; Menouar SAHEB, University of Oum El-Bouaghi ; Moussa HOUHAMDI, University of 08 May 1945, Guelma

A study was carried out on the waterbirds of Chott El-Hodna (Central High Plateaus of Algeria), a wetland of international importance under the Ramsar Convention, situated in a strategic part of Algeria, with a surface exceeding 362,000 ha. The avifauna of this wetland remains very poorly studied and the biological and ecological roles of the species

remain unknown. In this pioneering work we present results obtained through the monthly bird counts from September 2010 to September 2012. In total, 39 species of waterbirds, representing 12 families, were recorded. The duck family is the best represented, with 10 species. Some species were observed in relatively large numbers, such as the Greater Flamingo, *Phoenicopterus roseus* (2800); Shoveler, *Anas clypeata* (1640); Ruddy Shelduck, *Tadorna ferruginea* (643); Teal, *Anas crecca crecca* (2250); and Common Shelduck, *Tadorna tadorna* (2750). Out of all the species, 20 are wintering, 12 are migrants, six are breeder-resident species, including the Ruddy Shelduck, *Tadorna ferruginea*, and the Black-winged Stilt *Himantopus himantopus*. Only one species, the White stork, *Ciconia ciconia*, has breeder-migrant status. Eleven species are protected under Algerian law and one species (Marbled teal, *Marmaronetta angustirostris*) is listed in the vulnerable (VU) category of the Red List of endangered species by the International Union for the Conservation of Nature (IUCN). Overall, this wetland is exploited as a wintering ground, a stopover during migration and as a breeding site for several waterbird species. However, Chott El Hodna is under heavy pressure from man, due to such as sand extraction and habitat fragmentation and is in urgent need of protection measures.

SYMPOSIUM 24. ACHIEVING SOCIAL-ECOLOGICAL FIT THROUGH COLLABORATIVE GOVERNANCE

Angela Guerrero

The University of Queensland

Örjan BODIN, *Stockholm Resilience Centre*; Ryan MCALLISTER, *CSIRO*; Wilson KERRIE, *The University of Queensland*

Most of the world's most pressing environmental problems are directly affected by the problem of fit – when governance systems do not fit or align with the characteristics of the biophysical system. Yet empirical explorations of governance approaches that could ameliorate fit challenges are rare. Collaborative forms of decision-making are considered a possible solution to the problem of fit. We conduct the first empirical investigation of the problem of fit and assess the capacity for a collaborative conservation initiative to address two specific fit challenges: spatial scale mismatch and the management of interconnected ecological units. Employing new theory and methodological approaches for network analysis, we identify social-ecological network configurations that capture the hypothesised ways in which collaborative arrangements could address these challenges. For a large-scale conservation initiative in Australia, we determine how well observed the pattern of stakeholder interactions reflect these arrangements. We find that collaboration between stakeholders is evident when they manage the same locations, but not when they manage different, yet connected, locations. In addition, we find that the collaborative arrangement is structured in a way that promotes multi-scale management.

Our approach allows social-ecological interdependencies to be incorporated to evaluate the benefits and constraints afforded by collaboration. The information obtained provides a unique evidence-base for the design of future collaborative arrangements that might be better suited to solve environmental problems.

DYNAMIC OF THE BLACK-TAILED GODWIT, LIMOSA LIMOSA AND FIDELITY TO SENEGALESE WINTERING GROUNDS.

Khady Gueye

UCAD

Cheikh Tidiane BA, UCAD ; Ibnou NDIAYE, UCAD

The black-tailed godwits population, *Limosa limosa*, breeding of Western Europe that winters in West Africa is declining. The black-tailed godwit is classified on the IUCN Red List as near threatened species and is currently the subject of a plan of international actions of AEWA? This action plan has retained Senegal and Guinea-Bissau as the two most important countries for storage of the bird population. However, there are few data on the distribution of birds counted in the middle of the rainy season (January), when a large part of the population is expected back in the West. A 2008 study showed that only 10% of the population is observed in southern Senegal (Casamance) and Guinea-Bissau, so more than 100,000 people remained uncounted. Recent findings suggest that opportunistic birds are not limited to rice fields and are also in uncultivated wetlands near Dakar and Saint-Louis. The main purpose of this study is to better know the ecology and biology of the barge. The specific objectives are to know the phenology and the movements of the bird in the Senegalese wintering sites. We make statements barges found in each site, and a reading of color combinations and rings (or) flag banded individuals. We send the barges codes banded to manager databases. The presence of *Limosa limosa* is recorded from June to January from which the numbers begin to decrease. Distribution dynamics within Senegalese habitats is now well known with the maximum in October. The barges are very loyal to their wintering sites for Senegalese individuals banded comments are repetitive since 2012. Indeed by this reading of the rings, the movement of barges in the Senegalese wintering sites is revealed. This study is a first in Senegal. It is crucial to bridge the knowledge gap on the ecology, wintering sites and species migration strategies.

PUNAN PATHS FOR BIOCULTURAL CONSERVATION: TRAILING FOREST USES AND TREE DIVERSITY IN BORNEO

Maximilien Gueze

Universitat Autònoma de Barcelona

Community-based conservation schemes are largely based on the assumption that indigenous people enhance biodiversity in the environment they live. However, research on the impacts of indigenous peoples on biodiversity in tropical forests has mostly focused on land-use and cover change analyses – emphasizing uses that modify the canopy, such as shifting cultivation- and tends to ignore uses with more subtle effects, such as those involving cryptic or below-canopy disturbances, whose impacts on biodiversity are not necessarily visible on satellite images. In this study, I explore the association between tree diversity and structure in Borneo old-growth forests and the intensity of non-agricultural use by an indigenous group, the Punan Tubu of East Kalimantan. I asked people from two villages to carry a GPS tracking them during their daily subsistence activities – hunting and foraging of wild edibles and other non-timber forest products– and obtained one-year data on the intensity of use. I also inventoried and measured the diameter of trees (dbh>2.5cm) in 20 0.1-ha (50x20m) plots in the old-growth forest surrounding the two villages, where these activities took place. Analyses relied on multi-variable models at the plot level. I then constructed a 300-m buffer area around each of the inventoried plots to associate the intensity of use (proxied as the number of track points in each buffer area) with tree alpha diversity measured with different indexes (Fisher’s Alpha, Sorensen and Steinhaus indexes). This study represents an attempt to associate fine-scale indigenous impacts with real measures of biodiversity. Results will have important implications to determine what the actual impacts of indigenous peoples on their ecosystems are, at a time where development and resource demand constantly increase. Results will also allow a better understanding of the value of indigenous-used forests for future conservation strategies.

SHALL SURVEYS FOR OCCUPANCY ESTIMATION CONTINUE AFTER THE FIRST DETECTION?

Gurutzeta Guillera-Arroita

University of Melbourne

Jose J LAHOZ-MONFORT, University of Melbourne

During the last ten years, occupancy-detection models (MacKenzie et al. 2002, Ecology 83) have become standard tools in wildlife monitoring, ecological inference and the study of species distributions. In order to account for imperfect detection, the key is to collect the species data in a way that allows modelling the detection process. This is often achieved by sampling each site repeatedly (or at least some of them), recording species detection/non-detection in each visit separately. When it comes to designing a survey protocol, a natural consideration is whether sites should continue to be surveyed after the species is detected (‘standard design’) or whether surveys at a site should be discontinued after first detection (‘removal design’). At a first glance, removal design

seems best because it allows spreading a given budget of survey effort across more sites: once the species is detected at a site, effort can be redirected to surveying other sites, which appears to be a more efficient use of available resources. However concerns exist regarding the ability of removal design data to deal with scenarios where detectability is heterogeneous (MacKenzie & Royle 2005, J. App. Ecol. 42); this could compromise its expected efficiency gain. By analysing simulated datasets and drawing on statistical theory, we provide a thorough examination of the benefits and limitations of the removal design in comparison to those of the standard design, under a range of plausible scenarios.

RESPONSES OF OCTOPUS VULGARIS (LAMARCK, 1798) TO ATTACHED ELECTRONIC TAG

Benal Gul

Ege University

Egemen NEMLI, Ege University ; Ali ULAS, Ege University

Electronic tags help to determine behaviors and movements of marine animals. By this way, scientists make an effort to understand ecological process and to find solution for problems. However, attaching tags commonly cause of differences of animals behaviour. Response of animal should known, especially before field experiments. Unlike other marine animals, octopus has arms and suckers to touch and to grasp anything. Easy learning ability is also makes difficult to attach tag and ensure that it remains on octopus. In this study, 8 individuals of *Octopus vulgaris* were tagged with artificial tag at controlled pool area. Process were conducted under anesthesia and the tag were placed different parts of body. Response of individuals, during and after tagging, were monitored continuously. Results shows that, the octopuses does not accept the existence of tag. After recover from anesthesia, they immediately began to try to remove tag from body. Some individuals achieved that just in hours. Longest tag remain time was almost one week. Tag remove response commonly resulted in a permanent injury, lose a body part or sometimes led to death.

WHEN TO EXPLORE A NEW HABITAT? A MICROCOSM EXPERIMENT TO EXAMINE HOW HABITAT AND TRAVEL ROUTE CONDITIONS AFFECT EXPLORATION BY TERRESTRIAL ISOPODS

Panditha Vidana Sasindu Lakmini Gunawardana

Thompson Rivers University

Karl W. LARSEN, Thompson Rivers University

When do animals ‘decide’ to explore or relocate? Despite the importance of this process to conservation and ecology, the importance of conditions within the “home” environment and those encountered while travelling to other habitats have been rarely quantified. We focused on these questions

using microcosm experiments on two closely-related but morphologically-dissimilar species of terrestrial isopods (*O. Isopoda: Armadilidum vulgare* and *Porcellio dilatatus*). We conducted two studies looking at movements out of home habitats: the first focused on the effect of conditions in the home environment, and another examined the role of conditions within the travel corridor. In each study, 45 trials were conducted on each species (with $n = 16$ animals per trial) and isopods were measured and individually marked to track them through webcam 'checkpoints' along the travel corridor. In the first study, we manipulated moisture (3 levels) and food (3 levels) in the home environment. We found that the number of animals departing from home and the total distance traveled in the corridors were primarily influenced by moisture. Further, *Porcellio* showed a greater tendency to depart from the home environment. In the second experiment, we manipulated moisture (3 levels) and corridor permeability (obstacle density - 3 levels) within the travel corridor. In this study, we found that the less-mobile *Armadilidum* travel distances were mostly affected by the permeability of the corridor, whereas *Porcellio* travel was mainly affected by the humidity, likely due to a relative intolerance to lower humidity. Post-hoc examination also suggested that body weight and sex of individuals played a role in determining movement tendencies. Although not surprising, our results are some of the first concrete depictions of how different conditions factor into the movement 'decisions' of animals out of habitat patches, furthering our ability to predict the response of animals to environmental changes.

CAN WE TRANSLATE ECOSYSTEM SERVICES LANGUAGE ACROSS CULTURAL AND RELIGIOUS BARRIERS?

Richard Gunton

University of Leeds

David BOOKLESS, University of Cambridge ; Andrew BASDEN, University of Salford ; George OTIENO, Leeds Trinity University ; Yoseph ARAYO, Open University ; Mark GODDARD, University of Newcastle ; Eline VAN ASPEREN, Liverpool John Moores University ; David HANSON, West Yorkshire School of Christian Studies ; Gareth JONES, West Yorkshire School of Christian Studies ; David RAFFAELLI, University of York

"Ecosystem services" (ES) is increasingly used as the reference point of a common language intended to focus research and unite conservation efforts and policies around the world. However, this language does not always translate successfully into different cultural settings, and even within the scientific community there is disagreement about the merits of this conceptual language. The Faith-in-Scholarship Working Group on Ecosystem Services (FISWES) is exploring how a reformational-Christian perspective may assist in

communicating across cultural barriers and clarifying the overall goals and methods of conservation agendas. Using a non-reductionistic philosophical framework, it seeks to enrich the concept of ES and make it more robust to cross-cultural translation. As well as comparing classifications and nomenclature for ES, we offer a conceptual map of interactions among scientists, policy-makers, practitioners and the general public, designed to improve mutual understanding across societal spheres and international cultures.

SPECIES-SPECIFIC EFFECTS OF GROUND VEGETATION ON BIRDS OCCURRING IN VINEYARDS IN THE CANTON OF VALAIS

Claire Guyot

University of Bern

Alain JACOT, University of Bern ; Raphaël ARLETTAZ, University of Bern

Habitat degradation due to post-war agricultural intensification has triggered a dramatic decline in farmland biodiversity. Farmland birds suffer from massive application of agrochemicals, which is likely to affect them indirectly by modifying food supply and availability. Many of them forage on the ground making ground vegetation structure (height and cover) a key component in foraging site selection. However, the relevance of this optimal balance between food abundance and availability for other bird species and foraging guilds still deserves more attention. Intensively cultivated vineyards most remain bare, especially in places where the climate is hot and dry. Consequently, vineyards may often not deliver sufficient food supply because of lacking ground vegetation. We used transect monitoring of ten sites in south-western Switzerland (Valais) and mixed effects regression models to investigate habitat preferences of multiple bird species that use vineyards as feeding sites. We aimed to get species-specific preference curves over a whole year to highlight the importance of ground vegetation at the parcel scale. Here I will present overall, species-specific and if possible foraging guilds' specific habitat preferences with respect to ground vegetation structure and management types in vineyards. After backward model selection based on AIC, predicted bird occurrence and density will be plotted against significant habitat variables. These data will form a basis for future management recommendations of vineyards for specific times of the year. Because of a likely trade-off between food abundance and accessibility, we generally expect species-specific optima concerning ground vegetation structure (quadratic relationships), especially for ground foraging species.

ASSESSMENT OF THREATENED FISH SPECIES WITH AN ELECTRIFIED BENTHIC FRAME TRAWL IN THE DANUBE RIVER - EXPERIENCES OF THE THIRD JOINT DANUBE SURVEY (JDS3)

Ágnes Irma György

MTA Centre for Ecological Research, Danube Research Institute

Zoltán SZALÓKY, MTA Centre for Ecological Research, Danube Research Institute ; András WEIPERTH, MTA Centre for Ecological Research, Danube Research Institute ; Vinzenz BAMMER, Federal Agency for Water Management, Institute for Water Ecology, Fisheries and Lake Research ; Michael SCHABUSS, Pro Fisch OG. ; Horst ZORNIG, Pro Fisch OG. ; Björn DEUTSCHMANN, RWTH Aachen University Institute for Environmental Research ; Lachezar PEHLIVANOV, Institute of Biodiversity and Ecosystem Research, Bulgarian Academy of Sciences

There are many fish species that are conservationally important in the Danube, yet they are especially difficult to collect with conventional fishing gears (e.g. trammel nets, gillnets) used to sample deep habitats in slow flowing large rivers. Additionally, entangling nets and hook and line (i.e. long line) sampling can injure fish seriously. Until now the most comprehensive fish assessment method is night time shoreline electrofishing, however this method is not suitable for detecting sterlet (*Acipenser ruthenus*), the only native sturgeon species still present in the upper and middle Danube, but also facing increasing population decline due to overfishing and habitat loss. Other rather rare native bottom dwelling fish species (e.g. Zingel streber) are also usually underrepresented in shoreline catches. Previous studies proved the broad applicability of the recently developed electrified benthic frame trawl (EBFT) in monitoring benthic fishes in the Danube thus it was adopted by the core team of the JDS3. Samples were collected at 32 sites between rkm 15 and 2420. Results on the occurrence of sterlets in the middle Danube region were alarming; while in the lower reaches it was caught regularly, no individuals could be detected above the inflow of Tisa River. The abundance of gobies and zingels were also lower than expected. Overall we found that offshore areas were intensively used by a variety of species which were distributed relatively homogeneously in the river, at least regarding their occurrence, because their abundance can vary largely at the mesoscale (i.e. between 500 m long sampling stretches). The survey again proved the importance of using different methods, especially the EBFT, since it gave a completely different picture in case of rare species, and it also revealed the alarmingly low abundance of sterlet and the urgent need for certain active conservation measures, such as the restoration of spawning grounds and the control of cormorants.

RECENT INCREASING IN THE NUMBER OF RED-BREASTED GEESE (*BRANTA RUFICOLLIS*) IN THE HORTOBÁGY (HUNGARY)

Péter Gyüre

University of Debrecen

Ibolya CSÍDER, University of Debrecen

The wetlands and fishponds of the Carpathian basin have a great importance in the migration and wintering of several Eurasian goose species. The Hortobágy region is a traditional stopover site along the flyway of many migrating birds and several goose species population have increased in the last years. The White-fronted Goose (*Anser albifrons*) is the most numerous in migration but two globally endangered species the Lesser White-fronted Goose (*Anser erythropus*) and the Red-breasted Goose (*Branta ruficollis*) are regularly observed each year. The breeding population of Greylag Goose (*Anser anser*) also has increased, this is the only breeding goose species in the wetlands of the Hortobágy. Since a few decades the Red-breasted Goose became a regular annual visitor in small number between October and April but in recent years we observed a significant increase in the migrating and overwintering population. In November 2014, 1733 Red-breasted Geese were counted in the area, this is a remarkable increase and an important proportion of the declining world population which is about 37 000 birds. In the Hortobágy National Park the geese can find safe resting places and hunting pressure is relatively low in the protected areas. This increase is presumably caused by shifting migration routes or favourable climatic condition changes in migrating and wintering seasons. The management of the wetlands and the feeding habitats in the national park can have a positive impact on the population growth of these rare goose species.

PERSONALITY AND SURVIVAL IN CONSERVATION RESEARCH - REINTRODUCTION OF EUROPEAN MINK (*MUSTELA LUTREOLA*)

Marianne Haage

Stockholm University

Tiit MARAN, Tallinn Zoological Gardens and the Estonian University of Life Sciences ; Ulrika Alm BERGVALL, Stockholm University ; Bodil ELMHAGEN, Stockholm University ; Anders ANGERBJÖRN, Stockholm University

Animal personality is defined as consistent behavioural differences between and within individuals, repeatable over time or contexts/situations. Personalities have been identified in numerous species and empirical data indicates a connection to fitness, making personality a relevant but little studied aspect in conservation. The first steps towards implementing personality in conservation efforts include examining the structure and expression of personality in a species, and

developing measuring techniques. The next steps involve testing if personality type affects fitness and the success of a conservation effort. Here we investigated personality in the critically endangered European mink and how the expression of personality was affected by situation (season) and context (test environment). Three personality trait domains were identified; boldness, exploration and sociability. Furthermore, test environment influenced which personality trait domain that was expressed, showing the importance of proper measuring technique in order to avoid misinterpretation. Personality also changed plastically over seasons, indicating that potential fitness effects in the wild could vary depending on season. After this a field experiment was made to test the impact of personality on survival in reintroductions. Animals were personality tested in captivity and post-release survival was monitored via 60 days of radio-tracking in two years. Boldness had a positive impact on personality whilst the influence of exploration was more complex; the correlation was negative or positive depending on year. Sociability had no effect, which is expected in a solitary-living species. Overall the results show the importance of personality on survival and additionally give insights on the evolution of personality as spatiotemporal variation was influential. Future studies should assess if integrating personality with existing conservation methods, e.g. in reintroduction, can enhance success rates.

A CONCEPTUAL STUDY FOR CONSERVATION AND ECOLOGICAL RESTORATION OF THE DEGRADED ARID STEPPE-LANDS IN THE HAOUZ PLAIN, WEST CENTRAL MOROCCO

Nawal Hachimi

Cadi Ayyad University, Faculty of Science-Semlalia
Mohammed ZNARI, Cadi Ayyad University, Faculty of Science-Semlalia ; Radouane AIT EL CADI, Cadi Ayyad University, Faculty of Science-Semlalia ; Salwa NAMOUS, Cadi Ayyad University, Faculty of Science-Semlalia ; Safaa BENDAMI, Cadi Ayyad University, Faculty of Science-Semlalia

As other ecosystems, the arid steppes, which mainly constitute rangelands, are subject to significant alterations, especially under the effect of chronic drought and overgrazing. This is the case of the *Zizyphus lotus* steppes of the Haouz plain, West central Morocco. The aim of this study was to assess conservation and restoration potentials of this ecosystem and to propose development scenarios for a better use of the resources in the future. Conservation and restoration options proposed for key species populations, and more specifically *Z. lotus*, and for the entire arid steppe ecosystem including the abiotic (water and soil) and biotic (vegetation and wildlife) components, would return to alternative stable state (relatively to the historic state) on the one hand, according to the degree of degradation of the steppe and the demographic

status of populations, by improved resources management (conservation and reinforcement declining populations) and on the other hand, by rehabilitation through reintroduction of extinct plant and animal species. A preliminary diagnosis of the state of the steppe ecosystem was carried out through examination of vegetation, including the *Z. lotus*, and some elements of threatened wildlife that depend on such as the Moorish tortoise, a strictly herbivorous species. It is assumed that the local population will support the conservation and restoration project proposed at the regional level, and especially livestock breeders and grain producers who depend on the steppe rangelands during most of the year. Thus, the proposed measures should be of a direct (and indirect) benefit to these people. Measures would lead, on a large scale, to the improvement of groundwater recharge. However, this latter would not be directly available (accessible) in the grazing areas (for plants and livestock); It would indirectly assist in the protection of the region by providing water for irrigation for the production of fodder plants during dry periods.

91-THE ROLE OF SYSTEMATIC REVIEWS IN EVIDENCE-BASED CONSERVATION: CHALLENGES AND DEVELOPMENTS

Neal Haddaway

MISTRA EviEM

Conservation practitioners and policy-makers must regularly make decisions on which actions are most appropriate. Decision-makers know these choices must be made on the best available evidence, and this evidence may include; local indigenous knowledge, personal experience, expert opinion, and scientific research. Scientific research, available through reports and published papers, is the most readily documented and critically appraisable form of evidence. However, decision-makers often cannot access all of the relevant published research on a topic. Furthermore, the volume of published research papers is increasing at a rate that makes full assessment of the evidence challenging. Evidence reviews, including systematic reviews (SR) and systematic maps (SM), are transparent, objective, and repeatable methods for reliably summarising extensive bodies of evidence on specific topics of concern to conservation stakeholders. Originally developed within the field of medicine, evidence reviews have now been successfully translated into environmental management and conservation. These methods aim to minimise bias that can significantly affect traditional forms of review, providing concise summaries for decision-makers on the state of the documented evidence. The Collaboration for Environmental Evidence (CEE) has been established to promote the use of SRs and SMs in conservation and guide those wishing to undertake these reviews. In the years since the CEE was formed evidence synthesis has progressed significantly and is now seen as an

industry standard, with methods for improving these reviews progressing rapidly. Several challenges still exist, however, that limit the uptake of evidence reviews. Despite this, key success stories in the production of evidence reviews in conservation are emerging that demonstrate how this knowledge brokering plays a vital role in bridging the gap between research and practice.

POSITIVE EFFECTS OF ECOLOGICAL RESTORATION ON A RARE AND THREATENED GROUP OF INSECTS: THE FLAT BUGS (ARADIDAE).

Ruaridh Hägglund

Swedish University of Agricultural Sciences
Anne-Maarit HEKKALA, Finnish Forest Research Institute, University of Oulu ; Joakim HJÄLTÉN, Swedish University of Agricultural Sciences ; Anne TOLVANEN, Finnish Forest Research Institute, University of Oulu

Highly efficient forest management carried out from mid-20th century and onwards has decreased the state of biodiversity in many boreal forest landscapes. As dead wood, historically created by natural disturbances such as forest fire and small scale gap dynamics, is disappearing from the landscapes, saproxylic insects experience declining populations. One such group are the rarely studied flat bugs of the *Aradus* genus. Approximately one third of the 23 flat bug species present in Fennoscandia are red-listed in either Finland and/or Sweden. In response to declining biodiversity, efforts to improve habitat quality for disturbance dependent species such as flat bugs have to be intensified. Although forest restoration practices mimicking natural disturbances have been conducted, their impacts on these rare taxa have been poorly evaluated so far. This study aims to evaluate if such restoration actions are appropriate in improving habitat conditions for flat bugs. By conducting two restoration experiments with prescribed burning of standing forests (Finland and Sweden), artificial gap creation (Sweden) and untreated controls (Finland and Sweden) we addressed this question. Flat bug abundances and species richness increased in both Finnish and Swedish forest stands that were exposed to prescribed burns. Our study also suggests that more flat bug species than previously believed can be regarded as fire favoured. *Aradus betulae* and *A. betulinus* respond with higher abundances in burned stands compared to artificial gap cuttings and untreated controls. In order to maintain viable flat bug populations we recommend prescribed burning as an important tool in boreal forest management.

DEGRADATION IN MATRIX IS ASSOCIATED WITH BIOTIC HOMOGENIZATION IN PROTECTED AREAS

Matti Häkkinen

University of Jyväskylä

Merja ELO, University of Jyväskylä ; Eric LETORTOREC, University of Jyväskylä ; Risto TORNBORG, University of Oulu ; Mikko MÖNKKÖNEN, University of Jyväskylä

The main goal of protected areas is to maintain species diversity and the integrity of biological assemblages. For the integrity, functional and phylogenetic diversities are at least as important as taxonomic diversity. Functional diversity refers to the functioning of ecosystems, which has a direct effect on ecosystem services on which human welfare strongly relies. Phylogenetic diversity consists of evolutionary lineages, the maintenance of which ensures that future evolutionary potential is safeguarded. The process where taxonomic diversity is maintained but parts of functions and evolutionary history are lost is called biotic homogenization. Human population growth and pressures to intensify land use in the surrounding matrix create a challenge for biodiversity conservation based on protected areas. Earlier studies have mainly focused on taxonomic diversity and characteristics within the protected areas. However, functional and especially phylogenetic homogenization are less studied phenomena, especially with respect to matrix effects on protected areas. We studied whether intensity in land use in the surrounding matrix has an effect on bird community assemblages in protected boreal forest areas. We used line-transect count data from 91 forest reserves in Northern Finland collected between 1980's and 2002, and land-use data from buffer zones surrounding the reserves. We studied if the intensity of forest management has a consistent effect on taxonomic, functional and phylogenetic diversities. We found that forest management intensity in the surrounding matrix may have strong effects on the diversity of bird assemblages in protected areas. This indicates that boreal forest reserves are not able to maintain integrity if embedded in severely degraded matrix. We also point out the importance to focus on several different aspects of biodiversity when studying biotic homogenization.

#208: EXTREME CITIZEN SCIENCE: SOCIO-POLITICAL IMPACT OF CITIZEN SCIENCE

Muki Haklay

UCL

Jerome LEWIS, UCL

UCL's extreme citizen science group is dedicated to creating the tools, methodologies and techniques that will allow the creation of situated, bottom-up practice that takes into account local needs, practices and culture and works with broad networks of people to design and build new devices and knowledge creation processes that can transform the world. In other words, we are aiming to facilitate a process that will allow any community, regardless of literacy, to initiate, run and use the results of citizen science activities. Current Citizen Science practice assumes that educated citizens can participate

in scientific data collection, but not in its analysis or in formulating research questions. However, the greatest impact of science can be gained when participants use scientific tools to improve their environment locally and share the knowledge globally. Thus, 'extreme' in this case refers both to the extent of the scientific engagement and to formerly excluded environments in which it can be used. The talk will explore the extent in which such practice is transformative to both society and scientific practice.

HABITAT SELECTION OF THE GREAT BASIN SPADEFOOT (*SPEA INTERMONTANA*) ON THE TERRESTRIAL LANDSCAPE

Jo-Anne Hales

Thompson Rivers University

Karl LARSEN, Thompson Rivers University

Understanding habitat selection and how animals respond to abrupt change (i.e. habitat loss) is crucial in the creation and implementation of conservation plans for species at risk. The Great Basin Spadefoot (*Spea intermontana*) is a burrowing at-risk anuran in western Canada, where outside of a short breeding season, it occupies hot arid grasslands. Radio-telemetry has revealed that during the summer adult spadefoots travel through the grasslands, using a 'network' of daytime retreat sites. Individual animals often return to specific retreat sites, travelling up to 400 m between various sites before returning to their original site. We investigated the properties of these retreat sites to determine if specific characteristics make them favourable to the animals. A comparison of soil moisture at the retreat sites to that at neighbouring (5 m distance) random sites revealed no significant difference (correlation $r = 0.6882$). Vegetation percent cover comparisons also show little variation between used and available sites. These analyses suggest that, at least at the fine scale, adult spadefoots are not basing their selection of these retreat sites on these parameters. We also investigated habitat preferences of recently-metamorphosed spadefoots that are at a presumably much-higher risk of desiccation as they leave their aquatic environment. The small size of these animals precludes telemetry, so we conducted simple habitat selection trials within artificial enclosures. After 36 hours, 79% of metamorphs were located in moist bare habitat rather than dry bare, dry cover or moist bare habitats. Our work suggests that favourable habitat attributes for metamorphic spadefoots are quite different than that of adults, requiring a more complex approach to habitat management for this species. Specific management plans for each life-stage may be vital to the conservation of spadefoot populations on this landscape.

SYMPOSIUM 90: RESOURCE SHRINKAGE AND EXTINCTION DEBT: SOME THEORETICAL CONSIDERATIONS

John Maxwell Halley

University of Ioannina

Gabor LOVEI, Aarhus University, Flakkebjerg Research Centre

If an ecological community suffers isolation or loss of area, it may find itself with a large extinction debt. This is typically associated with oceanic islands or fragments of forest. But it may also happen in situations where an ecological community is dependent on a common resource that suffers shrinkage. Typically, this process will occur in a patchy fashion, so that areas that were once prime habitat become dead zones, leaving behind a fragmented ensemble of resources. Typically a community will reestablish equilibrium at a lower level of biodiversity, a process which proceeds according to a relaxation time. It may be possible to reverse the habitat losses before extinctions occur so that irreversible damage to the community is forestalled. However, there is a short time horizon for such interventions. With the use of a simple extinction model for the community, we show how this is likely to happen in a case where land usage changes over a widespread area creating an archipelago of habitat islands separated by inhospitable landscape.

MODELING POPULATIONS VERSUS SPECIES UNDER CLIMATE CHANGE: IMPLICATIONS FOR CONSERVATION DECISIONS

Maria Hällfors

at Berkeley ; Jessica HELLMANN, Department of Biological

Sciences, University of Notre Dame

The basic approach in ecological studies is to treat a species as a single entity although populations may occupy different environments and vary in their environmental tolerances. Also in species distribution modeling (SDM), a species' future distribution is predicted by considering the full range of current occupancy. Not taking population level differences into account, however, could lead to erroneous management decisions, in case the populations are locally adapted. Often, nevertheless, we do not know the degree to which populations are locally adapted. In lack of experimental evidence, we need to evaluate niche differentiation within a species' range in

order to make appropriate conservation decisions. We explored the effects of climatic niche differentiation on SDM using two species that have spatially separated populations and thus may be locally adapted: the Karner blue butterfly (*Lycaeides melissa samuelis*;) and the Siberian primrose (*Primula nutans* ssp. *finmarchica*). PCA and niche tests indicated that the two main populations of both species occupy distinct climatic environments. We constructed Maxent models based on occurrences of 1) the whole species and 2) distinct populations of the species, and projected them under climate change. Our results indicate different predicted suitable areas for the populations. We explore the magnitude of difference that the two approaches give and discuss the conservation implications and repercussions of making a type I or type II error in this context, i.e. assuming local adaptation when there is none or assuming no local adaptation when the populations actually are differentiated. We also present a workflow for dealing with similar situations, where disjunct populations may be locally adapted but experimental studies are lacking.

COMING TO TERMS WITH ASSISTED MIGRATION

Maria Hällfors

Finnish Museum of Natural History, University of Helsinki
Elina VAARA, Finnish Museum of Natural History, University of Helsinki ; *Marko HYVÄRINEN, Finnish Museum of Natural History, University of Helsinki* ; *Markku OKSANEN, Department of Behavioural Sciences and Philosophy, University of Turku* ; *Leif SCHULMAN, Finnish Museum of Natural History, University of Helsinki* ; *Helene SIIPPI, Department of Behavioural Sciences and Philosophy, University of Turku* ; *Susanna LEHVÄVIRTA, Finnish Museum of Natural History, University of Helsinki*

Intentional moving of species threatened by climate change is actively being discussed as a conservation approach. The debate, empirical studies, and policy development, however, are impeded by an inconsistent articulation of the idea. The discrepancy is demonstrated by the varying use of terms, such as assisted migration, assisted colonisation, or managed relocation, and their multiple definitions. When discussing and studying any topic, it is important that everybody involved is consistent with and aware of what terms and definitions refer to a specific idea. Since this conservation approach is novel, and may for instance lead to legislative changes, it is important to aim for terminological consistency. The objective of this study is to analyse the suitability of terms and definitions used when discussing the moving of organisms as a response to climate change. An extensive literature search and review of the material (868 scientific publications) was conducted for finding hitherto used terms (N = 40) and definitions (N = 75), and these were analysed for their suitability. Based on the findings, we argued that an appropriate term for a conservation approach relating to aiding the movement of organisms harmed by climate change is assisted migration defined as

follows: Assisted migration means safeguarding biological diversity through the translocation of representatives of a species or population harmed by climate change to an area outside the indigenous range of that unit where it would be predicted to move as climate changes, were it not for anthropogenic dispersal barriers or lack of time. We discuss the differences between assisted migration and other conservation translocations. A wide adoption of the clear and distinctive term and definition provided would allow more focused research on the topic and enable consistent implementation as practitioners could have the same understanding of the concept.

WHY DO RETENTION TREES DIE? FACTORS DRIVING TREE MORTALITY IN RETAINED FOREST FRAGMENTS

Martin Hallinger

Agricultural University Uppsala (SLU)
Victor JOHANSSON, Agricultural University Uppsala (SLU) ; *Samuel SJÖBERG, Agricultural University Uppsala (SLU)* ; *Thomas RANIUS, Agricultural University Uppsala (SLU)*

Green tree retention, the retention of living trees on harvested forest stands, is, due to law and certification requirements, nowadays often applied in forests harvested by modern forestry. Tree retention contributes to a continuity of live trees in the new generation of a forest, and increases the amount of large-diameter dead wood. Since this management practice started relatively recently, few studies have made an assessment of what happens to retention trees over a longer time period. We assess the survival of the trees left on clearcuts by analyzing mortality rates in relation with tree and clearcut characteristics after a time period of between one and 20 years after clearcutting. The mortality rates were 12 % for pine, 25 % for spruce and 16 % for birch. Mortality rates were only successively increasing for the first four years after felling. There was no significant increase in mortality over 20 years. Mortality rates thus did not accumulate on the long run but most of the mortality took place within the first four years after clear-felling. Higher tree volumes in retention groups, less exposure to wind, a former position at the forest edge compared to the stand interior reduced tree mortality. Wetter soils reduced mortality for pine and spruce but increased mortality of birch. Surprisingly, the time since clear-felling was not significantly increasing mortality and generally clearcuts had surprisingly low mortality rates of no more than 19% on average (10-20 year old). The practice of retaining trees on clearcuts successfully retains trees and thus biodiversity on clearcuts and leads to mortality rates that are increased compared to closed forests but still moderate on average. The benefits of tree retention are thus long-reaching. A focus on retaining high tree volumes in less wind exposed positions and preferably retaining trees on forest edges that are used to wind exposure may further increase longevity of retention tree forest patches.

HUNGARIAN MEADOW VIPER (*VIPERA URSINII* RAKOSIENSIS) CONSERVATION PROJECT

Bálint Halpern

MME BirdLife Hungary

Tamás PÉCHY, MME BirdLife Hungary ; Endre SÓS, Budapest Zoo ; Chris WALZER, Wildlife Ecology Institute

In order to stop the decline of Hungarian meadow viper (*Vipera ursinii rakosiensis*), we started a complex conservation program in 2004, supported by EU LIFE-Nature fund. Hungarian Meadow Viper Conservation Centre was started with 16 adult individuals, collected from 6 different populations. By 2014 number of vipers bred reached nearly 2000. First reintroduction took place in March 2010, releasing 30 snakes into a reconstructed habitat in Kiskunság National Park. Since that altogether 300 vipers were reintroduced to 5 different locations, including sites in Fertő-Hanság National Park. In order to develop a remote tracking method, pre-programmed radio-tags with a detection range of 100-150m were implanted surgically into the abdomen of vipers. These tags also operate as temperature loggers, recording data every five minutes for a year-long operation period. After successful testing during 2010 and 2011, we released 6 tagged individuals in July 2012. All 6 snakes survived until November, even though wild boars dig large part of the site in September. We detected regular movements within the area, with tendencies to higher parts later in the season. On sunny spells of mid-November and late December, after emerging for basking, 3 and later 2 snakes disappeared, very likely due to predation by raptors like Common Buzzards or Hen Harriers. One tag was found on the site and logged temperature data proved our theory. In parallel surface and ground environmental temperatures were recorded, therefore we can figure out daily activities of the tracked individuals, beside general assumptions about their average optimal body temperatures.

SYMPOSIUM 108: INTEGRATING OCEAN OBSERVING DATA TO MODEL MARINE ANIMAL DISTRIBUTIONS AND DENSITIES: CONTEMPORANEOUS VERSUS CLIMATOLOGICAL CONSIDERATIONS

Patrick Halpin

Duke University

Jason ROBERTS, Duke University ; Laura MANNOCCI, Duke University

Forecasting the distribution and density of marine animals requires accurate characterization of dynamic oceanographic habitats. The characterization of these habitats often relies on development of environmental covariates from remotely sensed earth observing data. The development of environmental covariates raises many considerations concerning the appropriate oceanographic indices to

be developed and the spatial and temporal scales of assessment. These considerations include the appropriate use of contemporaneous versus climatological covariates in the development of explanatory models. This presentation will focus on the choices and implications considered in the development of environmental covariates for the prediction of cetacean species along the US Atlantic coast. Many highly migratory marine animals in this region are vulnerable to human interactions such as ship strikes, fishing gear entanglement, and ocean noise habitat disruption. Cetaceans (whales and dolphins) are protected by the Marine Mammal Protection Act (MMPA) as well as the Endangered Species Act (ESA). These legal protections require federal agencies to estimate the potential impacts of activities on cetacean populations. These assessments require density estimates of the potential number of cetaceans expected to be found in different regions and different time periods. We have been working with federal agency partners to develop forecasting models and decision support tools to assist in the understanding and management of these migratory species. We combine times series of remotely sensed earth observing data with ship and aircraft observer data to create temporally dynamic forecasting models of species distributions and densities. In this presentation we depict the process from data collection, data aggregation, oceanographic feature development to forecast modeling.

POTENTIAL BIODIVERSITY IMPACTS OF FOREST BIOFUEL HARVEST: LICHEN ASSEMBLAGES ON STUMPS AND SLASH OF SCOTS PINE

Aino Hämäläinen

University of Eastern Finland

Jari KOUKI, University of Eastern Finland ; Piret LÕHMUS, University of Tartu

Harvest of stumps and logging residues for energy production has increased rapidly due to a growing demand for renewable energy sources. This biofuel harvest may have negative impacts on forest species, especially those associated with dead wood. We assessed the potential impact of biofuel harvest on epiphytic lichens by studying the lichen assemblages on stumps and downed fine woody debris (FWD) of Scots pine in clear-cut, mature managed and old-growth forest stands in eastern Finland. We also examined the impact of tree retention level (10m³/ha, 50 m³/ha or clear-cut) and prescribed burning on these assemblages. A total of 102 lichen species, 13 of which red-listed, were observed; 95 on stumps and 69 on FWD. Composition of the species assemblages differed between stumps and FWD, and between stumps of different age. Tree retention (in comparison to clear-cut sites) and prescribed burning resulted in a slightly higher species richness on cut stumps 12 years after harvest, but did not affect the assemblages on FWD or older stumps. We conclude

that stumps and FWD of Scots pine can host high numbers of lichen species, including red-listed ones. Most of the observed species were generalists, found to occur on various substrates, and thus not likely to be significantly affected by biofuel harvest. However, stumps and FWD hosted also several dead wood-dependent lichen species: for these species, intensive biofuel harvest is potentially harmful, though the severity of this impact likely depends on the landscape-level availability of other woody substrates. The impact of stump harvest is likely to be more pronounced than that of FWD harvest, as stumps were found to host more diverse lichen communities. To mitigate this negative impact, we suggest leaving part of the cut sites completely outside biofuel harvest. In addition, applying tree retention on these sites could further increase the lichen species richness.

BROWN BEARS IN THE GHIZER DISTRICT, PAKISTAN: STATUS AND CONFLICTS

Shoaib Hameed

Quaid-i-Azam University, Islamabad[INSTITUTE]Snow Leopard Foundation
Hussain ALI, Snow Leopard Foundation ; Muhammad YOUNAS, Snow Leopard Foundation ; Muhammad KABIR, Pakistan Museum of Natural History, Garden Avenue, Shakarparian, Islamabad 44000, Pakistan[INSTITUTE]Quaid-i-Azam University, Islamabad ; Khurshid Ali SHAH, Snow Leopard Foundation ; Muhammad AYUB, Snow Leopard Foundation ; Jaffar Ud DIN, Snow Leopard Foundation ; Muhammad Ali NAWAZ, Quaid-i-Azam University, Islamabad[INSTITUTE]Snow Leopard Foundation

The Ghizer district in northern Pakistan falls in the Hindu Kush range and its landscape represents a good habitat for brown bears. It also forms a connection of brown bear populations in Pakistan with that in Central Asia. In the present study, multiple methods were used to gather the aforementioned information. Questionnaires surveys were conducted in the entire district by dividing area into seven blocks on the basis of watersheds. Public sighting reports were divergent across the district, and higher sightings were reported in the western part of the district. We focused two western valleys (Phandar and Qurumber) for further investigation. The sign based occupancy survey was conducted in the Phandar valley, which yielded a low estimate of occupancy ($0.0916 \pm 0.0537SE$), despite the highest sighting reports in this valley. However a direct sighting of a brown bear female with a cub strengthened the evidences of presence and reliability of sightings reports from the area. Camera trapping was conducted in the Qurumber National Park (QNP) (the north-western valley of the district) and its adjacent Broghil National Park (BNP). The brown bear was photo-captured at two camera stations in BNP. Other threatened carnivores photo-captured included snow leopard,

grey wolf, and the Pallas's cat. The human-carnivore conflict surveys indicated brown bears to be the least dangerous to livestock and other public property in a predator community comprising of snow leopard, grey wolf, and the Himalayan lynx. Ironically, local communities had lower acceptance for bears as compared the snow leopard, which was otherwise more dangerous to livestock. This probably explains rarity of the species in the area. All of the three methods employed are in agreement and suggest that the Ghizer district has a small and scattered population of brown bears, which is experiencing multiple threats including competition with livestock in alpine pastures, and illegal shooting.

ACCOUNTING FOR MARINE ECOSYSTEM SERVICES AND BENEFITS TO PEOPLE TO IMPROVE CONSERVATION PLANNING: IT'S NOT JUST ABOUT FISHING

Mélanie A. Hamel

James Cook University
Robert L. PRESSEY, James Cook University ; Serge ANDRÉFOUËT, Institut de Recherche pour le Développement ; Louisa S. EVANS, University of Exeter ; Christina HICKS, James Cook University

Incorporating meaningful social and economic information into conservation planning is challenging but critical to minimize impacts of conservation actions on livelihoods, thereby maximizing compliance. The social impacts of reserves are often reduced to the socioeconomic impacts only, typically included in planning through opportunity costs. In many places where people are strongly connected to marine ecosystems, opportunity costs are often only measured for fishers. However, the services and benefits people gain from their marine environment go beyond just the food and income from fishing. People access and value marine ecosystems for benefits that include recreation, aesthetic enjoyment, spiritual connections, medicine, and culture. Therefore, designing reserves with approaches which aim to minimize lost fishing opportunities might not address impacts on other uses of the marine environment. We explore how conservation planning can be optimized and informed with data on how people value ecosystem services and benefits they gain from accessing their marine environment. We interviewed heads of households in Riwo, a coastal community of the Madang Lagoon, Papua New Guinea. We first developed a method to identify and map places of value (including fishing) to households, actively engaging with the community. Then, we proposed a novel way to incorporate these values into spatial prioritization exercises. We found that different places in the Madang Lagoon are valued for different reasons, and that designing reserves based only on opportunity costs to fishing will likely have incidental impacts on the other ways people benefit from their marine environment. Our results suggest that we need to move beyond solely accounting for socioeconomic costs

of conservation actions and to develop more comprehensive approaches to involving communities and estimating conservation costs for small-scale community conservation.

EXPERIMENTAL STUDY OF THE NEGATIVE EFFECT OF THE INVASIVE EXOTIC SHRUB FRANGULA ALNUS ON THE GROWTH OF PLANTED UNDERSTORY TREE SEEDLINGS

Caroline Hamelin

University of Regina

Daniel GAGNON, University of Regina ; Benoit TRUAX, Eastern Townships Forest Research Trust

Glossy buckthorn (*Frangula alnus*) is an invasive exotic shrub that has become dominant in several Eastern North American ecosystems, and it appears to have a negative effect on the regeneration of native tree species. The objectives of this study are to (1) test if buckthorn has a negative effect on the survival and growth of understory tree seedlings in eastern Canada, and (2) to determine how this effect varies depending on the seedling species and on overhead canopy type. In May 2014, seedlings of 2 species, *Acer saccharum* and *Quercus rubra*, were planted in the understory of a 15 year-old hybrid poplar plantation (with 3 replicate blocks). Five different hybrid poplar clones were used for the canopy types. In fall 2013, herbicide was applied to half of each experimental plot, and in April 2014 all remaining buckthorn stems were cut for a complete removal effect. This experimental design reduces confounding factors to a minimum (ex. canopy composition and structure, age of seedlings), and many factors were controlled (ex. transplantation, deer exclusion). Also, many environmental factors were quantified (light availability, soil nutrients, poplar biomass, understory vegetation biomass, buckthorn density and biomass (with a predictive allometric relationship developed using basal diameter of harvested buckthorns) to measure their effects on tree seedlings, and their possible interactions with the effects of buckthorn. After one growing season, mean height and diameter increments of both species of seedlings were higher in herbicide plots than in control plots, where buckthorn was significantly more abundant (density and biomass) and light availability was significantly lower. A significant statistical difference in growth was found only for diameter increment. Tree seedlings will be measured again in fall 2015, after 2 growing seasons, and growth differences between treatments are expected to be higher and all statistically significant.

HOW TO CONSERVE TAXONOMIC COMPLEXITY: GENETIC AND ECOLOGICAL INTERACTIONS IN SORBUS

Tracey Hamston

University of Exeter & Whitley Wildlife Conservation Trust

Natasha DE VERE, National Botanic Garden of Wales & IBERS, Aberystwyth University ; Jamie STEVENS, University of Exeter ; James CRESSWELL, University of Exeter

Species based conservation relies on being able to delineate and identify species, and gather data on distributions and threats in order to develop management plans. Many plant taxa, particularly those of conservation concern, have complex taxonomy, often derived from hybridisations and associated with polyploidy and mixed mating systems; sexual and uniparental (apomictic). These groups present particular challenges for conservation and there is a need for greater understanding of these processes and the spatial scale over which they operate. The genus *Sorbus* is an example of such a taxonomically complex group. There are high levels of endemism within this genus and the southwest UK is a 'hot spot' for *Sorbus* diversity within Europe. Many species are of conservation concern with threats primarily from changing land management, browsing and invasive non-native species. To investigate evolutionary relationships and interactions on a spatial scale we studied a group of seven apomictic and two sexual *Sorbus* species, found in the south west UK, with the aim of elucidating some of the important factors that may affect short term survival and long term evolutionary potential. Using nDNA microsatellite markers to determine the evolutionary relationships of this group we found complex relationships between clusters that represent taxonomic entities. Investigations of pollen flow between apomictic species of different ploidy levels showed a pollen limited system with reliance on interspecies pollination to maintain seed production. This suggests that we should consider these groups of species as a network of partially interacting units. Conservation action should seek to enhance the opportunities for future speciation and diversification across the core range of this group with particular priority given to areas of high diversity where there is evidence of continuing evolutionary activity.

185 - CONSERVATION DECISION-MAKING ON CHRISTMAS ISLAND: MANAGING ECOSYSTEMS USING LIMITED INFORMATION

Yi Han

The University of Queensland

Yvonne BUCKLEY, School of Natural Sciences, University of Dublin, Trinity College ; Eve MCDONALD-MADDEN, The University of Queensland

Invasive cats and rats are perceived to have a major impact on native species on Christmas Island. There is an attempt to control these pests to protect species of concern. However, the presence of multiple invasive species and their interactions with native species can complicate the management issue. Without sufficient planning, managements may cause

unforeseen and unwanted effects. The problem is exacerbated by a lack of knowledge about ecosystem structure and species interaction dynamics. We use a qualitative modelling approach to make predictions of system wide impacts of alternative management strategies for cats and rats, and consequently compare these strategies. The outcomes of our research shows that cat management will benefit most of the species we consider; however the potential of rat population increase is likely to present predation pressure on numerous species of concern, hampering the population persistence or recovery. Cat eradication with rat control efforts are more likely to benefit the native species of Christmas Island, and reduce the potential for perverse outcomes for native bird of prey, some of which only occur on Christmas Island. The model also shows unexpected outcomes for some species for which positive responses were anticipated. Qualitative modelling approaches, which focus on model structure and omit problem specific quantitative details, can be very useful when little information is available to model an ecological system – like we see on Christmas Island. It provides a way of identifying potential risks and benefits of management plans, allowing more informed decision-making in the face of limited knowledge.

LINKING ECOLOGICAL AND SOCIAL DATA TO INFORM BIODIVERSITY CONSERVATION IN FARMING LANDSCAPES

Jan Hanspach

Leuphana University Lueneburg

Ine DORRESTEIJN, Leuphana University Lueneburg ; Jacqueline LOOS, Leuphana University Lueneburg ; David ABSON, Leuphana University Lueneburg ; Joern FISCHER, Leuphana University Lueneburg

Farming landscapes present an arena where human activities and ecological processes are tightly interlinked. Especially landscapes shaped by low intensity farming often support high biodiversity while also providing goods and services to local people. However, the dual process of land use intensification and abandonment is threatening species and ecosystems in many low-intensity farming systems. To facilitate effective biodiversity conservation in such systems a holistic understanding of local characteristics and social-ecological dynamics is critically important. Here, we report on an original, regional scale dataset on richness patterns, land use, topography and socio-demographic variables in a 7440 km² study area in Southern Transylvania (Romania). We surveyed the distribution of breeding birds, butterflies, and vascular plants in 150 sites distributed across arable land, pasture and forest around 30 randomly selected villages. We modelled species richness using generalized linear mixed effect models and predicted it to the whole study area. Richness then was aggregated to the village level and related to land use, topographic and socio-demographic characteristics

of the villages using multivariate methods. Based on this, we developed a typology of villages, and for each “village type” assessed the threats and opportunities for biodiversity conservation. Our findings highlight the importance of pursuing conservation strategies that consider local social and ecological characteristics. Our approach can be applied to other systems, and thus could help inform biodiversity conservation in farming landscapes around the world.

CAPTIVE BREEDING AND REINTRODUCTION OF AMPHIBIANS - HOW FAR HAVE WE COME?

Gemma Harding

University of kent

Richard GRIFFITHS, University of kent

Although captive breeding and reintroduction programmes are still very much focussed on mammals and birds, the Amphibian Conservation Action Plan of 2007 stimulated renewed interest in ex situ approaches to conservation for amphibians. Here we review progress that has been made since this time. The number of conservation breeding programmes for amphibians has increased by 30% over the past seven years. Geographically, the largest increase in programmes was in South America, where 40% of projects are now carried out. Likewise, there was a combined increase of 12% for captive breeding and reintroduction programmes in the Caribbean and Central America. Although habitat destruction remains the main threat to species in conservation breeding programmes, the relative number of species threatened by disease that are now in captive programmes has increased since 2007. Critically Endangered amphibians in captive breeding and reintroduction programmes have increased from 18% pre-2007 to 38% of species in 2013. These results indicate that as amphibians become increasingly threatened captive breeding as a conservation tool has become more prevalent. Although amphibians possess many characteristics that make them favourable candidates for captive breeding and reintroduction programmes, many of the threats that they face are difficult to mitigate or neutralise. This poses significant challenges for many future reintroductions.

HABITAT HETEROGENEITY AND SPECIES RICHNESS UNDER THREE CONTRASTING AGRI-ENVIRONMENT SCHEMES

Chloe Joy Hardman

University of Reading

Simon Geoffrey POTTS, University of Reading ; Ken NORRIS, Institute of Zoology, Zoological Society of London

Agricultural intensification tends to reduce the availability of foraging and nesting resources for wildlife, and reduce habitat heterogeneity. Agri-environment schemes (AES) are currently our main policy mechanism in Europe for limiting

the negative impacts of agriculture on biodiversity. Restoring habitat heterogeneity has been suggested as a conservation priority in the farmed landscape, however the mechanism by which this should be achieved, and the scale that is most appropriate for different taxonomic groups is not clear. We compare the effectiveness of three AES in England, for creating habitat heterogeneity at different spatial scales: (1) Entry Level Stewardship is the baseline scheme, which all farms in the study are in, covering 67% of England's agricultural area but showing limited impact so far, (2) Organic farming is a holistic scheme with restrictions on synthetic inputs, which tends to support higher plant diversity and habitat diversity than non-organic farms, (3) Conservation Grade is a novel market-based AES in which sown margins for insects and birds are created alongside intensively managed crops. We characterise how habitat heterogeneity varies between the three AES at the patch, farm, local-landscape and wider-landscape scales. We evaluate how strongly habitat heterogeneity predicts the species richness of bees, butterflies and birds, at different scales. Initial results show the highest patch diversity occurs on organic farms, which is positively correlated with species richness of butterflies. The findings will help inform at what spatial scale AES should be targeted, and how the patterns of heterogeneity created by different approaches to AES relate to species richness of different taxonomic groups.

SURVIVAL AND MOVEMENT OF TRANSLOCATED HOUBARA BUSTARDS IN A MIXED CONSERVATION AREA

Loïc Hardouin

UMR 7204 MNHN-CNRS-UPMC

Yves HINGRAT, RENECO Wildlife Consultants LLC ; Marie NEVOUX, UMR Ecologie et Santé des Ecosystèmes ; Frédéric LACROIX, RENECO Wildlife Consultants LLC ; Alexandre ROBERT, UMR 7204 MNHN-CNRS-UPMC

For endangered species that are hunted, the establishment of mixed conservation areas including both hunting zones and sanctuaries to complement translocation actions (i.e., reinforcement) can improve both hunting yields and population sustainability. However, the effects of this type of management on the demography of the exploited species are not well understood. We used multi-event capture-recapture modelling in a population of captive-bred houbara bustards (*Chlamydotis undulata*) translocated into a mixed conservation area in Morocco. The specific management practice of our system (hunting regime varying in time and space) led to a quasi-experimental situation that allowed the differentiation of "natural" from "hunting-induced" mortality and movement between areas. The analysis uncovered strong asymmetries in both movement and survival that were not only due to direct hunting effects. First, movement probabilities were higher from the sanctuary to the hunting areas than vice versa,

even in years without hunting. Second, in addition to a direct effect of hunting on mortality in hunting areas, our results uncovered permanent differences in both areas (even outside the hunting period). Overall, our results were consistent with predictions under a source-sink dynamic model but illustrated that mixed conservation areas should not merely be treated as homogenous systems with spatially heterogeneous hunting pressure but rather as fully heterogeneous systems. The patterns observed may be related to (1) the choice and design of hunting and sanctuary areas by managers, which might not be neutral with respect to habitat quality, or (2) to indirect consequences of hunting via an effect on local growth rate and density.

COMPLEXITY AND UNCERTAINTY IN THE APPLICATION OF PRIVATE LAND CONSERVATION REVOLVING FUNDS

Mathew Hardy

RMIT University

James FITZSIMONS, The Nature Conservancy ; Sarah BEKESSY, RMIT University ; Ascelin GORDON, RMIT University

Protecting biodiversity on private land is a growing part of worldwide conservation efforts. Amongst the most prominent mechanisms used for private land conservation are in-perpetuity agreements such as conservation covenants and easements. Conservation organisations use a number of approaches to establish these agreements, including "revolving funds". In this approach private land with conservation value is purchased, protected with a permanent conservation agreement and then on-sold to conservation-minded owners. The proceeds from the sale including any profit are then reinvested to purchase and protect additional properties, thereby "revolving" the funds to continually add to the extent of protected private land. However, decisions about which properties to buy are inherently complex, involving tradeoffs between multiple and potentially competing financial, social and conservation objectives. These decisions often need to be made quickly, opportunistically and also under high uncertainty in order to purchase important properties as they become available. The dynamic, sequential nature of this approach also means the outcome of each property bought and sold has consequences for subsequent purchases, thereby affecting conservation success. Using semi-structured interviews, this research seeks to understand how conservation organisations in Australia currently apply their revolving funds and the main factors that influence their decisions. We find that decision makers are reasonably confident in their ability to identify properties of conservation value, but are heavily constrained by the need to balance this with the financial sustainability of their funds, with uncertainty over the ability to recoup costs within an acceptable timeframe posing a considerable challenge. Given these high levels of uncertainty,

we outline how a more structured approach to property purchase decisions will improve both revolving fund efficiency and conservation outcomes.

THERMAL LANDSCAPES AND THE MIGRATION OF RATTLESNAKES IN CANADA

Jessica Harper

Thompson Rivers University

Karl Larsen, Thompson Rivers University

Understanding habitat selection on multiple scales is fundamental in the conservation and management of wildlife species. Selection of habitat based on thermal attributes may be of particular importance for ectothermic species, particularly in colder climates. In western Canada, rattlesnakes (*Crotalus oreganus*) reach their northern limits. While commonly associated with low-elevation, hot grasslands, recent work shows that some populations of these animals use higher elevation forests. We investigated the reason(s) for this phenomenon by monitoring the migratory movements of the snakes away from 10 different den sites, and comparing it to thermal-landscape GIS maps generated for different periods of the active season. We found that snakes utilizing the higher-elevation forests not only moved relatively further, but were associated with landscapes receiving on average higher amounts of solar insolation compared to other available areas. However, this correlation only appeared during the latter stages of migration, when the animals were reaching their destination. Interestingly, snakes that did not move towards the higher-elevation forests tended to come from dens located in less rugged, less variable landscapes where heat may not be a limiting resource. Prey availability and/or outbreeding may also be at least partially responsible for these patterns, but at this time we have limited data to test this. Regardless, snakes utilizing the higher-elevation forests had better body condition, indicating a definite advantage to this strategy. Insight into these behavioural differences between neighbouring rattlesnake populations will allow managers to tailor management strategies to specific dens. Not only that, these local and landscape scale patterns have obvious repercussions for snakes using forest habitats in the event of shifting ecosystem boundaries and thermal regimes under various climate change scenarios.

134 EXPLORING TRADE-OFFS AMONG SPATIAL PLANNING SCENARIOS: A MULTIVARIATE APPROACH

Linda Harris

Nelson Mandela Metropolitan University

Matthew WATTS, The University of Queensland ; Ronel NEL, Nelson Mandela Metropolitan University ; David SCHOEMAN,

University of the Sunshine Coast ; Hugh POSSINGHAM, The University of Queensland

Conservation decisions are often required to be made under uncertainty. However, scenario planning (constructing and comparing multiple scenarios) can be useful to guide decision-making. Even though systematic conservation planning can generate protected-area networks for multiple and complex reserve-design scenarios, planners rarely compare different reserve networks explicitly, or quantify trade-offs among scenarios. We demonstrate the use of multivariate statistics traditionally applied in community ecology to compare reserves designed under different scenarios, using conservation planning for beaches in South Africa as an example. Twelve reserve-design scenarios were run in Marxan in a hierarchical experimental design with three levels: including/excluding the probability of site destruction; two different cost types; and three different configurations of existing terrestrial and marine reserves. Through our case study we show that multivariate statistics can be useful tools in the conservation planning context. They revealed that the trade-off associated with including the probability of site destruction during coastal reserve design depended on the cost type: if the cost is related to the site-destruction probability, then reserves are significantly larger; if not, then reserves are significantly more costly. In both cases, the configuration of existing reserves locked a priori into the solutions was more important and resulted in significantly larger and more costly reserves. Ultimately, we demonstrate a novel application of multivariate statistical tools to robustly quantify potential trade-offs among diverse sets of reserve-design scenarios. These statistics can be applied: to support negotiations with stakeholders and decision makers regarding reserve configurations in the face of uncertainty; in reserve-design sensitivity analyses; and in priority setting for future research and data collection to improve conservation plans.

SPATIAL AND TEMPORAL DYNAMICS OF THE CONSERVATION ESTATE

Nyeema Harris

Luc Hoffmann Institute

Brian MACSHARRY, UNEP World Conservation Monitoring Centre ; Edward LEWIS, UNEP World Conservation Monitoring Centre ; Naomi KINGSTON, UNEP World Conservation Monitoring Centre ; Joshua TEWKSBURY, Luc Hoffmann Institute ; Lucas JOPPA, Microsoft Research

Our primary strategy in conservation across all biomes remains the formal protection of land and ocean. And yet, this global conservation estate is not a static feature but is in a constant state of flux with protected areas being established, abolished and changed in spatial extent. Here, we use 14 annual versions of the World Database of Protected Areas to understand how

the global conservation portfolio has changed - through establishment, degazettement, expansion, or downsizing - over space and time. From having just over 40,000 records in 1998 the database has evolved dramatically to contain over 217,000 records by the end of 2014. This increase reflects a number of factors; from improved technical capacity in countries to digitise and manage their national data sets and improved delivery of this data to the WDPA to responses to national, regional and global obligations (e.g., increase in the number of protected areas in Estonia prior to EU accession). The greatest increase in sites corresponded to IUCN management categories IV, V, and "Not reported", whereas Ia and Ib remain relatively static. Tracking these dynamics is necessary to evaluate progress towards conservation targets as well as understand opportunities for protected areas to contribute to other societal priorities such as global sustainable development goals.

PROTECTED AREAS VERSUS ENVIRONMENTAL CONDITIONS: A CASE STUDY FROM SMALL MAMMALS IN GHANA

Nyeema Harris

Luc Hoffmann Institute

Reuben GARSHONG, University of Ghana ; Morgan GRAY, University of California Berkeley

Distangling the synergistic effects of climate and land use requires intensive sampling over large spatial extents. Here, we investigate the influence of these perturbations on the spatial distribution and composition of animal communities. Specifically, we sampled small mammals within and outside three protected areas located in distinct ecoregions throughout Ghana, simultaneously incorporating gradients of land protection and environmental conditions. We captured 221 individuals across 23 species; most species were captured only within one ecoregion. Both capture rate and species richness were highest at sites located in a protected area. Additionally, community composition was more similar for sites sampled within the same ecoregion irrespective of corresponding land uses (i.e. protection). Our findings suggest that disrupting climates will have greater influence on small mammal community attributes than dynamics associated with land protection.

118-RESEARCH TO ACTION: ESTABLISHING WHO IS POACHING AND WHY TO IMPROVE CONSERVATION INTERVENTIONS AT BWINDI NATIONAL PARK, UGANDA

Mariel Harrison

Imperial College London

Julia BAKER, Parsons Brinckerhoff Ltd ; Medard TWINAMATSIKO, Institute of Tropical Forest Conservation ; Panta KASOMA, Jane

Goodall Institute ; E. J. MILNER-GULLAND, Imperial College London

Unauthorised resource use is a threat to biodiversity in protected areas. In the developing world, interventions aimed at reducing unauthorised resource use by tackling poverty have had limited success. To be effective, we need to better understand who is offending and why, so that we can target interventions at the right people for the right reasons. However, this is rarely achieved because of the challenge of investigating sensitive behaviour. Working with Uganda Poverty and Conservation Learning Group (U-PCLG), we used a mixed-methods approach including household surveys, indirect questioning and focus groups, to find out who was involved in unauthorised activity at Bwindi Impenetrable National Park, Uganda. We found that, overall, offenders tended to display characteristics of poorer and marginalised people, living in larger households very close to the Park boundary but far from markets. However it was not just poverty that drove unauthorised resource use, but also resentment towards the park authorities at the perceived inequity of revenue sharing, lack of employment for local people and lack of support over crop raiding. U-PCLG is using the research to advocate for improving both conservation policy and practice. So far successes include the Uganda Wildlife Authority increasing the communities' share of the \$600 mountain gorilla viewing fees from \$5 to \$10 per permit. U-PCLG members are also trialling community-based monitoring of revenue sharing aiming to benefit those suffering from crop raiding, and conducting further research into local employment opportunities. This experience suggests that researchers, advocates, policy makers and practitioners can achieve real change by working more closely together. This ensures that research is targeted towards addressing relevant questions, the answers to which can translate into rapid and real change in conservation policy at the local level, for both biodiversity and people.

CONTRIBUTION OF SNARE REMOVAL TO CHIMPANZEE CONSERVATION: THE KANYAWARA CASE

Jessica Hartel

Aarhus University

Emily OTALI, Kibale Chimpanzee Project ; Rachel ELLIS, Bates University ; Sonya KAHLENBERG, Gorilla Rehabilitation and Conservation Education Center ; Martin MULLER, University of New Mexico ; Peter KJAERGAARD, Aarhus University ; Richard WRANGHAM, Harvard University

Chimpanzees living in Kibale National Park (KNP) in western Uganda have been ranked by the IUCN as a high priority for conservation. At over 1400 individuals, it is the largest population in Uganda and one of the largest for the eastern subspecies (Plumptre et al. 2010). The chimpanzees'

home is also an immensely important forest habitat with significant scientific and conservation value because of its high biodiversity and its history of long-term research and successful conservation initiatives (Wrangham & Ross 2008). The growing neighboring human population presses hard against the park's boundary with poachers entering illegally to snare small ungulates for bushmeat. While not the intended targets, chimpanzees' hands and feet become entangled in wire snares. In response to the long-term negative effects snaring has on chimpanzees, the Kibale Chimpanzee Project started the Kibale Snare Removal Program (KSRP) in 1997. At any given time, an estimated 15,000 snares are set in KNP, resulting in a 3.7% risk of a chimpanzee being snared each year (Wrangham & Mugume 2000). To date, two individuals in the study population have died from snare wounds and historically around half have lasting snare injuries, including a young male who lost both of his feet. Data collected by KSRP has been analyzed in relation to the Kanyawara chimpanzees' snare injuries. The initiation of KSRP is associated with a significant increase in the length of time between observed chimpanzee snare injuries, indicating that the patrol efforts are offering meaningful protection to the chimpanzees. Snares are now more commonly found near the park boundary and outside of the Kanyawara chimpanzee home range. Human interventions to remove snares from injured chimpanzees resulted in fewer permanent injuries than when no intervention attempts were made. While snares can cause serious physical damage, in general they offer much lower known mortality risk relative to orphaning, disease, and aging.

151-LANDSCAPE-SCALE PROTECTION OF BIODIVERSITY AGAINST THE DEVASTATING PLANT PATHOGEN PHYTOPHTHORA CINNAMOMI

Renée-Claire Hartley

N/A

Christopher DUNNE, Ecosystem Biosecurity & Management ; William DUNSTAN, Murdoch University

Phytophthora cinnamomi is one of the most destructive plant pathogens worldwide. This invasive species leads to changes in species composition, plant community structure and ecosystem function. In south-western Australia invasion by the pathogen has resulted in a permanent loss of biodiversity in more than one million hectares of native plant communities. In recent years, novel approaches to preventing the spread of the pathogen, reducing the impact of the disease, and containment or eradication of infestations have been developed through applied research within conservation management projects. The work has focussed on biodiversity assets and specific sites identified as the highest priority for protection. Management strategies were tailored for characteristics of each disease centre and the hazard/threat profiles of individual priority protection areas. The projects

used a catchment-based strategy that aimed to reduce the risk associated with the four modes of pathogen spread; autonomous spread in surface and subsurface water; root-to-root transmission between plants; animal vectoring; and human vectoring. Management techniques have included fine-scale surveying of infestations, in-situ baiting, hydrological modelling, hydrological engineering, fencing to exclude animal vectors, installation of root barrier membranes, destruction of host plants, and soil fumigation. Over four years of monitoring at the containment and eradication sites within the Fitzgerald River National Park (an International Biosphere Reserve) and Cape Arid National Park has demonstrated that these techniques can be successful, or show promise of success with further work. These strategies and techniques have broad applicability in the management of *P. cinnamomi* and other soil-borne plant pathogens for a range of other scenarios and are currently being employed where most needed, to protect threatened species and ecological communities.

SYMPOSIUM 163: CAN ECOSYSTEM-BASED ADAPTATION ADDRESS THE ADAPTATION NEEDS OF SMALLHOLDER FARMERS? INSIGHTS FROM SMALLHOLDER COFFEE AND SUBSISTENCE FARMERS IN CENTRAL AMERICA

Celia Harvey

Conservation International

Francisco ALPIZAR, CATIE ; Jacques AVELINO, CIRAD [INSTITUTE] IICA-PROMECAFE ; Pavel BAUTISTA, CATIE ; Jose Mario CARDENAS, CATIE ; Camila DONATTI, Conservation International ; Ruth MARTÍNEZ-RODRÍGUEZ, Conservation International ; Bruno RAPIDEL, CIRAD ; Milagro SABORIO-RODRIGUEZ, University of Costa Rica ; Raffaella VIGNOLA, CATIE ; Bárbara VIGUERA, CATIE

In many regions, climate change is having significant adverse impacts on the agricultural production and livelihoods of smallholder farmers, with important consequences for global food security. Helping smallholder farmers adapt to climate change has therefore become a priority for many of donors and governments. Ecosystem-based Adaptation (EbA, defined as the use of ecosystem services and biodiversity as part of an overall adaptation strategy to help people adapt to the effects of climate change) is one approach that could help smallholder farmers, yet there is still limited knowledge on whether EbA can meet the adaptation needs of smallholder farmers. Here, we provide an overview of what EbA means in the context of smallholder agricultural production. Drawing on expert surveys, field work and household surveys of smallholder coffee and subsistence farmers in Central America, we provide examples of EbA strategies that are suitable for smallholder farmers, characterize how farmers are implementing these strategies, and provide insights into the

perceived advantages and drawbacks of different practices for reducing farmer vulnerability. Our study highlights that many agricultural practices that smallholder farmers already use (e.g., agroforestry systems, soil conservation practices, live fences) can be considered EbA, as they are based on the management of biodiversity and ecosystem services and help and enhance the resilience of agricultural systems. Most smallholder farmers are aware of the relative benefits of EbA practices, but also acknowledge important constraints, such as the cost of setting up the practices and maintenance, and limited financial, technical and political support. Scaling up the use of EbA through targeted government policies, extension services and farmer programs could not only help smallholder farmers adapt to climate change, but also ensure healthy, sustainable agroecosystems that sustain local livelihoods.

LESSONS LEARNED IN MARINE PROTECTED AREA ESTABLISHMENT? THE CASE OF KOH RONG ARCHIPELAGO MARINE PROTECTED AREA, CAMBODIA

Jesse Hastings

National University of Singapore

For the last several years, Cambodia has been creating a large-scale marine protected area around the Koh Rong archipelago. Called the Koh Rong Archipelago Marine Fisheries Management Area (KRA MFMA), it has already seen several markers of progress including gathering biophysical data for use in zoning decisions, conducting community consultations on draft zoning maps, conducting private sector consultations on zoning and management, and creating a provincial management committee and a technical working group. 2015 is expected to bring the official governmental proclamation of the MFMA. The Cambodian government has indicated a desire for and movement towards establishing a representative MFMA network across its coastal provinces. Like with the Koh Rong Archipelago MFMA, future MPAs in this network will use community fisheries – marine areas where communities are empowered to govern their own fisheries resources – as the foundation of the effort. This presentation presents research which analyzes the enabling conditions and barriers to the establishment of the KRA MFMA. Data for this research was gathered through participant observation, semi-structured interviews with key stakeholders from across sectors, and a collaborative workshop (to be) held in May 2015. Preliminary results indicate that a governmental willingness to move away from historic mindsets, involvement of communities and the private sector in zoning consultations, and creation of targeted governance mechanisms all played an enabling role in the KRA MFMA's establishment. Meanwhile, barriers to establishment included a lack of intergroup trust and difficulty in balancing different perspectives on shared governance. With Cambodia

on the cusp of an expansion in marine management, this presentation begins a productive dialogue with the wider conservation community with the aim of informing Cambodian marine conservation planning.

SYMPOSIUM 24: USING SOCIAL NETWORK ANALYSIS TO UNRAVEL COMPLEXITY IN AGRICULTURAL BIODIVERSITY GOVERNANCE

Jennifer Hauck

Helmholtz Centre for Environmental Research - UFZ

Jenny SCHMIDT, Helmholtz Centre for Environmental Research - UFZ

In 2013 the EU launched the new EU Green Infrastructure Strategy to make another attempt to stop and possibly reverse the loss of biodiversity until 2020 (EC 2013), by connecting habitats in the wider landscape. This means that conservation would go way beyond current conservation practices to include landscapes that are dominated by conventional agriculture, where biodiversity conservation plays a minor role at best. Thus, for exploring the options of the green infrastructure implementation we consider it important to identify, analyse and include a) actors at the implementation levels (regional and local levels), b) other affected policy sectors and c) the vertical and horizontal interplay, between actors at different levels and from different policy sectors. We used the Net-Map tool for our analysis as it combines measures of attributes of actors – especially concerning their perceived influence and their goals – with structural measures. Further it provides vast information on institutional backgrounds and governance settings in particular for agricultural policy. The investigation started with interviews with key informants on the regional level in the German Bundesland Saxony-Anhalt such as regional planners, representatives of relevant federal ministries and continued at the local level with farmers and other members of the community. Concerning network concepts, multiplexity is considered important to uncover the diverse relations that connect actors and centrality and associated different roles provide important insights in combination with the notion of agency. Last but not least, the concept of cognitive social structure allows conclusions about diverging network perspectives and resulting learning opportunities.

TOURISTS' PREFERENCE FOR SENSE OF PLACE AND LESS CHARISMATIC BIODIVERSITY: UNVEILING NEW OPPORTUNITIES FOR CONSERVATION

Anna Hausmann

University of KwaZulu-Natal

Rob SLOTOW, *University of KwaZulu-Natal*; Iain FRASER, *University of Kent*; Enrico DI MININ, *University of Helsinki*

The 'Big Five', as well as other charismatic megafauna, are considered key flagships for ecotourism and conservation marketing in sub-Saharan Africa. However, this approach has neglected the value of broader biodiversity as well as the ecosystem services of sense of place that protected areas provide to people. By using a choice experiment approach followed by latent class modelling, this study investigated tourists' perception of biodiversity and sense of place experiences alternative to charismatic megafauna in South African protected areas. Sense of place experiences were mostly defined by outdoor activities and wildlife viewing, which were attributes driving choices for holiday destination. Results showed heterogeneity in preferences for a range of less-charismatic biodiversity, including small-body mammals, reptiles, birds, amphibians, insects and vegetation, depending on individuals' experiences and socio-economic background. All tourists expressed feeling of attachment, identity and dependence to the natural environments of protected areas. By understanding the demand for sense of place and less charismatic biodiversity, the results can be used to promote new ecotourism market segments alternative to charismatic megafauna. This is particularly important to unveil new opportunities for protected areas, which have high biodiversity and sense of place values, but lack charismatic species.

CHALLENGES IN SEED SOURCING FOR RESTORATION IN A CHANGING WORLD

Kayri Havens

Chicago Botanic Garden

Shannon STILL, *Chicago Botanic Garden*; Andrea KRAMER, *Chicago Botanic Garden*; Pati VITT, *Chicago Botanic Garden*; Jeremie FANT, *Chicago Botanic Garden*

Proper sourcing of seed for ecological restoration has never been straightforward, and it is becoming even more challenging and complex as the climate changes. For decades, restoration practitioners have subscribed to the "local is best" tenet, even if the definition of "local" was often widely divergent between projects. However, given our increasing ability to characterize habitats, and rapid climate change, we can no longer assume that locally-sourced seeds are always the best or even an appropriate option. We discuss how plants are responding to changing climates through plasticity, adaptation, and migration and how this may influence seed sourcing decisions. We show using species distribution modeling how plant species ranges may change and find drastically different responses in the eastern and western United States. Continued research is needed to better understand appropriate current and future seed transfer zones.

Banking native seed now is necessary to maintain these future options.

EFFECTS OF HIGHWAY NOISE ON GLUCOCORTICOID LEVELS OF THE GULF COAST TOAD (*INCILIUS VALLICEPS*) IN CENTRAL TEXAS

Aaron Haynes

St. Edwards University

Marsha BARNES, *St. Edwards University*; Michael WASSERMAN, *St. Edwards University*

Soundscapes are defined by the variation and interaction of sounds within a landscape, whether natural or anthropogenic. For many species, competition within the soundscape may influence physiology, morphology, behavior, and fitness. In this study, we addressed the physiological and morphological effects of anthropogenic highway noise on the Gulf Coast toad (*Incilius valliceps*) of Wild Basin Wilderness Preserve in Central Texas. To do so, we quantified the soundscape by recording sound intensity (decibels) using SoundMeter (an iPhone app that meets the National Institute for Occupational Safety and Health standards) while walking four transects across the preserve three times and mapping the sound data using ArcGIS. We then captured and released toads, measured body size, and quantified urinary corticosterone levels, the major stress hormone of amphibians, in individuals across the preserve. Using spatial analysis and multiple regression, we examined relationships between urinary corticosterone levels, body size, sound intensity, distance to highway, and distance to nearest water source. We documented variation in sound intensity across the preserve and displayed this using a heat map generated by ArcGIS. Our results have important implications beyond our study species, including the endangered Houston Toad, as well as other species in the Wild Basin community, such as the white-tailed deer, endangered golden-cheeked warbler, coyote, and bobcat. By understanding the sources of and spatial and temporal variation in noise pollution through quantification of soundscape, conservation and environmental management practices, particularly in urban protected areas, will be more able to effectively reduce the negative effects of chronic stress on species of concern by alleviating anthropogenic noise pollution. This will ultimately help to restore or conserve the abundance and distribution of the species the parks are intended to protect.

BARRIERS TO DIVERSIFYING THE ENVIRONMENTAL WORKFORCE: STUDENT PERCEPTIONS OF ENVIRONMENTAL CAREERS

Nia Haynes

University of Florida

Susan JACOBSON, *University of Florida*

The environmental workforce does not reflect the racial diversity of the U.S. population. This study analyzes barriers and opportunities for increasing diversity in environmental careers. We present a meta-analysis of literature on underrepresentation of racial/ethnic minorities in environmental careers. We used constructs from the Social Cognitive Career Theory (SCCT) to identify barriers and supports influencing career choices (personal, contextual, self-efficacy, and outcome expectations) across 4 age groups. The number of cited barriers differed significantly among age groups. Personal influences included race/ethnicity, gender, age, and perceptions or predispositions toward nature. The latter was the most cited barrier for youth. Contextual influences included social, familial, structural, and experiential, and varied significantly between age groups. Exposure to nature was the most cited contextual barrier for all groups. Self-efficacy was emphasized in studies referencing youth, high school and college age groups, while outcome expectations were only discussed in literature related to the career group. Based on these findings, we conducted a survey of undergraduates from environmental and non-environmental majors using a comparative cross-sectional design. This study focuses on the college age group and uses a modified SCCT framework. Students were asked about their perceptions of environmental careers, career-related self-efficacy and outcome expectations, and the strength and influence of contextual factors on their interest in environmental careers. Results show that perceptions of environmental careers vary significantly by major and along racial/ethnic lines. Findings provide recommendations for improved recruitment for a diverse environmental workforce.

VOLES AS BIOINDICATORS.

Tigran Hayrapetyan

Yerevan State University

George PAPOV, *Yerevan State University* ; Astghik GHAZARYAN, *Yerevan State University*

The development of mining operation in Southern Armenia weakly equipped with cleaning plants, application of intensive agricultural methods, lack of systems for neutralization and etc. had a negative impact on the environment. Developing an understanding of how natural animal populations will respond to anthropogenically caused environmental changes has become one of the major challenges in conservation and evolutionary biology. The study of level of influence of pollution on voles will use for environmental monitoring. The main objectives of the work were study of distribution, ecological and morphological diversity of voles (Rodents) and their relationship with ecosystems. Voles were discovered in unpolluted territories unlike the polluted territories where no voles were found. This work was made possible by a research

grant from the Armenian National Science and Education Fund (ANSEF) based in New York, USA

LEVERAGING NON-TRADITIONAL FUNDING TO FILL CRITICAL INFORMATION GAPS IN ENDANGERED SPECIES RECOVERY: A CASE STUDY ON MEXICAN SPOTTED OWLS AND THE COLLABORATIVE FOREST RESTORATION PROGRAM

Quentin Hays

Eastern New Mexico University

Christina WAMPLER, *United States Forest Service*

Shifting priorities and unpredictable budgets often make prioritizing conservation issues or filling critical information gaps in species recovery difficult, particularly for large-scale efforts or for species which primarily fall under the umbrella of land management agencies. Biologists and conservationists are now forced to look beyond customary avenues for funding conservation work, and leverage funds which may be considered non-traditional. The Collaborative Forest Restoration Program (CFRP) is a United States Forest Service grant program intended to provide funding for forest restoration and for creation of forest-products jobs in New Mexico, USA. Here we describe the CFRP program and a project utilizing CFRP funds to implement forest treatments in habitat of the federally-listed Mexican spotted owl (MSO). This project adheres to the guidelines of the CFRP program, while also providing funding for scientifically sound post-treatment monitoring of owls and their prey base. Mexican spotted owls are a driver of management activities in the Southwest, as forest-treatment guidelines from the MSO Recovery Plan currently restrict efforts to restore forests known to be departed from historic fire regimes. Problematically, research funding to determine impacts of forest treatments on owls and their prey base has proven difficult to obtain. Leveraged funding through the CFRP program has provided for implementation of restoration activities and post-treatment study which, to date, has shown no immediate demographic or habitat use response in owls or their prey. This information should prove critical to scientists and managers as they attempt to balance between species recovery and landscape-scale forest restoration in designated Mexican spotted owl habitat in the Southwest United States.

CONSERVATION OF DEEPOP BEEL, THE LONE RAMSAR SITE OF ASSAM(INDIA) ,THROUGH COMMUNITY PARTICIPATION

Arup Kumar Hazarika

Cotton College

Apurba Kumar DAS, Centre for Environment, Education and Economic Development ; Prakash CHETRY, Centre for Environment, Education and Economic Development

Deepor Beel wetland which is the lone Ramsar site of Assam in India is facing danger from various angles. In this study, attempt has been made to identify the current conservation threats to biodiversity of this Ramsar site. Field observation shows that Deepor Beel wetland is facing both natural as well as anthropogenic threats. Rapid urbanization, illegal settlements, industries, invasive species are the major cause of this wetland decline. It has been found that massive decline occurred between the period 2012 to 2014. Community consultation and participation are critical in the management and conservation of wetlands. However, wetland management is still based largely on 'protection' and 'law enforcement approach' and there is considerable confusion over both the meanings and implications of terms such as decentralized management and participation. By working together with local communities around the wetland, this project aimed to restore severely degraded wetland. The study followed an approach of combined environmental rehabilitation and socio-economic improvements, placing greater emphasis on the process than on outputs, and facilitating initiatives of the community, rather than ideas of the project team. It focused its main activities on strengthening community organisation, building environmental awareness; wetland rehabilitation through hydrological restoration, support to alternative livelihood initiatives, and information dissemination. Thus, our study could find that giving wetland stakeholders the opportunity to present, analyse and share their experiences was also a means of empowering their social capital through strengthening indigenous knowledge networks and adaptive capacity. Lastly, to protect the wetland from habitat loss, fragmentation and alteration recommendations like, monitoring, continuous environmental awareness, proper enforcement of the policies, eradication of invasive species and weeds at regular interval are put forwarded.

151-ENVIRONMENTAL REFUGIA AND CONNECTIVITY SUSTAIN AMPHIBIAN METAPOPULATIONS AFFLICTED BY DISEASE

Geoffrey Heard

University of Melbourne

Chris THOMAS, Department of Biology, University of York ; Jenny HODGSON, Department of Evolution, Ecology and Behaviour, University of Liverpool ; Michael SCROGGIE, Arthur Rylah Institute for Environmental Research ; David RAMSEY, Arthur Rylah Institute for Environmental Research ; Nick CLEMANN, Arthur Rylah Institute for Environmental Research

Metapopulation persistence in fragmented landscapes depends on habitat patches that can support resilient local

populations, plus sufficient connectivity among patches. Yet epidemiological theory for metapopulations has largely overlooked the capacity of particular patches to act as refuges from disease, and has suggested that connectivity can undermine persistence. Here, we show that relatively warm and saline wetlands are refuges from chytridiomycosis for an endangered Australian frog, and act jointly with connectivity to sustain frog metapopulations. We coupled models of microclimate and infection probability to map chytrid prevalence, and demonstrate a strong relationship between expected chytrid prevalence and frog population extinction. Simulations confirm that frog metapopulations are likely to go extinct when they lose connectivity and lack wetlands in which chytrid prevalence is low. This study demonstrates that environmental variables can mediate host-pathogen interactions in fragmented landscapes, and provides evidence that connectivity only facilitates the persistence of species afflicted by facultative pathogens.

195 AN ASSESSMENT OF THE FEASIBILITY OF INSURANCE SCHEMES TO MITIGATE HUMAN-ELEPHANT CONFLICT IN SUMATRA, INDONESIA

Simon Hedges

Wildlife Conservation Society

Insurance schemes aimed at mitigating human-wildlife conflict are related to compensation schemes but by making payments (either in cash or kind, such as rice) contingent on payment of a premium (and potentially also contingent on guarding of crops and crop type) one of the most serious problems affecting compensation schemes is reduced, i.e. the potentially reduced incentive for self-defense by farmers. Nevertheless, work by the Wildlife Conservation Society and Greenomics in Sumatra, Indonesia, found that commercial insurance against crop depredations by elephants was impracticable because (1) the premiums proposed by insurance companies were high relative to the cost of the damage done by elephants and (2) the difficulties of meeting commercially acceptable risk management standards for reinsurance. However, insurance schemes arguably lend themselves to small-scale micro-finance or village-credit schemes that do not have the administrative burden typical of state- or province-level compensation schemes. The advantages and disadvantages of such locally run, micro-finance based schemes are reviewed in the context of other approaches to reducing human-wildlife conflict.

THREATENED FOSSORIAL SKINKS POSE AN INTERESTING CHALLENGE TO CONSERVATION STRATEGIES: THE CASE OF SCELOTES GRONOVII AND SCELOTES KASNERI (LACERTILIA: SCINCIDAE) FROM THE WESTERN CAPE COAST, SOUTH AFRICA.

Neil Heideman

University of the Free State

The evolutionary relationships among populations of two threatened Red Data Book fossorial skinks, *Scelotes gronovii* and *Scelotes kasneri*, were investigated along the Western Cape coast of South Africa. Four localities of *S. gronovii* and seven of *S. kasneri*, encompassing all of their documented distributions. Sequence data derived from three mtDNA (16S ribosomal RNA, cytochrome b and nicotinamide adenine dinucleotide dehydrogenase 1 unit) and two nuclear (dynein axonemal heavy chain 3 and the natural killer tumor recognition) gene regions were used to reconstruct the evolutionary relationships within each taxon, under the hypothesis that cryptic diversity is likely prevalent in both species. Phylogenetic results inferred from combined evidence analyses using Bayesian and parsimony methods, recovered two well-supported reciprocally monophyletic groups representing all localities north and south of the Berg River drainage, respectively. In both of these clades we found co-distributed populations classified as *S. gronovii* and *S. kasneri* as sister groups, suggesting that these two morphotypes have evolved multiple times. Within each of the two clades we further observe multiple sympatric lineages delineated by both mtDNA and nDNA. These results support the hypothesis that cryptic speciation has occurred within these fossorial skinks. It is suggested that the conservation status of these and possibly other low vagility fossorial taxa should be based on molecular studies because their morphology may hide significant evolutionary diversity. From a conservation perspective it is proposed that all these populations be protected considering their genetic distinctiveness.

68: RETENTION FORESTRY, PRESCRIBED BURNING AND SAPROXYLIC BEETLES IN EARLY FOREST SUCCESSIONS

Osmo Heikkala

University of Eastern Finland

Petri MARTIKAINEN, University of Eastern Finland ; Jari Kouki, University of Eastern Finland

Intensive forest management and effective prevention of natural disturbances have caused fragmentation and loss of natural forest habitats. Prescribed burning and retention forestry are methods developed for bringing the biological legacies of harvesting closer to the legacies of natural

disturbances. However, the long-term effects of these methods on species assemblages and functional properties are still mainly elusive. We established a large scale empirical study in 2000 to explore the effects of prescribed burning and four levels of tree retention (0, 10 and 50 m³ ha⁻¹ and control) on saproxylic beetle diversity during ten post-harvest years. Not only species richness but also the proportions of different functional groups of saproxylic beetles were monitored. Both fire and logging increased the species richness in first post-harvest year. At burned unharvested stands the number of species was still raised after ten years, but decreased to about the pre-treatment level at the burned and unburned stands with retention trees, and even lower at clear-cuts. Furthermore, there were clear differences in the assemblages between different treatment combinations. In ten year period, increasing logging intensity decreased the amount and proportion of fresh wood feeders. All logging methods and burning increased the mean body size of the beetles and the proportions of late-stage xylophagous, but decreased the proportions of mycetophagous species. Burning increased also the number of rare and red-listed species, but only at unharvested stands. Our results emphasize the difference in functional legacies between logging and natural disturbance, but also suggest that prescribed burning and retention forestry are effective methods in order to alleviate the negative effects of forest management also in longer term.

CONSERVING THE LEGACY OF EUROPEAN BEECH FORESTS - THE CASE OF WOOD-INHABITING FUNGI.

Jacob Heilmann-Clausen

University of Copenhagen

Nerea ABREGO, Norwegian University of Science and Technology ; Claus BÄSSLER, Bavarian Forest National Park ; Morten CHRISTENSEN, Grontmij

Wood inhabiting fungi represent an important aspect of forest biodiversity, both in their own right, and as ecosystem engineers recycling carbon, and opening dead wood as a resource for other organisms. Fungal communities in dead wood are highly diverse, and many species are poorly known, both in terms of ecological functions and with regard to conservation needs. This is the case globally, and in relation to the highly fragmented and degraded temperate forests of Europe. Based on two decades of research in European beech forest reserves it is evident that local habitat factors, especially relating to wood decay stage and log size, are crucial and consistent drivers of species richness and community composition at resource level. At the continental scale climate is an important factor affecting species composition at site level, and as forest history and climate is strongly correlated at the European continental scale, it has been a challenge to disentangle effects of forest history and climate on fungal communities. However, ongoing research strongly suggests

severe effects of forest fragmentation and lack of naturalness on fungal communities. These effects include changes in guild structure, loss of specialist species and decreasing beta diversity in conservation areas situated in degraded forest landscapes. These findings highlights the importance of protecting larger remains of little disturbed forest in Central and Southeast Europe, and to enlarge conservation areas around remaining old growth forest patches in northern and western Europe, rather than expanding conservation efforts in areas lacking natural forest heritage.

ID142 THE EUROPEAN GREEN BELT INITIATIVE - CHALLENGES, EXPERIENCES AND ACHIEVEMENTS

Anne Katrin Heinrichs

EuroNatur Foundation

Gabriel SCHWADERER, EuroNatur Foundation ; Tomáš RUZICKA, Nadace Partnerství ; Uwe RIECKEN, German Federal Agency for Nature Conservation (BfN) ; Karin ULLRICH, German Federal Agency for Nature Conservation (BfN) ; Liana GEIDEZIS, Friends of the Earth Germany (BUND) ; Melanie KREUTZ, Friends of the Earth Germany (BUND)

The European Green Belt is an initiative which builds on the division of Europe, for around forty years, into the Eastern and Western bloc during Cold War times. This high security, border fortifications and restricted access, offered an excellent opportunity for nature to persist and recover without much disturbance. As a result, a zone of conflict has turned into an opportunity to protect a Green Belt of high-value natural and cultural landscapes, running through Europe from the Barents Sea in the north to the Black Sea in the southeast. It is more than 12,500 km long and traverses eight biogeographic regions and 24 countries. Since the fall of the Iron Curtain governmental and non-governmental organizations from most of these countries have joined the European Green Belt Initiative to jointly conserve the natural treasures along the Green Belt - a great variety of mostly well preserved European landscapes ranging from alpine peaks, arctic tundra, forests, mires, bogs, rivers and flood plains to coastal areas, grasslands and agricultural landscapes. Goals of the initiative are to conserve and restore the function of the European Green Belt as an ecological network and to enhance sustainable regional development based on the specific natural, historical, and cultural heritage of the border regions. The high political commitment of 17 countries of the European Green Belt was demonstrated by a Declaration of Intent. The latest step in order to advance governance has been the establishment of the European Green Belt Association. Eventually, this step will also help to secure continuous funding. The European Green Belt with its variety of landscapes and habitats is predestined to function as the backbone of a Green Infrastructure network across Europe. The European Green Belt Initiative demonstrates

that good will and cooperation do exist and can be clustered to support Green Infrastructure and to reduce land-use conflicts.

95 THE ROLE OF ROADSIDE HABITATS FOR THE CONSERVATION OF BIODIVERSITY

Jan Olof Helldin

Calluna AB

Andrew BENNETT, La Trobe University

Roadsides provide habitat for a wide range of plants and animals, most of them common but also some species that are threatened in the landscape as a whole. There is a growing understanding and appreciation worldwide of the role and value of the grasslands, forest strips, treerows, hedgerows, live fences and other linear vegetation structures that skirt road networks. Pervasive through most landscapes, the green network formed by natural or semi-natural vegetation along roads has been labelled "a centrepiece of conservation". Strips of roadside vegetation may range from just a few metres in width to 100m or more, and together cover immense areas. Moreover, in agricultural regions, urban areas and other highly modified environments that increasingly occupy Earth's surface, roadsides may harbour the only natural or semi-natural vegetation that remains. The characteristics of roadside vegetation vary greatly, influenced by historic transportation and land uses, and reflecting its value as both a natural and cultural asset. Roadsides can contribute to biodiversity conservation: 1) by the value of the soil and vegetation at a particular site as habitat; 2) by the value of the overall linear network, representing a large component of natural or semi-natural vegetation, or contributing to connectivity through the landscape; and 3) by the interactions with surrounding land, either positive, where species of conservation concern move to and from nearby farmland, or negative, where invasive species spread along roadsides or invade adjacent environments. The value of roadside vegetation is influenced by its width, the composition and structural complexity of the vegetation, roadside management, traffic intensity, road structure, interactions between species, and landscape configuration. We summarise these concepts with particular reference to roadside vegetation in contrasting environments, and illustrate with examples from northern Europe and Australia.

193-REWILDING IN PRACTICE

Wouter Helmer

Rewilding Europe

Rewilding Europe was founded in 2011 to develop a new conservation strategy for the European continent. Large scale land abandonment - often perceived as a major socio-economic and ecologic problem - can also be used as the start of new rural economies, based on wild values. Giving more

space to wildlife and natural processes will lower the costs of conservation and at the same time improve conditions for wildlife and nature related enterprises. Human interventions are only done if nature can ultimately take over (i.e. act now, in order to act less in future). Out of more than 30 nominations, Rewilding Europe has selected 9 areas of at least 100.000 ha each, to be the showcases for this new approach. These areas represent different ecosystems in different parts of Europe, from the Coa-Valley in Portugal to the Danube Delta in Romania, and from the Central Apennines in Italy to Greater Laponia in Sweden. In all these areas the comeback of natural processes goes hand in hand with the support of rewilding enterprises. European wide marketing and communications help to attract people towards these new nature destinations. At the same time local involvement is improved, for example by training bear ambassadors, bison rangers, wildlife guides or other rewilding entrepreneurs. Innovative tools as the European Wildlife Bank, Rewilding Europe Capital, the European Safari Company and the Rewilding Europe Travel Club are key in reconnecting man and nature in a modern context. Results from the first four years of Rewilding Europe will be presented.

THE DYNAMIC OF LOCAL COMMUNITY RESPONSE TOWARDS MARINE CONSERVATION AREA (CASE STUDY : THE MARINE CONSERVATION AREA OF BATANG, INDONESIA)

Alfian Helmi

Hokkaido University

Arif SATRIA, Bogor Agricultural University ; Ilham TAWAKAL, Bogor Agricultural University

Reconciling fishers –while sometimes regarded as enemy by conservation managers—becomes critical issues in developing marine conservation area in Indonesia. Conflict between fishers and the managers is rooted on establishment of conservation area that avoiding interests among the social actors. However, local community members have multiple perspectives in regard to the marine conservation areas and their impact. This paper seeks to analyze local community response (especially for fisher's response) towards marine conservation area in Indonesia. The local responses consist of zonation, rule of the game, sanctions, monitoring and evaluation, authority and the bundle of rights. The research involved in-depth interviews, observation and household questionnaires. It was found that over all the data indicated that local community member support marine conservation area. Nevertheless, it was also found that there were considerable difference responses among local government, community, and conservation managers. The reasons for those differences are outlined.

OPTIMAL THREATENED SPECIES TRANSLOCATIONS: HOW MANY, HOW OFTEN, AND FOR HOW LONG

Kate Helmstedt

University of California Berkeley

Hugh POSSINGHAM, University of Queensland

One primary aim of biodiversity conservation is to halt the extinction of threatened species. A common requirement in threatened species recovery plans is the establishment of multiple self-sustaining populations. Species translocation from either a successful captive breeding program or from a robust existing population can be an effective way to reintroduce locally extirpated populations into the wild. When individuals become available for release over the span of multiple years conservation managers must decide where to release these animals, a decision complicated by the presence of more than one potential release site. We present a method for determining an optimal schedule for threatened species translocation into multiple potential release sites using population modelling and mathematical optimization techniques. Our model takes into account both monetary and temporal setup costs as well as ongoing management costs. The optimal schedule for releasing individuals over multiple years strongly depends on the cost of maintaining infrastructure, staff and management actions at active release sites. Suboptimal choices can be very costly and can jeopardize the outcome of the recovery program. By ensuring the best management practices are followed, conservation decision-makers can maximize the biodiversity benefit achieved from their dollar.

WHO TO TRUST? ASSESSING AND IMPROVING EXPERT PERFORMANCE IN CONSERVATION BIOLOGY.

Victoria Hemming

The University of Melbourne

Expert opinion is routinely relied upon in conservation biology, particularly when data are absent, rare or unreliable. Expert opinion is used to inform model parameters, make predictions and judgements, or in advisory role on committees and expert panels. The quality of judgements made by experts can influence the quality of conservation decisions. However, there is tantamount evidence that experts, like lay people, are subject to a range of heuristics and biases that can affect their ability to make accurate judgments. Susceptibility to these heuristics and biases differs between experts. Given that not all experts are equal how should we pick an expert? My research examines 1) how experts are selected in conservation biology, 2) whether we may be able to test expert performance before selecting those experts we entrust with crucially important judgements, 3) can we improve expert performance via feedback from

ongoing testing of experts. My research has found that experts are typically chosen based on perceived predictors of expert performance, including years of experience, peer recommendation, professional affiliations, and age. These traits are unreliable predictors of expert performance, and can be akin to a leap of faith. Could assessing expert judgements against a set of test questions be a more reliable indicator of expert opinion? Testing expert performance has been trialed in engineering and public policy, however, conservation biology adds its own nuances. For example, what the type of questions, elicitation procedures, the scoring protocols, the limitations of the method and the costs and benefits of the method. Furthermore, deliberate practice and feedback have been shown to improve expert performance. Feedback in conservation is often absent, rare, or delayed. Could repeated testing of expert performance create feedback loops that eventually improve performance? Thus creating more experts?

EFFECT OF CHEMICAL STRESSORS ON CRAYFISH FOOD CUE RESPONSE

Brianna Henry

Clarion University of Pennsylvania

Rachael BERRY, Clarion University of Pennsylvania ; Erica FAZIO, Clarion University of Pennsylvania ; Krystalyn KOVACS, Clarion University of Pennsylvania ; Andrew KETH, Clarion University of Pennsylvania

Atrazine, a triazine herbicide used to kill broadleaf weeds in agricultural and roadway applications, is one of the most widely used pesticides in the United States. While this herbicide is meant for landscape use, rain and other storm events often carry the chemical from terrestrial to aquatic systems, where it has been associated with several negative effects. A number of studies have related Atrazine exposure to reduced olfactory reception in fish and suggest that Atrazine acts as an endocrine disruptor in fish and amphibian species that come into contact with this chemical at ecologically relevant levels. As aquatic species sense most of their information about environmental conditions through olfaction, this is particularly important for crayfish, who only replace their olfactory cells during molting. In this study we examine the impacts of the herbicide Atrazine on crayfish responses to food cue and pursue possible explanations for behavioral changes based on observation of olfactory structure surface morphology utilizing scanning electron microscopy. Because Atrazine has been observed to be an endocrine and olfactory disruptor in other species, its non-lethal effects in crayfish could potentially disrupt the food web dynamics of aquatic systems. We hypothesize that exposure to ecologically relevant concentrations of Atrazine will result in irregular behavior in crayfish presented with chemical cues indicating the presence of a food source. Behavioral changes in response to these chemical cues may indicate a need to further

consider the non-lethal effects of Atrazine, in addition to other understudied pollutants.

188_ BARRIERS TO BIODIVERSITY IN FLUVIAL ECOSYSTEMS-SYSTEMATIC PLANNING OF DISCONNECTION TO ENHANCE CONSERVATION SUCCESS IN A MODIFIED WORLD

Virgilio Hermoso Lopez

Centre Tecnologic Forestal de Catalunya

Stephanie R JAMUCHOWSKI-HARTLEY, Texas A&M University ; Simon LINKE, Griffith University

Maintaining connectivity within and between systems is often desired in conservation to foster ecological processes and the persistence of biodiversity. However, conservation practice in human-modified environments can benefit from existing or prescribed disconnection through the implementation of barriers. These barriers can help reduce the pressure of threats, create refuge areas for native biodiversity and help reduce economic losses caused by invasive species. Here we propose that the use and implementation of barriers for conservation should be systematically planned, considering trade-offs between ecological pros (easing threats) and cons (interruption of ecosystem processes) for multiple species and economic cost/benefits, rather than using ad-hoc opportunistic criteria or accommodating conservation needs for individual species. However, any implementation of disconnection for conservation should be cautiously considered if uncertainty and ecological risk are high. Monitoring programs are needed to learn from previous successes and failures and enhance the use of this conservation tool. Systematic planning methods should guide future decisions about the retention and allocation of barriers to maximize ecological benefit and minimize negative impacts across terrestrial, freshwater and marine realms.

ECOLOGY AND CONSERVATION OF AN ENDANGERED CARNIVOROUS MARSUPIAL IN A SEMI-ARID ENVIRONMENT: INVASIVE PREDATOR IMPACT

Lorna Hernandez Santin

University of Queensland

Diana FISHER, University of Queensland ; Anne GOLDIZEN, University of Queensland

As with many carnivores throughout the world, populations of marsupial carnivores in Australia are declining. Once abundant, quolls (*Dasyurus* spp.) are the largest native mammalian predators on mainland Australia. Of the three species remaining in Australia, the northern quoll (*D. hallucatus*) is in the most imperilled IUCN's category of 'endangered', because of a rapid and severe population decline of >50% in the last

decade in most of its range. They appear to have declined recently and to still be declining in the semi-arid region of the Pilbara in Western Australia, which represents a potential refuge from invasive threats (especially the cane toad). This project aims to determine why this species has declined in grassland and retreated to rocky habitats in the Pilbara. The species recovery plan suggests a hypothesis- that feral fox, cat and / or dog activity is greater in grassland. Using live and camera trapping, and focusing on two sites with both rock outcrops and spinifex grassland, we test if outcrops in rocky habitat provide a haven from introduced predators. We have caught and photographed 103 quolls. This represents 17 individuals (5 photos and 12 trapped) at Millstream Chichester National Park, and 86 quolls (46 photos and 40 trapped) at Indee Station. These two sites have different management. Millstream National Park does not cull dingoes, while Indee Station – a cattle station with tourism activities - does. In areas surrounding trapping sites, we have caught 46 invasive predators. In Millstream we have photographed 13 cats and 8 dingoes, while at Indee Station we have caught 20 cats, 3 dingoes, and 2 foxes. By collaborating with WA Department of Parks and Wildlife, this project contributes to a management plan for the conservation and recovery of the species. Understanding trends of decline of this species contributes to the general pool of knowledge of carnivore ecology.

BELOWGROUND COMMUNITY RESPONSES TO GRASSLAND MANAGEMENT INTENSIFICATION IN MONTANE AND SUBALPINE REGIONS

Chantal Herzog

University of Bern

Jean-Yves HUMBERT, University of Bern ; Malie LESSARD-THERRIEN, University of Bern ; Marcel VAN DER HEIJDEN, Agroscope Reckenholz-Tänikon ; Raphaël ARLETTAZ, University of Bern

Nowadays, montane and subalpine European grasslands are confronted to different pressures due to changes in agricultural practices. The application of liquid manure instead of solid manure and the progressive replacement of traditional ground irrigation by aerial irrigation with sprinklers are two examples of novel practices. Their effects on plant and numerous animal communities have already been studied. However, there is a lack of knowledge about belowground responses. Belowground communities and particularly arbuscular mycorrhizal fungi (AMF) play a fundamental role in ecosystem functioning and are crucial drivers of vegetation dynamics and ecosystem services such as nutrient cycling. This study investigates the response of diverse belowground components to different intensity levels of fertilisation and irrigation in montane and subalpine meadows. It is part of a long-term project conducted in mountain grasslands with the main objective to find the best trade-off between biodiversity

conservation and hay production. Our different study sites consist of eleven extensively managed hay meadows situated in the Central Alps of Switzerland (Valais). Six different intensity levels of irrigation and fertilisation are experimentally applied to 314 m² plots in all sites (n = 11 replicates). We hypothesise that intensification of farming practices, especially the broad use of fertilisers, is causing negative effects on soil microbial communities and their activities. We will focus on AMF, plant root architecture, as well as on litter breakdown and nutrient uptake as important ecosystem processes. Finally, we will link above- and belowground grassland communities regarding their reaction to agricultural intensification. This study will consequently provide management recommendations for farmers in order to promote sustainable agriculture in montane and subalpine grasslands.

HABITAT LOSS FROM HYDRAULIC FRACTURING LOWERS AVIAN NEST SURVIVAL IN A WESTERN NORTH AMERICAN LANDSCAPE

Matthew Hethcoat

University of Wyoming

Anna CHALFOUN, University of Wyoming

Addressing the impacts of habitat loss, fragmentation, and alteration embodies a primary challenge in conservation biology. An emerging source of anthropogenic disturbance globally is from energy development activities. Global energy demand has doubled since 1970 and is forecast to increase 40% by 2030. As a consequence, habitats have been increasingly reduced and fragmented by road networks, pipelines, drill pads, and other components associated with energy extraction. However, research on wildlife impacts has tended to focus on economically important game species of western North America. We assessed the influence of habitat loss from hydraulic fracturing activities on a critical component of fitness (nest survival) for three species of sagebrush-obligate songbirds that are of conservation concern in western North America. In addition, we tested the hypothesis that energy development influenced nest predation rates via increases in local predator abundance. During 2008-2009 and 2011-2012 we monitored 887 nests within two natural gas fields in western Wyoming, USA. In 2011 and 2012, we identified predators using infrared cameras and assessed predator abundance via point counts, scent stations, and live-trapping. Daily nest survival rates decreased with habitat loss for Brewer's sparrows (*Spizella breweri*) and sage thrashers (*Oreoscoptes montanus*) during 3 of 4 years, while the null model of constant nest survival was most supported for sagebrush sparrows (*Artemisiospiza nevadensis*). Diurnal and nocturnal rodents comprised 70% of predation events. Concordant with decreased nest survival, rodent detections increased with energy development intensity; suggesting energy development activities modified local predator assemblages.

North America is anticipated to develop 200 000 km² of new land for energy development by 2035. Thus, an important next step requires understanding why certain predators increase in areas with increased habitat loss from hydraulic fracturing.

RECOGNITION OF INVASIVE ALIEN PREDATORS BY TADPOLES OF THE AGILE FROG (RANA DALMATINA)

Attila Hettyey

Lendület Evolutionary Ecology Research Group, Plant Protection Institute, Centre for Agricultural Research, Hungarian Academy of Sciences

Kerstin E THONHAUSER, Konrad Lorenz Institute of Ethology, University of Veterinary Medicine Vienna ; Dustin J PENN, Konrad Lorenz Institute of Ethology, University of Veterinary Medicine Vienna ; Herbert HOI, Konrad Lorenz Institute of Ethology, University of Veterinary Medicine Vienna ; Veronika BÓKONYI, Lendület Evolutionary Ecology Research Group, Plant Protection Institute, Centre for Agricultural Research, Hungarian Academy of Sciences ; Matteo GRIGGIO, Department of Biology, University of Padova

Invasive alien species (IAS) can have devastating ecological effects. Their success may be due to a lack of a shared history of coexistence with native species: IAS may not be recognized as potential predators. Empirical tests of this prey naiveté hypothesis have obtained equivocal results, perhaps because many ignored ecological differences and phylogenetic relationships among the studied predators, while others did not take the recent history of coexistence with the prey population into account. We performed a comprehensive test of the prey naiveté hypothesis. We investigated how tadpoles of the agile frog (*Rana dalmatina*), originating from hill-land or floodplain populations, decrease their activity when exposed briefly to chemical cues from either endemic, earlier invasive, recent invasive or allopatric fish predators. We used four percid, four silurid and two cyprinodontid fish species, and fed fishes either with conspecific tadpoles, bloodworms or spinach. Our results indicated that predator-naïve tadpoles reduced their activity only when exposed to endemic or earlier invasive percid predators that had been feeding on tadpoles, but not in response to recent invasive or allopatric percids, or to any of the silurid or cyprinodontid fishes. Also, tadpoles originating from isolated hill-land populations responded weaker than their conspecifics from floodplain populations co-existing with predatory fishes. These results provide evidence that the lack of a shared history of coexistence can prevent prey recognizing predatory IAS. However, less than 40 generations are sufficient for tadpoles to evolve the ability to recognize predatory invasive fish species. Finally, our results suggest that the responsiveness of prey to predatory IAS may depend on several ecological factors, including the recent feeding history of predators, the ability of predators to conceal chemical cues

of predation, and whether prey populations coexisted with ecologically similar predators.

DEMOGRAPHIC DECLINE AND POTENTIAL VULNERABILITY TO EXTINCTION IN THE SOUSS VALLEY TORTOISE, TESTUDO GRAECA SOUSSENSIS PIEH, 2001 (CHELONII: TESTUDINIDAE) IN CENTRAL JBILET MOUNTAINS, WEST CENTRAL MOROCCO

Nawal Hichami

Cadi Ayyad University, Faculty of Science-Semlalia
Safaa Bendami, Cadi Ayyad University, Faculty of Science-Semlalia ; Mohammed ZNARI, Cadi Ayyad University, Faculty of Science-Semlalia ; Moulay Abdeljalil AIT BAAMRANE, Cadi Ayyad University, Faculty of Science-Semlalia ; Mohamed NAIMI, Cadi Ayyad University, Faculty of Science-Semlalia

The Moorish tortoise, *Testudo graeca*, is the only terrestrial chelonian species in Morocco. It is listed on Appendix II of CITES and is considered “vulnerable” (IUCN, 2008). In the central Jbilet, west central Morocco, in an arid and overgrazed steppe-land, one of the largest populations of the endemic subspecies, the Souss valley tortoise, *T. g. soussensis*, at regional level, has been in decline during the last 10 years due to a combination of climatic and human factors. Indeed, an estimate of the spring population size by Mark-Recapture method from 2003 to 2012, showed that the population size was reduced to more than 50% (from 196 to 88 ind. within a central area of 33 ha) with a mean density of less than 3 ind./ha vs. 6 ind./ha. The degree of stress in this population was assessed by fluctuating asymmetry (FA) defined as the random deviation of perfect bilateral symmetry at the plastron, used as an indicator of developmental perturbations. This asymmetry has proved to be in relation to the instantaneous growth rate and is more important than that of more supportive tortoise’ environments. Using the VORTEX software, we carried out a preliminary population viability analysis (PVA) on the basis of the last known population size, longevity and demographic parameters. Based on the estimated mortality rates between 2003 and 2012, it appears that the population of central Jbilet mountains would face a potential risk of extinction in the forthcoming 30 years. Finally, and taking into consideration conservation issues identified by the AVP along with different identified direct and indirect threats, a population and habitat management plan is proposed including a captive-breeding programme for population reinforcement and ecological restoration of the degraded and overgrazed steppe-lands in the study area.

TESTING A NEW METHOD FOR AN UNBIASED ABUNDANCE ESTIMATE OF MOUNTAIN GORILLAS (GORILLA BERINGEI BERINGEI) IN THE VIRUNGA MASSIF, CENTRAL AFRICA

Jena R. Hickey

International Gorilla Conservation Programme

Population estimates of the endangered mountain gorilla (*Gorilla beringei beringei*) need to be as accurate as possible in order to understand trends and achieve high stakes conservation across 3 countries with recent history of transboundary conflicts. Methodology for estimating mountain gorilla abundance has changed over the past 2 decades, such that robust trend estimates are not yet possible. Mountain gorillas exist in two populations: Bwindi Impenetrable National Park, Uganda and the Virunga Massif of the Democratic Republic of Congo, Rwanda, and Uganda. The first use of DNA samples to identify the minimum number of mountain gorillas (302) occurred in Bwindi in 2006; whereas, the first application of DNA-mark-recapture for an un-biased abundance estimate (400-430) occurred in Bwindi in 2011. This study builds on previous work by estimating mountain gorilla abundance in the Virunga Massif using DNA-mark-recapture, with important adjustments to previous study designs. For each gorilla group, samples of DNA from every nest at 3 nest sites (rather than 1 nest site) were analyzed to unique individual. Intra-group detection probability was then estimated treating nest sites as a given group's occasion history. Summing the unbiased estimates of group size across all groups allowed for the first unbiased estimate of gorilla abundance in the Massif. Next steps will include a second full survey of the Massif within the year, in order to calculate population-level detection probability, to complement the intra-group detection probability shown here. Multiple occasion histories per group, as well as for the entire population, lend insights into primary sources of error and ways to further improve mountain gorilla population estimates. With future DNA-mark-recapture studies planned in Bwindi for 2016, robust estimates of gorilla abundance can be compared over time to build estimates of population trends that include confidence intervals and that acknowledge sources of error.

194. LEAVING EDEN: SOCIAL SCIENCE AND THE QUEST FOR SUSTAINABILITY IN THE ANTHROPOCENE

Christina Hicks

Stanford University

Arielle LEVINE, San Diego State University ; Arun AGRAWAL, University of Michigan ; Xavier BASURTO, Duke University ; Sara BRESLOW, NOAA Northwest Fisheries Science Center ; Caroline CAROTHERS, University of Alaska ; Susan CHARNLEY, USDA Forest Service ; Sarah COULTHARD, Northumbria University ; Nives DOLSAK, University of Washington ; Jamie DONATUTO, Swinomish Indian Tribal Community ; Carlos GARCIA-QUIJANO, University of Rhode Island ; Michael MASCIA, Conservation International ; Karma NORMAN, NOAA Northwest Fisheries

Science Center ; Melissa POE, NOAA Northwest Fisheries Science Center [INSTITUTE] University of Washington ; Satterfield TERRE, University of British Columbia ; Kevin ST MARTIN, Rutgers University ; Phillip LEVIN, NOAA Northwest Fisheries Science Center

Contemporary environmental problems are intentionally and unintentionally caused by humans, harm humans, and can only be solved by humans. Social science is therefore central to the quest for sustainability in the Anthropocene. We describe six concepts, which capture the social processes that influence how people behave, and are thus fundamental to charting a path to a sustainable future. First, the different ways in which the world is understood and knowledge is created must be embraced if we are to engage with the complexity of science for the Anthropocene. Second, culture and values shape our identity, actions, and aspirations and as such should be at the core of any sustainable future. Third, governance is about far more than government, and engagement with the myriad of informal rules, norms, and processes that together influence behavior will be necessary to bring about change. Fourth, people act purposefully to achieve what they perceive as desirable, and a failure to consider the ability of people to make dynamic choices in response to social and environmental changes can generate unintended outcomes that may undermine the goals of sustainability. Fifth, societal responses to environmental change can alter how ideas, organizations, and people influence each other. Likewise, when policies threaten existing powers of influence those policies are likely to be subverted with potentially disastrous consequences or conflict. Finally, inequities in the distribution of knowledge, wealth, resources, opportunities and influence exert social pressures and tensions that exacerbate negative environmental impacts. Equity is therefore both a moral imperative and central to achieving sustainability. Together these six concepts can help science for the Anthropocene embrace a diversity of preferences, interests, and epistemologies and chart a path to a just and equitable future.

DRIVERS OF FISH SPATIAL VARIATION ACROSS THE SUNDA BANDA AND BIRD'S HEAD SEASCAPES, INDONESIA

Ismu Hidayat

Conservation International

Mikaela Provost, World Wildlife Fund ; Purwanto PURWANTO, The Nature Conservancy ; Gabby AHMADIA, World Wildlife Fund ; Estra DIVARI, World Wildlife Fund

Multiple environmental and social variables together drive the distribution of fish populations. Knowing which covariates primarily explain spatial variation in fish abundance and biomass across large seascapes provides useful broad picture information for stakeholders and managers and captures

the current ecological state. Furthermore, looking at both environmental and social covariates can help to disentangle the contribution of habitat characteristics and human influences. In Indonesia, the Bird's Head Seascape and Sunda Banda Seascape are two regions spanning more than 1.79 million square km in the heart of the Coral Triangle. Both seascapes house highly productive coral reefs for artisanal and commercial fisheries and are well known for having some of the healthiest, most diverse reef ecosystems in the world. Using best available data for a suite of environmental (e.g. reef type, exposure, slope, and distance to mangroves and deep water) and social (e.g. distance to nearest fishing village, primary market, and pollution risk) contextual variables and fish biomass data collected from nearly 300 sites across 2010-2014, we found that distance to primary market explained the most variation in fish abundance and biomass compared to all other covariates. Even compared to critical habitat covariates, reefs in close proximity to a primary market had much lower density and abundance than more remote sites. This suggests that fishing pressure is the most important factor explaining patterns of fish abundance and biomass throughout the seascapes, reinforcing the need to strengthen fisheries management in these regions.

VARIATION IN ECOSYSTEM RESPONSE FOLLOWING MARINE PROTECTED AREA ESTABLISHMENT IN RAJA AMPAT MPA NETWORK, INDONESIA

Nur Ismu Hidayat

Conservation International Indonesia

Defy Nataniel PADA, Conservation International Indonesia ; PURWANTO, The Nature Conservancy ; Gabby N AHMADIA, World Wildlife Fund ; Muhammad Erdi LAZUARDI, Coral Triangle Center ; Andreas H MULJADI, Coral Triangle Center ; Christine L HUFFARD, Monterey Bay Aquarium Research Institute ; Helen E. FOX, Rare

The rich coral reefs of Raja Ampat, Indonesia located in the heart of the Coral Triangle, supports some of the highest fish biodiversity in the world. Unfortunately, with rapid development in the region, this has led to increasing threats to coral reef ecosystems. To mitigate these threats and maintain biodiversity and sustain fisheries in the region, local community, governments and partners developed a conservation agenda that led to the establishment of a network of Marine Protected Areas (MPAs). To measure the performance of MPAs, a large scale underwater monitoring program began surveying coral reef fishes populations in seven MPAs during MPA establishment, and have since all been repeated 2-4 years later. Initial results indicate that ecological performance varies among MPA with stable, increasing and decreasing trends. We specifically focus on changes in fish abundance, fish biomass and fish community structure of different trophic groups and key fisheries species. Further

analyses are currently investigating the relationship between the frequency of infringements of MPA regulations and corresponding changes in fish populations.

ALLOMETRY AND THE EXTINCTION VULNERABILITY OF BIRDS AND MAMMALS: WHY ARE LARGER SPECIES MORE VULNERABLE TO EXTINCTION?

Jelle Hilbers

Radboud University Nijmegen

Aafke SCHIPPER, Radboud University Nijmegen ; Jan HENDRIKS, Radboud University Nijmegen ; Francesca VERONES, Radboud University Nijmegen ; Henrique PEREIRA, German Centre for Integrative Biodiversity Research (iDiv) ; Mark HUIJBREGTS, Radboud University Nijmegen

Although extinction risk is known to be positively associated with body size, a consistent process-based framework that explains this relationship is still lacking. Here, we address the key scientific question why larger species are more vulnerable to extinction than small species. We present a new framework that systematically quantifies extinction risk based on allometric relationships between various wildlife demographic parameters and body size. These allometric relationships have a solid theoretical and ecological foundation. Extinction risk indicators included are the probability of extinction, the mean time to extinction and the critical patch size. We applied our framework to assess the global extinction vulnerability of terrestrial carnivorous and non-carnivorous birds and mammals. Irrespective of the indicator used, large-bodied species were found to be more vulnerable to extinction than their smaller counterparts. Carnivorous mammals had higher extinction risks than non-carnivores, while birds were more prone to extinction than mammals. These results are explained by the allometric relationships predicting vulnerable species groups to have lower intrinsic population growth rates, smaller population sizes, lower carrying capacities or larger dispersal distances, which in turn increase the importance of losses due to environmental stochastic effects and dispersal activities. Our study is the first to integrate population viability analysis and allometry into a novel, process-based framework to quantify extinction risk. The framework facilitates a better understanding of the key underlying factors that determine how extinction vulnerability varies with body size compared to findings of correlative studies. It may be applied to forecast extinction vulnerability in response to a changing environment, by incorporating quantitative relationships between wildlife demographic parameters and environmental drivers like habitat alteration, climate change or hunting.

197. MOVING TOWARD A NATIONAL STRATEGY IN THE UNITED STATES

Jodi Hilty

Independent consultant

David THEOBALD, Conservation Science Partners ; Craig GROVES, Science for Nature and People ; Michael SCOTT, University of Idaho ; Jocelyn AYCRIGG, University of Idaho

Many agencies and entities across the US implicitly or explicitly support the support conservation through land management. Although these land protection efforts represent a significant investment in conservation, they have been necessary but insufficient to stem the tide of biodiversity loss and degradation of ecosystem services. What is needed now is a cohesive and comprehensive vision and framework for designing this cornerstone strategy. We discuss the current state of conservation, the historic precedent for such a system in the US, and discuss the challenges toward moving to a comprehensive strategy across the US. Given the different global models, what approaches might best suit the US for moving forward?

TRANSLOCATION OF A PARTIAL MIGRANT BIRD: WHAT, WHERE AND WHEN TO RELEASE?

Yves Hingrat

Reneco Wildlife Preservation

Bénédicte MADON, Reneco Wildlife Preservation

The efficiency of translocation programmes requires sound knowledge on the ecology and behaviour of the targeted species and accurate estimations of the survival and breeding performances of released individuals. Such estimations, generally challenging, become seriously puzzling in the case of partial migrant species. A first prerequisite is a good knowledge on the genetic structure of populations in order to define suitable population management strategies, especially in the context of captive-breeding and reinforcement. To maximise survival and breeding performances of released populations, it is essential to define where and when to release, as these choices may have opposite outcomes for resident compared to migrant individuals. Beyond the difficulties in gathering data, this theoretical approach relies on the assumption that migration behaviour is mainly genetically controlled and that captive-bred released individuals will behave according to their genetic origin, the location and timing of release. The Asian houbara bustard, *Chlamydotis macqueenii*, is a partial migrant bird whose decline led to the creation of a network of captive breeding programmes designed to reinforce wild populations in Central Asia and the Middle East. Migrant and resident wild populations have been intensively monitored since 1994 with more than 550 wild individuals tracked using satellite transmitters. Besides, about 1000 captive-bred houbara (CBH), from migrant and resident origins, have also been released and monitored via satellite tracking. Here we present our current knowledge on the genetic and movement behaviour of wild Asian houbara (migrant and resident), provide original

results on the behaviour of released CBH (migrant and resident origins), highlighting the importance of understanding “what, where and when to release” for the success of a translocation programme.

HETEROGENEITY IN CONSUMER PREFERENCES FOR ORCHIDS IN INTERNATIONAL TRADE AND THE POTENTIAL FOR THE USE OF MARKET RESEARCH METHODS TO STUDY DEMAND FOR WILDLIFE.

Amy Hinsley

University of Kent

Diogo VERISSIMO, Georgia State University ; David ROBERTS, University of Kent

The demand for wildlife products drives an illegal trade estimated to be worth up to \$10 billion per year, ranking it amongst the top transnational crimes in terms of value. Orchids are one of the best-selling plants in the legal horticultural trade but are also traded illegally and make up 70% of all species listed by the Convention on the International Trade in Endangered Species (CITES). To study consumer demand for horticultural orchids we use choice experiments to survey 522 orchid buyers online and at large international orchid shows. Using latent class modelling we show that different groups of consumers in our sample have distinct preferences, and that these groups are based on gender, genera grown, online purchasing and type of grower. Over half of our sample, likely to be buyers of mass-produced orchids, prefer white, multi-flowered hybrid plants. Of greater conservation interest were a smaller group consisting of male hobbyist growers who buy their orchids online, and who were willing to pay significantly more for species that are rare in trade. This is the first in-depth study of demand in the international orchid trade and our findings confirm the importance of rarity as a driver of hobbyist trade. We show that market-research methods are a new tool for conservationists that could provide evidence for more effective conservation of species threatened by trade, especially via campaigns that focus on demand reduction or behaviour change.

IDENTIFYING THE GAPS IN ACCESS AND BENEFIT SHARING IN THE SOUTHEAST ASIAN ORCHID TRADE

Amy Hinsley

University of Kent

David ROBERTS, University of Kent

The equitable sharing of benefits from natural resources was emphasised as being important in 1992 by the Convention on Biological Diversity and has relevance to the commercialisation and trade of wildlife products. Horticulture is one industry that relies heavily on wild genetic resources for the development of new products but little attention has been paid to sharing the benefits of this trade with the range states of traded plant

species. Using a regional case study of Southeast Asia we analysed the online sales of orchids, one of the most important horticultural products in trade, to determine to what extent countries are benefitting from trade in their own native and endemic plants. We found that 20.8% of Southeast Asian orchid species and almost 9.9% of national endemics were being traded, with species from every country represented in trade. Although their species were traded widely, we found that the three lowest income countries in the region (Lao, Myanmar and Cambodia) had little or no trade. Lao in particular contributed 52.1% of its native species and 21.4% of its endemic species to trade but was selling none of these species itself. Further, we found endemic species on sale outside the country of origin for which no CITES permits seem to have ever been issued. Orchids are traded illegally in the region and although this can bring economic benefits to those who collect and trade them, these benefits are often unsustainable and the conservation implications can be serious. We conclude that the most effective way to tackle the gaps in access and benefit sharing observed in the region would be to build both the botanical and horticultural capacities of those countries currently benefitting least from their own species. This may also help to provide an incentive to address the issue of illegal trade.

A 3000 HA SPATIAL EXPLICIT FIRE HISTORY ILLUSTRATING THE MOSAIC STRUCTURE OF BOREAL LANDSCAPES IN NORTHERN EUROPE

Julia Hjalmarsson

Mid Sweden University

Bengt Gunnar Jonsson, Mid Sweden University ; Evan LARSON, University of Wisconsin ; Yingyue YANG, Mid Sweden University ; Per LINDER, National Property Board of Sweden

Although with some regional variation and differences among forest types, fires have been the major natural disturbance throughout the boreal forests of Northern Europe. As a consequence, several forest types and a large range of forest species are dependent on the natural fire regime. Since the late 19th century efficient fire suppression and changes in land use have basically excluded fires from a large part of the region. For that reason efforts are now taken to re-introduce fire as a management tool in protected areas as a mean to secure fire dependent forest types and species. However, there is limited knowledge of the natural fire regime calling for detailed studies on the spatial and temporal pattern of historical fires. This was done in a 3000 hectare large nature reserve in central Sweden, and by using fire scarred trees we were able to reconstruct the fire patterns for more than 600 years. The results show that fires has been very common in the area and on average, seen over the entire area, one fire occurred every 8 years. We identified in total about 100 individual fires out which 12 fires are considered as large. The fire pattern over time showed three distinct periods. Prior to the 18th century the area was

dominated by a few relatively rare but large fires. Between 1700 and late 19th century many small fires dominated the pattern, while from late 19th century to modern times, fires have basically been excluded. This pattern is likely linked to changes in human land use and potentially to climate variation.

SYMPOSIUM #68: RESTORATION OF NATURAL FOREST DYNAMICS TO PROMOTE INSECT DIVERSITY: A TEST OF DIFFERENT STRATEGIES

Joakim Hjältén

SLU

Ruaridh HÄGGLUND, SLU ; Therese JOHANSSON, SLU ; Jörgen OLSSON, SLU ; Jean-Michel ROBERGE, SLU ; Mats DYNESIUS, Umeå Universitet

Because of world-wide forest degradation, eroding biodiversity and ecosystem services, ecological restoration has become a global priority. Today, the importance of natural disturbance regimes, natural habitat structures for biodiversity, and ecosystem processes in forest is widely recognized. The aim with this project is to evaluate ecological effects of two different ecological restoration methods (prescribed burning and gap cutting) in low quality voluntary set-asides on saproxylic (wood living) beetles, a group of insects severely threatened by forestry. We used a before-after experimental study in 21 spruce dominated stands in Sweden. The stands were randomly subjected into one of 3 treatment groups 1) prescribed burning 2) gap cutting 3) no treatment control. Saproxylic beetles were trapped in window traps before and directly after treatment. Abundance, species richness and assemblage composition did not differ between the treatment groups prior to treatment. However, treatments resulted in an higher abundance and species richness of saproxylics in burned stands and differences in assemblage composition between all stands. Strongly fire favoured species e.g. *Stenotrachelus aeneus*, *Henoticus serratus* and *Placusa atrata* increased dramatically after burning. However, some fire favoured species, e.g. *Corticaria rubripes* and *C. ferruginea* also increased after gap cutting. Both burning and gap cutting resulted in changes in assemblage composition, favouring saproxylic species otherwise disfavoured by modern forestry. Both methods are recommended as cost efficient restoration methods for voluntary set-asides as some of the trees were removed to cover cost for the restoration treatments. Voluntary set-asides provide excellent opportunities for restoration due to the large area that they cover in many countries.

THE BUTTERFLY HIGHWAY: CONNECTING PEOPLE AND NATURE

Angelique Hjarding

University of North Carolina Charlotte

Citizen science is becoming widely recognized as a valuable tool for collecting species observation data. Online citizen science reporting tools, such as eBird (<http://ebird.org>) and iNaturalist, (<http://www.inaturalist.org/>) make it easy for backyard nature enthusiasts to report species they observe visiting their yards. In theory, this network should provide equal access for anyone wishing to participate in citizen science biodiversity monitoring. But is there truly equal participation? A correlation between income, race and participation in citizen science biodiversity monitoring has been observed and these populations participate the least in this type of activity. Potential factors that could contribute to low participation are lack of conservation and biodiversity knowledge, a weak connection to nature and access to data reporting tools such as smart phones and computers. Additionally, residential urban areas could be experiencing a reduction in biodiversity due to the effects of urbanization resulting in a reduced number of species to observe. I will present a project called the Butterfly Highway that was designed to address these issues. The project is a university-community partnership focused on biodiversity monitoring and environmental restoration in urban residential neighborhoods in Charlotte, NC. The project consists of two primary activities: developing a community-based citizen science butterfly monitoring program and the creation of the "Butterfly Highway" in urban residential areas. The Butterfly Highway is a network of sustainable perennial pollinator gardens that have been installed in neighborhood resident's yards, parks and other pockets of under utilized green space. The project has faced many challenges including recruitment, sustainability and participant safety and it is hoped that our learned experiences can be used to create a model for establishing meaningful and sustainable university-community conservation partnerships.

195 LESSONS FROM 15 YEARS OF HUMAN-ELEPHANT CONFLICT MITIGATION: MANAGEMENT CONSIDERATIONS INVOLVING BIOLOGICAL, PHYSICAL AND GOVERNANCE ISSUES IN AFRICA

Richard Hoare

Independent Consultant

The further researching, refinement and re-assessment of Human-Elephant Conflict (HEC) mitigation methods that has occurred since 2003 can be summarized into biological, physical and governance categories. The most important distinction is between those measures applied against animals and used within the conflict zone, which are mostly used in the shorter term (except some fencing), and those measures working with people in the longer term, which rely heavily on official policy and administration often situated beyond the conflict zone. Effective HEC mitigation is difficult to understand

and problematic to implement; it remains a complex package of apparently disparate measures that have to be used in combination and flexibly, at different scales, for both animals and people. Future HEC mitigation will be as much an art as a science, but since we now have a solid research foundation, we can proceed with some confidence to address the inherent socio-political difficulties.

SAVING SEEDS: HOW TO IMPROVE THE EFFECTIVENESS OF SAMPLING PROTOCOLS FOR EX SITU CONSERVATION SEED COLLECTIONS

Sean Hoban

University of Tennessee

Allan STRAND, College of Charleston ; Scott SCHLARBAUM, University of Tennessee

In the face of continued environmental change, conservation and natural resource agencies are initiating or expanding ex situ seed collections from natural plant populations. The purpose of these seed collections may be long-term conservation, habitat restoration, or study of plant germination and ecology. In all cases it is advisable to capture as much phenotypic and genetic diversity from the natural populations as possible. General and widely-used guidelines for sampling strategies were developed in the 1990s, but these guidelines may be ad hoc and/or suboptimal for genetic representation. In this talk, I will explain and demonstrate a new approach to optimize sampling protocols for a conservation collection. I use spatial, demographic and genetic data from three species, as well as simulated data under an individual-based model, to lead to tailored collections that maximize diversity while minimizing collection size. I find that characteristics of plant reproduction and dispersal, as well as logistical factors, significantly influence the genetic diversity captured in seed collections. As one example, a highly self-pollinating, low dispersal species needs sample sizes five times larger than current guidelines. Results show that minimum collection protocols should be customized for the target species, rather than commonly implemented "rules of thumb." It is possible to improve planning and implementation of conservation practice by quantitatively integrating current knowledge of plant biology, spatial distribution and genetics into collection design. This work is important and timely knowledge for managers and policy makers because: (1) optimizing when, where and how to sample will influence restoration and conservation success, and (2) limited resources in restoration ecology and rare species preservation demand effective, efficient investment.

126-REWILDING BRITAIN: INDICATORS FOR ECOSYSTEM FUNCTION COULD PROVIDE EFFECTIVE MEASURES FOR PRIORITISING SITES FOR WILDERNESS RESTORATION

Peter Hobson

Writtle College

Lisa BIBER-FREUDENBERGER, Center for Development Research, Department for Ecology and Natural Resources Management, University of Bonn, ; Monika HOFFMANN, Centre for Economics and Ecosystem Management, Eberswalde University for Sustainable Development, ; Pierre IBISCH, Centre for Economics and Ecosystem Management, Eberswalde University for Sustainable Development,

The recently established organisation, "Rewilding Britain", has stated in its vision a commitment to support initiatives to create at least 300,000 hectares of wilderness within the UK by 2030. Notwithstanding, many scientists and conservationists remain unconvinced because of what they perceive to be unrealistic objectives given the radical alteration to the countryside and the loss of all natural ecosystems in the UK. Furthermore, there is deep scepticism amongst scientists about the principles and evidence used to support wilderness conservation. Currently, wilderness is classified on the basis of size, intactness, biodiversity and limited levels of human activity. In this study indicators for ecosystem growth and function are used to determine potential areas for rewilding based on principles of ecosystem theory and non-equilibrium thermodynamics. Landscapes are analysed at local scale using plant functional traits and microclimatic surface temperature, and at macro-scale by adopting six global indices that include vegetation density, plant species and functional diversities, and carbon storage. The findings indicated 'semi-natural' woodlands and wetlands unmanaged for more than 50 years supported more stress-tolerant and competitive plants, and local temperatures were significantly attenuated when contrasted with human disturbed landscapes dominated by ruderal plant species. Above ground and soil biomass was also higher in the manage-release sites. A global map of ecosystem functionality indicated higher values for upland areas across the west of Scotland and also for patches of western sea-board hill land in Wales although many of these areas were under secondary woodland. Apart from the north-west of the country there was little evidence for ecosystems with high functional value in England. Combined with data for roadless areas the results of this study can provide valuable information for use in prioritising areas across the UK for rewilding.

THE LEGAL BACKGROUND AND GENETIC CONFLICT OF PRESERVING WALL LIZARDS IN CENTRAL EUROPE

Axel Hochkirch

Trier University

Joscha BENINDE, Trier University ; Ulrich SCHULTE, Trier University

The common wall lizard (*Podarcis muralis*) is listed on annex IV of the European habitats directive. Therefore, a strict protection regime must be applied across its entire European range. In Germany, the species naturally occurs along the rivers Rhine, Neckar and Moselle. However, intended introductions of this species by hobby herpetologists and non-intended translocation by transport systems (particularly rail traffic) has led to a large number of non-native populations outside the natural range of this species. Due to its legal status, compensation payments and translocations of (non-native) populations of this species took place, often with high costs (200,000 € for a translocation in Mainz). We studied the genetics of natural and non-native populations of the common wall lizard in Germany, using nuclear markers (microsatellites) and a mitochondrial marker (cytochrome B). Our aim was to compare genetic diversity of native and non-native populations and study the effects of non-native lineages on natural populations. For the latter purpose, we sampled 800 individuals from four cities in Germany, which are known to have a high density of the common wall lizard, two cities with only native lineages and two cities with both native and non-native lineages. We identified eight different source regions (mainly from Italy, France and the Balkans) of introduced populations. Mixed populations of native and non-native lineages showed a strong admixture despite the strong genetic differentiation of the lineages. The degree of hybridization between native and invasive lineages poses a serious threat to the native lineage. Our results show that a nonreflective application of the habitats directive could have negative consequences on regional biodiversity.

MIND THE GAP - PUTTING INVERTEBRATES ON THE CONSERVATION AGENDA

Axel Hochkirch

Trier University

Invertebrates are by far the most species-rich group of biota on earth. However, they are rarely considered in conservation practice, even though their contribution to biodiversity is sometimes acknowledged. The International Union for the Conservation of Nature (IUCN) aims at assessing the IUCN Red List status of 160,000 species by 2020, including a global target of 45,344 invertebrate species. Currently, a total of 17,218 species has been assessed for the Red List, but the

yearly progress is much too slow to reach the 2020 target. Red List assessments of invertebrates are mainly driven by the IUCN SSC Specialist Groups or by funded projects (e.g. the European Red Lists). Hence, there is a need for more Specialist Groups focusing on invertebrates and the identification of enthusiastic people, who are able and willing to lead such groups and provide data and knowledge for more Red List assessments. Furthermore, there is a need for better data sources, particularly concerning the geographic distribution of invertebrates. A better representation of invertebrates will assure a more comprehensive function of the IUCN Red List as a “barometer of life”, but it will also allow to identify priority species for conservation. The IUCN Red List status is an important criterion for several funding mechanisms and political decisions. Invertebrate conservation will thus profit from the voluntary involvement of entomologists and other invertebrate experts.

LAND-USE AFFECTS THE RATE AND PATTERN OF RANGE EXPANSION IN BRITISH MOTHS

Jenny Hodgson

University of Liverpool

Chris SHORTALL, Rothamsted Research ; Zoë RANDLE, Butterfly Conservation ; Tom OLIVER, NERC Centre for Ecology and Hydrology

There is widespread concern that habitat fragmentation exacerbates climate change threats to species. Models predict that species will fail to track the climate if habitat is too scarce or insufficiently connected. However, until now there is very little direct evidence on how the pattern of habitat is affecting expansion at species’ cool range margins. We analysed the colonisation events that have occurred in continuously monitored locations for 54 species of southerly distributed moths in Britain between 1985 and 2011. Whether or not a continuously monitored trap was colonised, and the time until colonisation, could be related to the baseline distribution of each species (1965-1985), the characteristics of landcover in-between the trap and the baseline distribution, and the landcover immediately around the trap. Continuously monitored locations were the light traps in the Rothamsted Insect Survey network. Baseline distributions were defined by combining Rothamsted data with the National Moth Recording Scheme database. When all species were analysed together, we found that woodland-associated species were on average expanding slightly more rapidly than other species, but only where there was a relatively high proportion of woodland in the landscape. Traps located in suburban areas were less likely to be colonised, even by “wider countryside” species (associated with gardens, parks or farmland). Wider countryside species were on average expanding faster, but non-woodland species were impeded through landscapes with high proportions of woodland. When we only analysed the 36

woodland-associated species, we found that range expansion rate was better predicted by a metric of landscape resistance calculated from the pattern of woodland, than by the simple proportion of woodland in the landscape. We conclude that habitat availability is an important factor controlling the rates of range expansion even for relatively mobile, non-threatened species.

ARE WE RESTORING ENOUGH? SIMULATING THE IMPACTS OF CLIMATE CHANGE, BOREAL FOREST MANAGEMENT AND RESTORATION ON FUTURE HABITAT SUITABILITY FOR A THREATENED WOODPECKER.

Anouschka Hof

Swedish University of Agricultural Sciences

Joakim HJÄLTÉN, Swedish University of Agricultural Sciences

Intensive forestry has altered and continues to alter boreal forest ecosystems. To mitigate negative effects of intensive management practices habitat restoration is often implemented, and it will likely increasingly be adopted in future to alleviate possible additional effects of climate change on ecosystems and their biodiversity. We simulated the effects of climate change and different management and restoration practices on the forest dynamics in boreal Sweden to assess the level of mitigation that is needed to allow viable populations of species in need of conservation. We focused on a large and long-running restoration project in Sweden that aims to restore forest ecosystems to allow the re-colonization of an umbrella species, the white-backed woodpecker (*Dendrocopos leucotos*), which is critically endangered in Sweden. Its protection may serve the protection of a range of other species. We found that whereas it may be relatively easy to fulfil certain goals in the project plan, such as acquiring high levels of dead wood, other goals, such as increasing the proportion of deciduous forest, require considerable more effort. Simulations are never perfect. We however show that forest landscape simulation models like LANDIS II can give valuable information with regard to the required levels of management or restoration that are needed to fulfil project goals. Their use may prevent the misuse of large amounts of time, effort and money when simulations can indicate whether or not current efforts are sufficient to fulfill project goals.

INVASIVE ANTS: CLIMATE CHANGE PREDICTIONS AND CONTROL PROSPECTS

Ben Hoffmann

CSIRO

Invasive ants among the world’s worst invasive taxa and are well known globally for their severe ecological impacts. The issue of invasive ants is so great because there are hundreds

of species being accidentally dispersed by people due to us having a poor history of preventing their spread, coupled with a poor history of eradicating them after they arrive. Opinion is that invasive ants are predicted to increase their influence with climate change. However, I will present recent work that has shown that this is not necessarily the case for most of the current suite of invasive species, and instead changing conditions may lead to a rise of a new suite of invasive ants. Similarly, species dispersing into new environments and experiencing climate change may also experience adaptive change. I will present recent work showing dramatic morphological change at a global scale for the African big headed ant, which will “set the scene” for what to expect for other species. Despite a very poor history of dealing with ant invasions, recently more than 100 eradications have been achieved, making ants one of the most eradicated taxa in the world. These successes are expected to increase exponentially in the near future. I will provide a broad overview of all ant eradications, detail what information, technologies and techniques are needed to improve ant eradications, and provide insight into what is predicted to provide the greatest change for all invasive species management, including ants, within 10 years.

INVASIVE ANTS AND ISLAND CONSERVATION: THE INCREASING NEED, MANAGEMENT RECORD, AND FUTURE PROSPECTS

Ben Hoffmann
CSIRO

Invasive ants among the world’s worst invasive taxa and are well known globally for their severe ecological impacts. Recently we conducted an analysis of the distribution of the six worst species on islands. We found 5,909 records on 711 islands globally, predominantly throughout the Pacific. We then crossed this information with the distribution of threatened species on islands that ants may affect to demonstrate the issue posed by invasive ants. We also compiled a database of ant eradication attempts since the banning of organochlorines. We found 244 eradication attempts, of which only 105 (43%) were successful. 63 successful eradications were on islands, but predominantly only on a portion of an island. We then demonstrated patterns that resulted in success or failure. We then compared all of these results with similar analyses of rodents, which are now the most eradicated taxa on islands. We identify clear differences and similarities in the distribution and management of ants and rodents, and specify what information, technologies and techniques are needed to improve ant eradications. We envisage that ant eradications on islands are likely to rapidly improve and increase in the near future as the management need becomes greater, and technologies improve.

156-BLOW FLIES AS URBAN WILDLIFE SENSORS

Constanze Hoffmann

Robert Koch-Institute

Kevin MERKEL, Robert Koch-Institute ; Pablo RODRIGUEZ, Parque Zoológico Buin Zoo ; Fabian Hubertus LEENDERTZ, Robert Koch-Institute ; Sébastien CALVIGNAC-SPENCER, Robert Koch-Institute

Detection of wildlife in urban areas is a challenging task. Conventional monitoring techniques based on e.g. direct observation, are faced with the limitation that urban wildlife is extremely elusive and shy. It was recently shown that blow fly derived DNA can be used to assess wildlife diversity in tropical rainforests. As blow flies are ubiquitous it is conceivable that this new molecular invertebrate-DNA based tool could also be used to detect wildlife in urban areas. However the overwhelming quantity of domestic mammal DNA sources could mask the presence of wildlife species in the urban context. To test whether it is possible to use blow flies for urban wildlife detection we captured blow flies in ten different parks in the city of Berlin, Germany. Their DNA was screened using various pan-mammal PCR assays with different combinations of blocking primers to maximize the ratio of wildlife/domestic animal sequence. The corresponding amplicons were sequenced using a MiSeq sequencing platform. As expected domestic animal sequences were dominant. Nevertheless wild mammal sequences could also often be retrieved. We conclude that it is indeed possible to use blow fly derived DNA for the detection of wild mammals in urban settings. This very cost-efficient tool may be used for quick scans of urban wildlife diversity and, possibly, for more in-depth study of species distribution and abundance across urban landscapes.

76-THE DIFFERENCE CONSERVATION MAKES

Michael Hoffmann

IUCN

Will DUCKWORTH, IUCN ; Katherine HOLMES, IUCN ; David P. MALLON, Manchester Metropolitan University ; Ana S.I. RODRIGUES, CNRS - Université de Montpellier ; Simon N. STUART, IUCN

Previous studies show that conservation actions have prevented extinctions, recovered populations, and reduced declining trends in global biodiversity. However, all studies to date have substantially underestimated the difference conservation action makes because they failed to account fully for what would have happened in the absence thereof. We undertook a scenario-based thought experiment to better quantify the effect conservation actions have had on the extinction risk of the world’s 235 recognized ungulate species. We did so by comparing species’ observed conservation status in 2008 with their estimated status under counterfactual scenarios in which conservation efforts ceased in 1996. We

estimated that without conservation at least 148 species would have deteriorated by one International Union for Conservation of Nature (IUCN) Red List category, including 6 species that now would be listed as Extinct or Extinct in the Wild. The overall decline in the conservation status of ungulates would have been nearly 8 times worse than observed. This trend would have been greater still if not for conservation on private lands. While some species have benefited from highly targeted interventions, such as reintroduction efforts, most benefited collaterally from conservation such as habitat protection. We found that the difference conservation action makes to the conservation status of the world's ungulate species is likely to be higher than previously estimated. Increased, and sustained, investment could help achieve further improvements.

210 A GLOBAL MAP OF ROADLESS AREAS BASED ON THE FREELY AVAILABLE OPENSTREETMAP DATA SET

Monika Hoffmann

Centre for Ecnics and Ecosystem Management, Eberswalde University for Sustainable Development, Eberswalde, GERMANY

Nuria SELVA, Institute of Nature Conservation, Polish Academy of Sciences ; Guy PE'ER, Department of Conservation Biology, Helmholtz Centre for Environmental Research - UFZ ; Pierre L. IBISCH, Centre for Ecnics and Ecosystem Management, Eberswalde University for Sustainable Development, Eberswalde, GERMANY

Mapping roadless areas on continental and global scales has recently become achievable through enhanced efforts of road mapping and the provision of easily accessible data platforms. Due to the fast and dynamic nature of road expansion, a global assessment ideally would become an ongoing and decentralized process, based on crowd-information sourcing and citizen science. Therefore, we used the OpenStreetMap data set to create a global map of roadless areas including all road categories. For the purpose of the study, "roadless areas" are defined as terrestrial areas that are not dissected by roads and whose boundaries are within at least 1 km to the nearest road. As expected, the highest concentrations of large roadless areas are found in the most remote places on the planet such as deserts, polar and boreal regions. Still, there are also considerably large roadless blocks in the tropics. In general, mapping quality in industrialised, densely roaded regions is better than in economically developing countries. In many tropical countries, this can easily lead to underestimating road impacts. Additional criteria are needed to reflect the critical role of roads in contributing to ecosystem degradation, directly and indirectly. In the poorest countries, precarious dirt roads can have a much higher impact on biodiversity than some paved roads in industrialised countries. In scarcely roaded regions in developing countries, roads often trigger more intensive and

less regulated pressures on biodiversity, which, in addition tends to be characterized by higher richness and uniqueness.

WHITE NOSE SYNDROME, WIND TURBINES, AND BATS OF THE DELMARVA PENINSULA

Aaron Hogue

Salisbury University

Andrew MCGOWAN, Salisbury University

Bats hibernating in or migrating along the Appalachian Mountains have been heavily impacted by White Nose Syndrome (WNS) and wind turbines, respectively. The extent to which these impacts extend to summer resident bats along the east coast of the United States is not fully known, particularly on the Delmarva Peninsula, which forms the eastern border of the nation's largest estuary, the Chesapeake Bay. Since bats are ecologically and economically important regulators of insect populations, including insect pests on agricultural lands (the peninsula's largest industry), it is important to understand what impact these emerging threats will have on local bats. With the recent expansion of WNS onto the peninsula, and several proposed wind turbine facilities, a peninsula-wide assessment of the bat fauna was urgently needed. We surveyed bats at 280 sites along 28 18 km driving transects across the peninsula. One transect was sampled per night June-August, 2015, starting a half hour after sunset on nights with no rain, temperatures above 10° C, and wind speeds below 20km/hr. Sampling sites were located 2km apart and surveyed for 12 minutes using a MiniMIC microphone extended 4 meters above ground, and connected to a tablet running SPECT'R software. An additional 23 sites were monitored in randomly selected habitats over night to compare results with transects. 4,448 bat passes were recorded in 248 hours of recordings, representing 8 species, the largest ever recorded on Delmarva. While most species were well-represented, only 16 passes could be attributed to the three *Myotis* species known to occur on the peninsula, none of which were *M. septentrionalis*, currently being considered for listing as endangered under the Endangered Species Act. This suggests the heavy mortality experienced by these bats from WNS in the region may have affected summer populations on the peninsula. Additional data on habitat selection and the potential impact of wind turbines will be discussed.

163. A RAPID INTRODUCTION TO ECOSYSTEM-BASED ADAPTATION AND ITS POTENTIAL ROLE IN CONSERVING EARTH'S BIODIVERSITY

David Hole

Conservation International

Ecosystem-based adaptation (EbA) is generally defined as "the use of biodiversity and ecosystem services as part of an

overall adaptation strategy to help people adapt to the adverse effects of climate change". Over the past 5 years interest in EbA has increased exponentially and it now draws on strong support from international bodies (such as the UNFCCC and CBD), to conservation and development organizations, to multi-lateral funding agencies. Indeed, it is increasingly being seen as a win-win for meeting both human adaptation needs and biodiversity conservation goals. However, although EbA has significant potential for reducing the continuing loss of biodiversity, conservation is not the principle goal of EbA – the goal is "to help people adapt". As such, EbA is usually implemented as the targeted management, conservation or restoration of an ecosystem (or ecosystem component) in order to maintain or restore the delivery of a specific ecosystem service(s), as a means of increasing the resilience of, or reducing the vulnerability of, a target group of human beneficiaries. Hence it is largely blind to the conservation value of the ecosystem stock. This has important ramifications for its potential to contribute to biodiversity conservation. We explore some of these ramifications and highlight why a significant focus on biodiversity should nevertheless be a key element of any EbA project. We then explore mangrove ecosystems as a case study to demonstrate the potentially significant role that EbA can play, both in helping people adapt to climate change and in providing a new pathway for conservation.

TROPHIC CASCADES FOLLOWING DISEASE-INDUCED DECLINE OF THE TASMANIAN DEVIL

Tracey Hollings

University of Melbourne

Hamish McCallum, Griffith University ; Menna JONES, University of Tasmania ; Nick MOONEY, Environmental Consultant

Infectious diseases of wildlife can have consequences beyond the species they infect. Tasmanian devil facial tumour disease is a host specific infectious cancer that continues to spread across Tasmania, with population declines of up to 90% in affected populations. The Tasmanian devil is the apex mammalian predator in Tasmanian ecosystems and its decline has the potential to cause trophic cascades, including mesopredator release and impacts on prey populations. Two independent lines of evidence, a spotlighting time series and surveys comparing sites with different extents of disease-induced devil decline, provide strong evidence that introduced feral cat numbers have increased concomitant with devil decline. There is evidence that mammal communities are increasingly dominated by invasive species, cascading effects of mesopredator release of cats on prey and decline of the native eastern quoll, a predator smaller than the cat. Further, toxoplasmosis, a parasite for which cats are the obligate definitive host, occurs in wallabies at higher prevalence where devils have declined. Effects on devil prey species are less

obvious, likely because of the influence of bottom-up factors such as food supply, but giving up density experiments show brushtail possums become bolder following devil decline. Tasmania maintains populations of at least four mammal species that are extinct on the Australian mainland because of feral cat and European red fox predation. Foxes were illegally introduced to Tasmania a decade ago, but remain at very low numbers. Disease induced devil decline in Tasmania threatens to cause increases in both cat and fox numbers, leading to declines or extinctions in native species. Tasmanian devils were widespread on the Australian mainland until about 5000 years BP. Our work suggests that reintroduction of disease free devils to the Australian mainland may produce biodiversity benefits beyond those to the devil itself, by suppressing introduced feral predators.

117 PRIVATE PROTECTED AREAS AND MARKETS IN CONSERVATION IN SOUTHERN CHILE

George Holmes

University of Leeds

This paper examines the diversity and complexity of initiatives labelled as market-based conservation, particularly expanding our ideas for what constitutes market-based conservation, and the implications this has for how we consider the perils and promises of this trend. It does so through an exploration of private protected areas - conservation areas owned and managed by NGOs, businesses, individuals and co-operatives - in southern Chile. Here over 300 private areas cover over 4% of land surface area, including large extensions of endangered habitat. They display a broad range of approaches to markets and making money, from businesses using ecotourism and carbon markets to generate profits to those funded by philanthropic largesse and which consciously minimise commercial activities. Yet all these areas have been made possible by government structures, particularly property rights and land market reforms, designed to foster investment in land. Ironically, these reforms were intended to foster the extractive industries and plantation forestry, but have been used by conservationists to buy land and prevent such exploitative uses. By using free markets in property, private protected areas can be considered a form of market-based conservation, even if they contain no other commercial activities. The paper argues that market-based conservation should be thought of not just in terms of how money for conservation is generated, or through creating incentives for pro-biodiversity behaviour, but through wider political and economic context in which they occur, such as property rights, government policies and broader social attitudes towards markets and conservation, and that our assessment of its perils and promises should reflect this.

WHO HAS CONTROL? ASSESSING THE SIGNIFICANCE OF SELF-DETERMINATION IN CONSERVATION

Danielle Holstein

University of Washington

With the shift to ecosystem-based management (EBM) there are increasing calls to assess how human wellbeing is related to ecosystem health and conservation success. Research in the social sciences suggests that self-determination, or the power and freedom to control one's life and one's choices, is a fundamental requirement for wellbeing, enabling independent economic decisions, cultural expression, lifestyle choices, and political participation. While there is growing documentation of the material and cultural benefits of ecosystem services, self-determination as a domain of human wellbeing has received less attention in ecosystem assessments. This paper discusses the significance of self-determination in the context of conservation and EBM, and models a method for assessing key dimensions of self-determination using measurable indicators. Self-determination can be conceptualized via a typology that accounts for how power and freedom operate at different scales (personal vs. widespread) and at varying levels of influence (daily life vs. political power). Based on an exhaustive literature review, over 50 potential indicators of self-determination relating to marine and coastal management of the US West Coast were evaluated according to predefined screening criteria. Top-scoring indicator categories included stakeholder participation in decision-making, formal co-management arrangements, and tribal rights and sovereignty. With self-determination as an example, this paper introduces a systematic and transparent method for selecting a suite of human wellbeing indicators to inform ecosystem-based management in a range of contexts. Ultimately, an understanding of self-determination suggests how the process of ecosystem assessment can itself improve wellbeing by ensuring that local stakeholders guide definitions of wellbeing, resources of interest, and the final selection of indicators.

WORKSHOPS 217 : PROPAGATION OF NATIVE TREES BY LOCAL COMMUNITIES IN THE FORESTS OF KETOU: A NEW CHALLENGE FOR HABITAT RESTORATION IN BENIN REPUBLIC

Alfred Hounnon

LIRDEF EA3749

Christian REYNAUD, LIRDEF EA3749

This work, supported by the Rufford Foundation, is a pragmatic, substantial and long lasting contribution to nature conservation. It aims at including the contributions of the stakeholders in the sustainable management of natural resources from a remnant forest in Ketou region (Benin

Republic). Ketou region has a long history of cultures combined with its biodiversity, including endemic plant species, concentrated in the unique Ewe-Adapklamey fragment forest. An exploration of available plants from this forest allowed to establish a preliminary list of useful tree species. So, knowledge of their current status would be updated and improved for conservation priority in Benin. In order to understand how the stakeholders can participate to the conservation activities, Farmer Field Schools known as a Group Extension Method based on adult educations method have been used to assess and take into account the expectation of local population. It consists to test an inexpensive Vegetative Propagation method, reproducible by local communities. We will present this group-based learning process and how it allows us to collect data from the current indigenous conservation practices. This study gives us an instance to understand how indigenous people can participate to the conservation function and the sustainable management of plant resources at local scales. It would be of the utmost interest if our project could beneficiate of collaborative Web tools and we will discuss the requirement to setting up.

THE POPULATION TRENDS OF EUROPEAN MIGRANT BIRDS: UNDERSTANDING THE DRIVERS ON BOTH THE BREEDING AND NON-BREEDING GROUNDS

Christine Howard

Durham University

Philip A STEPHENS, Durham University ; James W PEARCE-HIGGINS, British Trust for Ornithology ; Stephen G WILLIS, Durham University

Over recent decades a trend has emerged, whereby migratory species are experiencing more rapid population declines than their resident counterparts, a phenomenon increasingly being attributed to changes in climate. However, the relative contribution of climate and/or habitat changes on species' breeding and non-breeding ranges is contentious and has not been satisfactorily addressed to date. Here, we evaluate the relationship between changes in climate suitability across the breeding and non-breeding ranges and the long term population trends of 108 resident, short, and long-distance migratory species of European breeding birds. We demonstrate a striking relationship between recent changes in climate and trends in population sizes at a supranational level. Moreover, we identify significant variation in the relative importance of climate and habitat between a species' breeding and non-breeding grounds for determining population sizes and that the strength of these relationships varies between short and long distance migrants. With the current focus of conservation activity principally on these species' breeding grounds, our findings provide important insight into how to stem the decline of migrants.

DEMAND-SIDE APPROACH TO DELIVERING THE BENEFITS FROM ECOSYSTEM SERVICES

Caroline Howe

UCL

Georgina MACE, UCL

Ecosystem services (ES) are the biophysical processes of ecosystems that provide benefits for human well-being. Most ES assessments explicitly assume spatial and temporal connections between ES provision and beneficiaries. However, most ES are only consumed after input of natural, social and manufactured capital (conversion to benefits). To date ES research has focused predominately on the supply of ES, with little attention on the demand for the benefits they provide. ES projects for human well-being also often focus on achieving 'win-wins', despite the fact that many social, economic and ecological goals are competitive. Previous research has shown that there are a number of predictors for a trade-off but no generalisable profile of a win-win. In this paper we take a novel approach to ES research by focusing on demand for benefits produced, through looking at the trade-offs between benefits and their respective beneficiaries. Using systematic mapping of the literature from 2000 to 2013, we identified 1324 potentially relevant papers, 92 of which were selected for the review, creating a database of 231 actual or potential recorded ES trade-offs and synergies. Firstly, we looked at observed ES trade-offs curves across these multiple ES studies, at both the ES level and the benefit level. Secondly we explored the metrics of biodiversity that underpin these different benefits, using counterfactuals that explore how benefits alter under natural and managed ecosystems. We find that there are key thresholds and tipping points between different ES and benefits, as well as specific regions where trade-offs are more likely to occur, which often overlap with regions of high poverty. By looking at the biodiversity metrics underpinning these trade-offs it is possible to identify regions that are critical to maintaining the supply and flow of benefits and to prioritise areas for conservation or development.

99-CONNECTING PEOPLE WITH NATURE

Helen Hoyle

University of Sheffield

James HITCHMOUGH, University of Sheffield ; Anna JORGENSEN, University of Sheffield

What sort of designed urban planting makes the average person happy? Is the most biodiverse urban planting the least attractive to people or can designed urban planting that is attractive to people also be beneficial to 'wildlife'? How do the general public react to urban planting with an unfamiliar character which might be better adjusted to our warmer future? To answer these questions we surveyed 1403 members of the public using site – based questionnaires, whilst

walking through woodlands (n=13), shrub planting (n= 8) and herbaceous sites (n=10) of varying structure and species character in relation to the semi – natural vegetation of the UK. Semi – structured, in – depth interviews were then carried out with 34 of the questionnaire respondents. A model is proposed linking perceptions and preferences to planting stimuli, human socio – demographic factors and underlying values. 'Preference' in relation to the structure and species character of the planting is then explained in terms of both perceived attractiveness and potential to induce relaxation and well – being. The relationship between the perceived attractiveness and perceived biodiversity value of planting is explored. This research shows that ordinary people can appreciate diverse urban planting. Both perceived attractiveness and potential to induce relaxation and well – being were positively related to perceived biodiversity value of the planting. People can prefer planting which is better adapted to future climates, yet reactions were varied, complex and largely dependent on existing beliefs and values relating to climate change.

MONITORING WILD MAMMALS IN COUNTY DURHAM WITH A CITIZEN SCIENCE WEB PLATFORM

Pen-Yuan Hsing

Durham University

Steven BRADLEY, Durham University ; Vivien KENT, Durham Wildlife Trust ; Russell HILL, Durham University ; Mark WHITTINGHAM, Newcastle University ; Philip STEPHENS, Durham University

Changing land uses, the spread of invasive species and disease, and anthropogenic climate change have exacerbated the loss of habitat and biodiversity. Tackling these issues require effective ecological monitoring over large spatial and temporal scales. The ease with which such monitoring can be implemented varies among taxa. Many mammal-monitoring methods, such as track or scat counts, line transects, or mark-recapture studies, require intensive effort and are seldom employed over large scales. This is problematic, because good monitoring data are essential to managing these species of ecological, economic, and cultural importance. We developed a wildlife monitoring network, named Mammal Web, consisting of motion sensing camera traps, which are non-intrusive and need little user intervention. We started with a core set of monitoring sites established by student volunteers on Durham University grounds. To scale the network over a larger geographical area, we augmented our camera traps with those volunteered by citizen scientists in County Durham, U.K, a first for a citizen science website. Resultant photographs are uploaded to the Mammal Web website, where users can collectively classify the imaged fauna. To attract and retain citizen scientists, we are implementing (1) an achievement system based on user metrics such as the number of images classified, and (2) interactive graphs showing outputs from

the project. The achievement system could identify the most skilled users, who would be invited for advanced work such as resolving uncertain classifications, or classifying the age and sex of animals. Also, we are developing quantitative techniques based on mark-recapture or random-encounter models for deepening ecological understanding within the monitoring network. It is hoped that these efforts will provide Mammal Web with high scalability, and supplant existing wild mammal monitoring in the U.K., which is low intensity and reliant on direct sightings.

GAINS AND LOSSES FOR BIODIVERSITY IN THE LARGE-SCALE REFORESTATION UNDER CHINA'S GRAIN-FOR-GREEN PROGRAM: REGIONAL INSIGHTS FROM SW CHINA

Fangyuan Hua

Princeton University

Xiaoyang WANG, Kunming Institute of Zoology, Chinese Academy of Sciences ; Douglas W. YU, Kunming Institute of Zoology, Chinese Academy of Sciences ; Scott K. ROBINSON, University of Florida ; Ya TANG, Sichuan University ; David S. WILCOVE, Princeton University

China's Grain-for-Green Program (GFGP), among the world's largest PES programs, has established >20 million hectares of forest on former farmland and scrubland since 1999. The enormous scale of ensuing land cover change suggests potentially massive biodiversity implications, but our understanding of GFGP's biodiversity impacts and their determinant factors remains minimal. We aim to assess the biodiversity impacts of GFGP reforestation on farmland and understand factors determining such impacts in west-central Sichuan Province, a region with high biodiversity value that has undergone substantial reforestation under GFGP. In five habitat types involved on large scales in GFGP (farmland, mixed forest, eucalyptus forest, bamboo forest, and Japanese cedar forest) and in natural forest, we used point and transect count and fluorescent pan trapping to survey for bird and native bee biodiversity in summer and winter 2014. We combined metabarcoding techniques (for bee identification) with robust abundance modeling to estimate species abundance and richness. Our finding suggests that while the four types of reestablished forests do harbor forest-dependent bird and bee species not found on farmland, they support 30~70% fewer such species and 40~80% lower species abundance compared to natural forest. Open-habitat species associated with farmland are minimally represented in reestablished forests, suggesting a biodiversity tradeoff in converting farmland to forest habitats. Importantly, reestablished mixed forest harbors far more biodiversity than monoculture forests, accounting to ~60~80% of that found in natural forest. Given that households decision making in tree species choice and forest use crucially

determines the type of reestablished forest particularly between mixed and monoculture forest, our finding suggests the great, but not yet utilized, potential of GFGP to benefit biodiversity by incentivizing and influencing reforestation approaches.

#134 - NON-SPATIAL USES OF MARXAN AS A CONSERVATION PLANNING TOOL

Patrick Huber

University of California Davis

Symposium number 134 Marxan is a conservation planning tool used in a variety of reserve selection contexts. Typically these are spatially-explicit landscape assessments for the identification of a complementary set of reserves that address a full suite of conservation goals. However, the algorithm driving the tool is not inherently spatial in nature; it is a general optimization process. Therefore, it has potential uses for conservation planning in non-spatial contexts as well. Here I present two examples of the use of Marxan in such situations. The first is an effort to identify short lists of sustainability indicators for agricultural sourcing that address a wide array of sustainability issues. Each indicator was linked to the issues that it could be used to measure. Then the issues were treated as "species" and the indicators as "planning units". Marxan was used to reduce the total set of 2,064 indicators to 23-31 which fully covered the 369 issues, depending on the specifics of the scenario. This dataset of issues and indicators coupled with an optimization tool such as Marxan can then be used to identify small sets of indicators across a wide variety of sustainability assessment efforts. The second project used this approach to identify a potential plant palette for a riparian restoration site that would provide a wide variety of ecological resources. The 1.3 ha Lower American River Mile 0.5 Aquatic Riparian Habitat Enhancement Project in Sacramento, California, USA is an effort to restore 335 m of river to a historic riparian condition. We linked 172 native plant species to resources such as bloom periods, pollinator use, and bird use. Then, treating the plant species as planning units and the resources as species we identified suites of 32-42 species that could potentially provide the full set of resources at the site. These novel examples demonstrate the utility of Marxan in contexts outside those for which it was designed, and we believe could be replicated in many new ways.

THE LOIRE NATURE RESOURCES CENTER AS A RESEARCHERS - CONSERVATION PRACTITIONERS LINKING TOOL

Stéphanie Hudin

Fédération des Conservatoires d'espaces naturels

The Loire nature program has since 1992 given great opportunity to natural areas practitioners for working together on wider scale conservation projects. At the end of the second phase of the program (2006) they identified a need to collect non edited literature, know-how and to present their work in a common project. The natural areas Conservancies Federation was a partner of the coordination from the start and initiated a project of a resources center. It collects the relevant literature, reports and documentation of all sorts, to inform the community of managers in the Loire catchment. The meta data presented in a single website helps the collectivities to find the information on the wetland and biodiversity of the basin. The associated team also organizes events to link the research and practitioners communities, focusing on certain topics of common interest: e.g. natural heritage, protocols and indicators, sedimentary transport and alluvial forests. The resources center has been involved in following research project on the ecosystems, as a bridge for collaboration as well as a diffuser of the results. It has also been included in research projects to coordinate the work with the practitioners, some research results being translatable in change of practices by the managers, or tool to prioritize actions. As a tool mainly aimed at practitioners and with more than 1500 contacts registered to the newsletter, is it still little known by a wider audience. The fourth phase of the Loire nature program (2015-2020) will give new opportunities to reach the public and facilitate the link with the research.

NEAR REAL-TIME LAND CHANGE AND PHENOLOGY MONITORING USING A DATA PROCESSING MIDDLEWARE: EXAMPLES FROM AFRICAN FOREST CONSERVATION AREAS

Christian Huettich

Friedrich-Schiller-University Jena

Jonas EBERLE, Friedrich-Schiller-University Jena ; Ralph ADEWOYE, Friedrich-Schiller-University Jena ; Victor ODIPO, Friedrich-Schiller-University Jena

Earth Observation data are available around the globe and can be used for a wide range of applications. Dependent on the spatial resolution local and regions conservation projects can facilitate from global Earth observation (EO) data. A lot of applications are reasonable with the use of vegetation time-series information based on EO data. To support local stakeholders in the usage of information from space existing barriers – especially in data processing – need to be limited. Therefore a web-based earth observation data middleware infrastructure (Earth Observation Monitor - EOM) provides automated and operational time-series access and analysis of several EO data. Data is being automatically downloaded and processed. Time-series analysis tools (breakpoint and trend

detection, phenological analyses) were integrated to extract Essential Biodiversity Variables (EBV) relevant information (phenology, habitat change). Two EOM applications of land cover change and vegetation phenology monitoring are demonstrated for afro-montane forests in Nigeria and the savanna ecosystem of the Kruger National Park in South Africa. Time-series data from NASA MODIS sensor from the year 2000 to 2014 were analysed using the Break For Additive Season and Trend (Bfast) model to detect deforestation patterns of the forests of the Mambilla Plateau in Nigeria. Results from the web based EOM analysis showed that deforestation started in 2002 ongoing from the surrounding settlements. A retrospective survey of the deforestation patterns could be realized using web-processing techniques of MODIS time series. Applications of phenological monitoring of savanna vegetation types are demonstrated for different disturbance regimes in the Kruger National Park in South Africa. This presentation is linked to the round table discussion Essential Biodiversity Variables for Conservation needs (147) where the presenting author is involved in.

#134: STRATEGIC CONSERVATION PLANNING FOR THE POLAR REGIONS

Falk Huettmann

Uni of Alaska Fairbanks

The polar regions are essential for mankind and the globe. Three Poles exist (Arctic, Antarctic and the Hindu Kush-Himalaya), and the maintenance of (cold) temperature unites them across borders. Here I show a refined Strategic Conservation Planning run how areas relevant for ice and world temperature can be maintained and optimized, and be put onto the global agenda. Based on Marxan and OpenGIS I use 'biodiversity' as one metric for assessment and success of the model runs. High latitude and altitude show as focus areas, but also the ocean shelf region play a role. While the human population is not well included yet, together with other stakeholders and socio-economic data, such gaps are to be filled in subsequent efforts involving agencies and NGOs. The current state of the poles shows a striking disconnect with the global community, and which is to be overcome further.

HOW HAS CARRYING CAPACITY OF PANTHERA TIGRIS CHANGED FROM 2008-2013 IN BARANDABAR CORRIDOR FOREST ? A PREY SURVEY ANALYSIS OF P. TIGRIS IN THE BUFFER ZONE OF CHITWAN NATIONAL PARK IN SOUTHERN NEPAL.

Audra Huffmeyer

University of Michigan

Chitwan National Park (CNP), in southern Nepal, is home to one of the highest population densities of Royal Bengal tigers

(*Panthera tigris*). Isolation of tigers within CNP threatens the future of this species. Thus, a bufferzone, Barandabar Corridor Forest (69 km²), was created to provide additional habitat. The goal of this study is to estimate the current carrying capacity of tigers in Barandabar Corridor Forest and determine how carrying capacity has changed from 2008-2013 in order to better understand how tigers use the buffer zone and if the bufferzone is important for tiger conservation. Since the local people claim forest quality has improved over time, I hypothesized there will be an increase in prey abundance each year and an increase in tiger carrying capacity each year. Ungulate survey data was collected each spring from 2008-2013 and analyzed using Program DISTANCE 5 to estimate ungulate densities. Data analyses revealed Barandabar Corridor Forest is, currently, able to support three adult tigers and from 2008-2013 the carrying capacity of Barandabar Corridor forest increased by one whole tiger. The results of this study are identical with the 2010 national camera trap data, which revealed three adult females occupy the bufferzone

CAN COCOA IMPROVE CONSERVATION OUTCOMES? ASSESSING THE AVIAN DIVERSITY OF A TROPICAL FOREST/AGRICULTURE LANDSCAPE IN WEST AFRICA

Mark Hulme

RSPB Centre for Conservation Science

Fiona SANDERSON, RSPB Centre for Conservation Science ;

Juliet VICKERY, RSPB Centre for Conservation Science

Agricultural landscapes in the tropics often incorporate or lie alongside tropical forest, a declining habitat of high biodiversity value. Wildlife populations may be dependent on habitat connectivity between and around forest patches and assessments of wildlife in forest and associated human-altered landscapes can indicate which land uses might result in improved connectivity. We present findings from the first stage of a three year project aimed at determining the impact encouraging cocoa production might have on wildlife in and around the Gola Rainforest National Park (GRNP) in Sierra Leone, part of the Upper Guinea Forest Ecosystem, a top priority region for conservation due to high levels of endemism. GRNP consists of three forest blocks making connectivity particularly important and we must also find win-win solutions for wildlife and the very poor human population, which benefits from cocoa as one of the few sources of income locally. Cocoa may represent a better habitat for wildlife than other agriculture, often requiring less tree-felling activity. We investigated how best to quantify avian diversity across habitats, from slash-and-burn agriculture, active and abandoned cocoa, community forest outside GRNP and forest inside GRNP, using bird point count data collected between 2013 and 2014. We estimated encounter rate by habitat for each bird species and grouped these by forest dependency to compare between habitats using geometric means. We found

that forest dependency can highlight differences between GRNP and human-impacted habitats whilst differences between human-impacted habitats might be better described using variations in use by generalist species. The greater use of slash-and-burn by generalists suggests that this may not represent a good substitute habitat for forest. We finish by discussing some possible impacts of the Ebola outbreak on conservation and agriculture in West Africa.

LANDSCAPE GENETICS OF GREY WOLVES AT THE RANGE EDGES IN CENTRAL EUROPE

Pavel Hulva

Charles University in Prague

Barbora BOLFÍKOVÁ, Charles University in Prague ; Vendula Woznicová, University of Ostrava ; Milena SMETANOVÁ, Czech University of Life Sciences ; Miroslav KUTAL, Mendel University Brno

Local extinctions and range fragmentation of the grey wolf, followed by recent re-expansion is raising many controversial conservation issues. At the range edges of re-expanding populations, many biological processes affecting fitness may play the role. For example, due to recurrent bottlenecks, founder effect and drift, reduction of genetic variation may occur. Loss of heterozygosity may result in inbreeding depression, Allee effect in low density populations may affect reproduction success. Hybridization with feral dogs and introgression of "domestic" alleles can affect the species as well. These phenomena may be partly compensated by high mobility and gene flow typical in large carnivore populations, however, it may prevent evolution of local adaptations as well. These issues are especially pronounced in Central Europe. We describe the genetic structure of the species within this region using nuclear microsatellites and mitochondrial sequences. This region is connecting relatively large population in the east and fragmented ones in the west and may serve as a bridge between the East-European and Balkan populations via Carpathian mountains. Also different ecological forms of the species including lowland and mountain ecotypes are present here. Moreover, wolves of both mitochondrial haplogroups, which possibly represent lineages with different ecology, can meet in this region, providing further options for increasing of the genetic variability. Central Europe thus represents a diversity hotspot and a crossroad of potential dispersal corridors of grey wolves with urgent need of respective conservation management.

IMPACTS OF NITROGEN ADDITION ON PLANT BIODIVERSITY IN MOUNTAIN GRASSLANDS DEPEND ON DOSE, APPLICATION DURATION AND CLIMATE: A SYSTEMATIC REVIEW

Jean-Yves Humbert

University of Bern

John DWYER, The University of Queensland ; Aline ANDREY, University of Bern ; Raphaël ARLETTAZ, University of Bern

Although the influence of nitrogen (N) addition on grassland plant communities has been widely studied, it is still unclear whether observed patterns and underlying mechanisms are constant across biomes. In this systematic review, we use meta-analysis to investigate the influence of N addition (here referring mostly to fertilisation) upon the biodiversity of temperate mountain grasslands (including montane, subalpine and alpine zones). 42 studies met our criteria of inclusion, resulting in 134 measures of effect size. The main responses of mountain grasslands to N addition were increases in phytomass and reductions in plant species richness, as observed in lowland grasslands. More specifically, the analysis reveals that negative effects on species richness were exacerbated by dose (ha⁻¹ year⁻¹) and duration of N application (years) in an additive manner. Thus, sustained application of low to moderate levels of N over time had effects similar to short term application of high N doses. The climatic context also played an important role: the overall effects of N addition on plant species richness and Shannon index were less pronounced in mountain grasslands experiencing cool rather than warm summers. Furthermore, the relative negative effect of N addition on species richness was more pronounced in managed communities, and was strongly negatively related to N-induced increases in phytomass. Altogether, this review not only establishes that plant biodiversity of mountain grasslands is negatively affected by N addition, it also demonstrates that several local management and abiotic factors interact with N addition to drive plant community changes. This synthesis yields essential information for a more sustainable management of mountain grasslands, emphasizing the importance of preserving and restoring grasslands with both low agricultural N application and limited exposure to N atmospheric deposition.

SYMPOSIUM #20: TRACKING TECHNOLOGIES AND GREAT APE TRANSLOCATION: CHALLENGES AND POTENTIALS

Tatyana Humle

Durrell Institute of Conservation and Ecology, School of Anthropology and Conservation, University of Kent
James ROBINS, Tabin Orangutan Project, Tabin Wildlife Reserve

Great ape rehabilitation centres across Africa and Asia continue to witness an increase in residents, often orphans of the bushmeat and pet trade or victims of people's intolerance towards sharing resources and space with their closest living relatives. As wild populations decline, releasing individuals back to the wild is increasingly perceived as a viable conservation option. However, post-release monitoring

can oft be challenging, and information on predictors of rehabilitation and release success remain scarce. Tracking technologies can provide an effective means to facilitate post-release monitoring; however, several factors challenge their application and usage across great ape species and different habitat types. This paper aims to review different systems used or piloted to date among great apes and their advantages and disadvantages. Lessons will be drawn especially from the Tabin Orangutan Project, Sabah, Malaysia and the Chimpanzee Conservation Center (CCC). The CCC is the only sanctuary caring for chimpanzee orphans in Guinea, West Africa and has released 16 rehabilitants since 2008 in the High Niger National Park where it is located. Post-release monitoring of released chimpanzees at the CCC involves distance monitoring using simple VHF and/or ARGOS and GPS store-on-board radio collars. GIS data generated has yielded useful information on release individuals' social dynamics, habitat preferences, day and home range use. Tabin was the first field project to trial implanted VHF radio transmitters developed at the University of Vienna in 2009. This new method for relocating reintroduced individuals has to date enabled behavioural data collection on nine orphaned orangutans. However, implants suffer from reliability and range issues. Our results highlight the costs and benefits of different tracking technologies, species-specific challenges, and the scope and importance of developing novel systems for effective post-release monitoring of great apes.

EFFECTS OF PASTURE BASED DAIRY FARMING ON GRASSLAND BIRD SPECIES IN SOUTHWEST MICHIGAN, USA

Lindsay Hunt

Michigan State University
Brian MAURER, Michigan State University ; Gary ROLOFF, Michigan State University

Changes in land use, agricultural practices, and the subsequent reduction of mosaic grassland, which vary spatially and temporally in structure, have resulted in dramatic and range wide population declines of grassland birds. These grassland species have exhibited more substantial and continuous population declines than any other behavioral or ecological guild. To understand the impact of agricultural practices, we investigated if grassland bird communities differed on dairy pastures and grassland fragments and if vegetation structure and composition contributed to bird community differences in southwest Michigan, United States. Rather than relying on bird counts, we created utilization distributions to analyze these bird communities. Correspondence analysis indicated that pasture and grassland bird communities differed. Based on this analysis, specific species were shown to be more strongly associated with dairy pastures or grassland fragments. Canonical correlation analysis confirmed that vegetation structure and composition contributed to variation in species

distributions, suggesting that the species-specific associations found in the correspondence analysis were at least partially due to the vegetation structure of the dairy pastures and grassland fragment. Species-specific models indicated that some grassland birds were associated with unique vegetation characteristic. We concluded that species-specific habitat requirements are generally fulfilled through mosaic grasslands and that both grasslands and agriculture fields should be managed to maintain mosaics vegetation structure that varies spatially and temporally in order to maintain a diverse community of grassland bird species.

REINTRODUCING TASMANIAN DEVILS TO MAINLAND AUSTRALIA CAN RESTORE TOP-DOWN CONTROL IN AREAS WHERE DINGOES HAVE BEEN EXTIRPATED

Daniel Hunter

University of New South Wales

Mike LETNIC, University of New South Wales ; Thomas BRITZ, University of New South Wales ; Menna JONES, University of Tasmania

Loss of strongly interactive species, particularly large carnivores, is a global phenomenon that can be a catalyst for species extinction and ecosystem degradation. Restoring missing ecological interactions by reintroducing locally extinct or surrogates for extinct species has been mooted as an approach to restore degraded ecosystems. Australia's apex predator, the dingo, is subject to population control in order to prevent attacks on livestock. Dingo control has been linked to ecological cascades evidenced by irruptions of herbivores and introduced mesopredators and declines of small and medium mammals. Maintenance of dingo populations is untenable for land managers in many parts of Australia due to predation on livestock. However, it may be possible to fill the apex predator niche with the Tasmanian devil which has less impact on livestock. Devils once occurred throughout Australia, but became extinct from the mainland about 3000 years ago. To explore the feasibility of reintroducing devils to mainland Australia we used a species distribution model (SDM) and fuzzy cognitive mapping (FCM) to determine if suitable climatic conditions for devils exist and predict the effects of devil reintroduction, respectively. Based on devil distribution in Tasmania, our SDM indicates suitable areas for devils exist in south-eastern Australia. In our FCM we tested ecosystem responses to predator control scenarios by manipulating the abundances of devils, dingoes and foxes. Our FCMs showed devils have cascading effects similar to, but weaker than those of dingoes. Devil introduction was linked to lower abundances of invasive mesopredators and wallabies. Small and medium mammals and understory vegetation increased with devil introduction. However, threatened species vulnerable to fox predation benefited little from devil introduction in our

simulations. Our study suggests that reintroducing ecological surrogates for apex predators can yield benefits for biodiversity conservation.

101 AN INTRODUCTION TO CONSERVING SMALL NATURAL FEATURES WITH LARGE ECOLOGICAL ROLES

Malcolm Hunter

University of Maine

Many places have small natural features that are far more important for maintaining biodiversity or providing ecosystem services than their size would indicate, thus making them keystone elements in landscapes. Examples include springs in a desert, rock outcrops, and temporary pools and waterways. The importance of some of these features, most notably riparian zones, has long been recognized. In other cases, our recognition of their role is just emerging: e.g., caves that harbor large bat colonies known to effect widespread control of insect pests. Even single large, old trees have disproportionate value. A diverse set of conservation tools has emerged to conserve these features, but these tools lack strategic coordination and ecological coherence. These landscape elements arguably are too small and scattered to be effectively managed at the usual scale of ecosystem management. Furthermore, the usual tensions between private property rights and public rights to environmental protection are exacerbated in these cases by a spatial mismatch between regional accrual of beneficial services and local costs of protection. Nevertheless, small natural features present novel opportunities because they can usually be protected while allowing traditional activities such as forestry, fishing, and grazing to continue nearby and they are often owned by a single landowner, thus avoiding difficult multi-landowner coordination. We will examine seven examples of these features, asking: 1) why are these features important, both ecologically and economically; 2) what are the current management challenges; and 3) what are some innovative approaches to conserving these features. We will then detail one emergent example of an innovative approach to conserving small features and, finally, take a synthetic look at the socio-economic issues that underlie their conservation.

WAITING TO SPEND CAN BE AN OPTIMAL STRATEGY, EVEN IN A CRISIS DISCIPLINE

Gwenllian Iacona

University of Queensland

Michael BODE, University of Melbourne ; Hugh POSSINGHAM, University of Queensland

Biodiversity conservation is a crisis discipline, plagued by increasing threats and chronic funding constraints. We explore the consequences of conservation organizations

reacting to this state of crisis by rushing to spend money as soon as possible after they secure it. "Front-loading" of spending on conservation goals is understandably common because agencies want to address imminent threats. Rapid spending may also be driven by funding sources' demands for demonstrable outcomes within a few years, and conservation agencies desire to use successful projects as justification for further funding. We demonstrate that this approach may not always be the best strategy for promoting conservation outcomes. Waiting to spend has a range of benefits that can justify conservation inaction under the right conditions. Delays allow for time to invest in capacity building or to leverage additional money. We developed a theory of conservation investment that outlines the costs and benefits of two manager options: spend now or invest to spend later. Our modelled system allows manager actions to counteract declining biodiversity decreases with time but also includes the potential for available funds to increase if spending is delayed. We find that waiting to spend can be the optimal strategy, regardless of interest rate, if funding is limited and the regional biodiversity decline is not instantaneous after local degradation. The optimal timing of spending represents a balance between the rate at which conservation funds appreciate in value (e.g., through interest rates), and the rates of biodiversity decline. Competing rates of biodiversity decline and potential funding increase are present in many systems, but we illustrate an application where restoration can counteract an extinction debt in forest dwelling birds. We show that with feasible interest rates, greater conservation outcome can be achieved by front-loading only a small proportion of available funds.

210 WHERE THE ROADS DON'T GO: ECOLOGICAL CHARACTERISTICS AND PROTECTION STATUS OF THE WORLD'S ROADLESS AREAS

Pierre L. Ibisch

Centre for Ecomics and Ecosystem Management, Eberswalde University for Sustainable Development

Monika HOFFMANN, Centre for Ecomics and Ecosystem Management, Eberswalde University for Sustainable

Development ; Nuria SELVA, Polish Academy of Sciences

; Lisa BIBER-FREUDENBERGER, Center for Development Research, Department for Ecology and Natural Resources

Management, University of Bonn ; Guy PE'ER, UFZ - Centre for Environmental Research, Dept Conservation Biology ; Vassiliki

KATI, Department of Environmental & Natural Resources

Management. University of Patras ; Dominick A. DELLASALA,

Geos Institute ; Mariana VALE, Ecology Department, Federal University of Rio de Janeiro ; Stefan KREFT, Centre for Ecomics

and Ecosystem Management, Eberswalde University for

Sustainable Development ; Peter R. HOBSON, Centre for Ecomics and Ecosystem Management, Writtle College

We present the first comprehensive global assessment of roadless areas (excluding Antarctica and Greenland), based on OpenStreetMap data, that revealed almost 600,000, mostly very small patches of roadless areas (e.g., mean patch size in Europe is 26.5 km² vs. >500 in Asia). Following the 'anthromes approach' of land classification (Ellis et al. 2010), worldwide, 26% of the roadless areas are associated with 'uninhabited or sparsely inhabited treeless and barren lands,' 21% correspond with 'natural and remote semi-natural woodlands,' and just 17% are 'wild woodlands.' Roadless areas were also recorded for cultural landscapes including a third of the world's rangelands, suggesting the correlation between roadless areas and naturalness is not consistent. For the biomes, 'Tundra,' 'Rock and Ice-Covered' regions are almost 100% roadless, whilst 'Temperate Broadleaf and Mixed Forests' record lowest values of <40%. In the Tundra also a relatively high share of roadless areas are strictly protected (10% IUCN I or II). In comparison, in 'Tropical Moist Broadleaf Forest' around 6% and in 'Temperate Broadleaf and Mixed Forests' less than 2% of the roadless areas are strictly protected. In general, protection efforts do not seem to give special attention to roadless areas. Protection coverage of roadless areas is particularly low in Asia and Africa (2.5 and 3.9%, respectively). The detailed analysis of land cover and biodiversity values as well as protection coverage of roadless areas provides concrete guidance to global conservation priority-setting and action.

ADAPTATION OF OASIS OWNERS TO THE ERG CONSTRAINTS, AN ANCIENT PROCESS OF STRUGGLE AGAINST SAND DUNE CASE STUDY OF TAGHOUI OASIS - SOUTHERN LIMITS OF THE GREATEST WESTERN ERG

Salem Idda

Laboratory of Environment, Energy and Information Systems LEESI, university of Adrar

Hamidi MANSOUR, Laboratory of Géo-ressources, Environment and hazards Earth Sciences faculty, University of Oran

Considered as one of the largest stretches of sand in the world, the Greatest Western Erg covers a large areas of the south-western part of Algeria. Despite multitude constraints it poses to through and operate its surfaces, farmers were able to adapt with these conditions and to settle on its southern border. This installation, which began since many centuries, is conditioned by the mastery of struggle against the sand dunes. The choice of these sites for the occupation results of hydrogeological conditions characterized by groundwater found less than 1 meter deep, it is the Erg water table which is easy to use in inter-dune areas and allows a culture without irrigation. In parallel, a huge job to be carried out during the year to fight

against the silting of cultivated land. In this context we have tried to schematize the process of creating an oasis in this hyper-arid area, without using technical means and modern equipment. The choice of our oasis is mainly based on the possibility of finding a model that can be used to improve the presentation and diagnosis of this oasis system. Our work was based on a survey together with the field observation that allowed us to highlight the steps for creating the oasis of Erg, this creation is accompanied by three types of fight against sand dune siltation: dredging that lasts along the quiet period of the year, mechanical control by the dune-affreg and biological control through the implementation of the palm and other crops in the form of strata. It is through these control methods, depend on a very specific socio-economic organization, that oasis of Erg could resist the centuries.

CAN AMPHIBIANS BE USED AS UMBRELLAS FOR BIODIVERSITY CONSERVATION IN PONDS?

Christiane Ilg

Hepia, University of Applied Sciences and Arts Western Switzerland

Beat OERTLI, Hepia, University of Applied Sciences and Arts Western Switzerland

Amphibian decline led to worldwide conservation efforts, including the prioritization of sites for their protection. These sites could also contribute to the conservation of other freshwater taxa. Our study aimed to test whether amphibians could act as a potential umbrella for biodiversity in ponds, a particular type of freshwater ecosystem often characterized by a rich and diverse fauna and flora. We assessed the role of amphibians as surrogate for dragonflies, aquatic beetles, gastropods and aquatic plants in 89 ponds belonging to the Swiss amphibian breeding sites of national importance. Cross-taxon correlations in species richness and conservation values between the amphibians and the four other taxonomic groups were low in the studied ponds. Significant but weak congruence in community composition was found between the amphibians and the dragonflies, aquatic beetles and plants. The use of amphibians as surrogate for pond biodiversity is therefore questionable. Further, some ponds of low interest for amphibian conservation were important for the other freshwater taxa. A global pond biodiversity conservation strategy should therefore also consider ponds poor in amphibians. Furthermore, we suggest considering several taxonomic groups both for pond biodiversity evaluation and selection of sites for biodiversity conservation.

24: SUSTAINING THE USEFUL LIFE OF NETWORK GOVERNANCE: LIFE-CYCLES AND DEVELOPMENTAL CHALLENGES IN WATERSHED PARTNERSHIPS

Mark Imperial

University of North Carolina Wilmington

Governance networks for large landscape conservation are important because they are used to make collective decisions, set shared policies or priorities, improve coordination, and find new ways for members to productively work together. This paper focuses on the dynamic nature of governance networks reflected by the way they form, disappear, or change in response to new programs, problems, capacities, funding opportunities, and leaders. This paper presents a 4-stage life-cycle model is used to describe the cluster of challenges confronting network members when designing and sustaining healthy and useful governance processes. The model is then used to contrast the development of governance networks in 4 watersheds in the United States – Delaware Inland Bays, Narragansett Bay, Tampa Bay, and Tillamook Bay. These cases demonstrate that advice related to sustaining healthy and useful network processes must consider where the network is in its developmental process. The concept of a healthy and useful life is draws attention to the constant nurturing that network processes require. The cases also demonstrate that while some networks are designed to endure for long periods of time, this is not always the case. Networks, like other organizational forms are a functional enterprise and have a useful life. When the useful life has passed, it is time to disband, re-orient, or re-create the network to allow its resources to be redeployed in more productive public purposes. Just as we believe that network processes are best left to develop at their own pace, they should also be allowed to die when their useful life has passed. This frees up scarce network resources that can be deployed to better address landscape conservation problems.

EFFECTS OF HABITAT FRAGMENTATION ON THE DIVERSITY OF INSECT PARASITOIDS

Diego Inclán

University of Padova

Pierfilippo CERRETTI, University of Padova ; Lorenzo MARINI, University of Padova

Habitat fragmentation is one of the main drivers affecting parasitoid diversity. Although many empirical and theoretical studies have elucidated the effects of habitat fragmentation on the third trophic level, little attention has been paid to the impacts of this driver on more generalist groups of non-hymenopteran parasitoids. Here, we used the highly-diverse group of tachinid flies as an alternative model to test the effects of landscape fragmentation on insect parasitoids. Specifically, we evaluated the relative importance of habitat area and connectivity losses and their potential interaction on tachinid diversity, and we tested whether the contribution of different semi-natural habitats to the local tachinid community

composition in the agricultural matrix changes according to landscape composition. Our results demonstrate the negative effect of habitat loss on the diversity of tachinid parasitoids, but the strength of this effect depends on the degree of habitat connectivity as the processes of habitat loss and loss of connectivity significantly interacted. This suggests that management practices aimed to mitigate the negative effect of habitat loss at the local scale need to consider the surrounding landscape. Specifically, the conservation of habitat connectivity needs to be particularly considered in landscapes with small remnant habitats. In addition, our results demonstrate that the community of tachinids was affected not only by the proportion of semi-natural habitats in the landscape, but also by the specific type of semi-natural habitats. Therefore, strategies to conserve semi-natural habitats in agricultural landscapes needs to take into account the area, connectivity and type of habitats.

117-IMPACTS, OPPORTUNITIES AND CHALLENGES OF USING MARKET BASED MECHANISMS FOR SECURING CONSERVATION OUTCOMES: WHEN, WHERE AND WHY DO THEY WORK, FAIL OR LAND SOMEWHERE IN BETWEEN?

Jane Carter Ingram

Wildlife Conservation Society

Increasingly, the use of market-based approaches for securing biodiversity and ecosystem services is viewed as critical for meeting global conservation funding needs. Many observers maintain that market based approaches may be more efficient than other conservation tools for meeting biodiversity and ecosystem protection goals. Thus, in recent years, multiple market-based instruments, such as Payments for Ecosystem Services (PES), nature-based enterprises and biodiversity offsets, have been implemented to help conserve biodiversity and ecosystem services (BES). Yet, the interest in using such approaches may have outpaced scientific understanding on the effectiveness of different market-based instruments for conserving various aspects of biodiversity and/or enhancing specific ecosystem functions, especially in many tropical, developing countries where these mechanisms have high potential for reconciling the tradeoffs between conservation and economic development. Because of these knowledge gaps, a paucity of guidance exists on the types and combinations of market-based mechanisms that are most useful for achieving conservation goals in different social, environmental and economic contexts. Thus, it's important to examine how well various market-based instruments work for conserving biodiversity and ecosystem services across a range of conditions. This research reviews and evaluates market-based instruments such as PES, nature-based enterprises and

biodiversity offsets and asks: 1) what is the state of knowledge related to the effectiveness of market-based instruments for conserving various components of biodiversity and enhancing different ecosystem services; 2) how are positive or negative impacts on BES measured; and 3) under what conditions do different mechanisms effectively conserve BES? From this analysis, we will identify major challenges and opportunities that should be addressed to better leverage market-based instruments for achieving conservation outcomes.

INDIGENOUS COMMUNITIES IN THE EASTERN HIMALAYA, THEIR PERCEPTIONS AND ADAPTAION STRATEGIES TO CLIMATE CHANGE

Tenzing Ingty

University of Massachusetts, Boston

Kamal BAWA, University of Massachusetts, Boston

Studies in the Himalayas indicate that climate change has significantly impacted biodiversity and the indigenous communities of the region, and that they have been actively adapting to the cascading impacts of climate change. Although there is limited scientific data on climate change on the Himalayas, there is a wealth of information in the form of traditional ecological knowledge (TEK) of the people of the region, based on their observations, perceptions and coping strategies over the years. We used an interdisciplinary approach complementing participatory tools with ecological plots and remote sensing, in the Lachen and Lhonak valleys of the Indian eastern Himalayas to assess local perceptions and adaptations to climate change. Their observations were very detailed and provided numerous insights into local concerns. Additionally, we were able to validate these perceptions using vegetation plots and geographic information systems (GIS). The data clearly suggests that local people have been experiencing changes in their climatic conditions and their resource landscape, including their grazing pastures and agriculture. We also documented their response and their adaptation strategies, particularly adaptation strategies implemented by their traditional governing institution the Dzumsa. The study suggests that indigenous people have much to offer to the regional and global discourse on and strategies to address climate change. It is important that such local perceptions, adaptations, responses and solutions are kept in mind, while also being inclusive of traditional institutions, to effectively develop and implement adaptation and mitigation strategies.

PEOPLE, TIGERS AND THE SUNDARBANS: EXPLORING THE HUMAN DIMENSIONS OF HUMAN-TIGER CONFLICT IN BANGLADESH.

Chloe Inskip

Chester Zoo

Zubair FAHAD, WildTeam ; Thomas ROBERTS, University of Surrey ; Douglas MACMILLAN, University of Kent

The negative impacts of endangered species, such as tigers (*Panthera tigris*), on people can be financially and emotionally devastating. Likewise, local communities' low levels of tolerance for these species can undermine conservation efforts and impact species presence and persistence. Across tiger range countries, rapid human and livestock population growth, increasing rates of habitat conversion, and widespread poverty and natural resource dependence, mean that even small increases in tiger populations can significantly increase negative human-tiger interactions and (further) reduce local tolerance for the species. Effective human-tiger conflict (HTC) reduction and prevention is therefore imperative for securing tiger populations long-term. However, even when wildlife impacts on people have been reduced, engendering tolerance for, and halting the killing of, species by local communities has proven challenging. A better understanding of the people who live along-side tigers, and of lethal control behaviour, is, therefore, urgently required if global efforts to double tiger numbers are to be effective. Using a combination of qualitative and quantitative data this research provides insight into three important aspects of the human dimensions of HTC in the Bangladesh Sundarbans, the site of the most severe HTC range-wide. First, the cultural and socio-economic context of HTC in this area is described and its influence on local community members' perceptions of the risk tigers present discussed. Second, local levels of tolerance for tigers are quantified and the experiential and psychological basis of tolerance examined. Finally, the drivers for tiger killing behaviour and the factors that render this behaviour socially acceptable are identified. The research makes apparent the complexity of the human dimension of HTC and the relevance and importance of in-depth social research to the conservation of species which come into conflict with local communities.

BIRD BIODIVERSITY IN THE NEVA BAY: THE POSITIVE INFLUENCE OF THE ST. PETERSBURG FLOOD PROTECTION BARRIER AND PROBLEMS OF ITS CONSERVATION IN URBAN CONDITIONS

Natalia Iovchenko

Saint Petersburg State University

The St. Petersburg Flood Protection Barrier (FPB) is a unique object by its structure and size (length of 25.4 km with 22.2 km across water, width of 30 m and height of 6.5 m above sea level). The construction includes dams, water sluices, navigation structures, a six-lane motorway on the crest of dams with bridges, tunnel, and navigation channels. It separates the Neva Bay from the rest of the Gulf of Finland, being a part of the city of five million people. Owing to its location (the

most eastern part of the Baltic Sea and on the White Sea-Baltic flyway), climatic, landscape and habitat features, the Neva Bay is an important territory for stopovers of migratory waterfowls and shorebirds. The creation of artificial sandbars and wetlands, favourable for breeding and used as stopover sites, is a significant positive aspect of the FPB. 11 stone and earthen embankment dams of two or three-tiered structure are suitable nesting sites for the different birds. In 2012, two large colonies of Charadriiformes (including 7 rare species of terns, waders and ducks) were found on two dams. FPB is the only regular breeding site of the Little and Arctic Terns, Terek Sandpiper and Ringed Plover in the city. The Little Gull and range-expanding Gadwall nest there in high numbers. At the same time the dams of FPB are new recreational zones for the people of St. Petersburg, whose presence has negative consequences for birds. The analysis of monitoring stopovers in the Neva Bay during the period of building and functioning of FPB and the study of features of breeding on dams in 2012–2014 allow us to estimate biodiversity changes and to reveal main limiting factors and problems of conservation in urban conditions. Some preliminary measures were elaborated for conservation of biodiversity with special attention on rare species. To protect the Neva Bay stopovers and breeding sites it is necessary to establish a federal protected area of cluster type.

CONFLICT BETWEEN GUANACO POPULATION AND LIVESTOCK FARMING IN THE SURROUNDING OF A PROTECTED AREA IN PATAGONIA

Esperanza Irazo

Universidad Autónoma de Madrid

Pablo ACEBES, Universidad Autónoma de Madrid ; Juan MALO, Universidad Autónoma de Madrid ; Cristina MATA, Universidad Autónoma de Madrid ; Cristián ESTADES, Universidad de Chile ; Benito GONZÁLEZ, Universidad de Chile ; Juan TRABA, Universidad Autónoma de Madrid

Expansion of wild ungulates outside protected areas often conflicts with human activities. Guanaco population of Torres del Paine National Park, Chile, was near extinction in the early 80s, but it has recovered and expanded to surrounding livestock ranches in the last decades. Nowadays there is a large population of guanacos established and living outside the National Park. To evaluate the intensity of conflict between wild herbivores and livestock, owners of the ranches surrounding the National Park were interviewed. Surveys included questions about the effect of herbivores on livestock, estimated losses and their willingness to assume them and alternatives to resolve the conflict. Guanaco is perceived as a threat to livestock farming due to its presence in all ranches, their relative abundance (grade of "abundant- very abundant") and its competitive ability (assessed as 5.7 out of 10). Farmers estimate that they lose (mean \pm SD) $14.8 \pm 15.2\%$ of production (range 0-52%) due to the presence of guanacos.

Moreover, 64.7% of the owners were willing to assume some level of economic losses in livestock farm in exchange for the benefits (tangible or intangible) provided by the presence of wildlife in their ranches. In parallel, 43.8% of farmers stated that the presence of the National Park provides economic benefits, either directly by owning accommodation or tourist activities, or indirectly through increased sales. Finally, the common perception (88% of owners) is that is necessary to control guanaco population growth and integrate wildlife management and socioeconomic development.

65 - BIAS, INFORMATION, SIGNAL AND NOISE IN CITIZEN SCIENCE DATA

Nick Isaac

Centre for Ecology & Hydrology

Citizen science has tremendous potential to produce large quantities of information about the state of the natural world, at scales relevant to both scientific and policy applications. Drawing inference about biodiversity over large spatial scales usually requires the collation of data from a multiple sources, usually with different protocols. Thus, collated datasets contain a number of spatial and temporal and sampling biases. These biases have limited the application of citizen science data and led to criticism about the inferences on which they are based. Fortunately, the growth of citizen science has been paralleled by the development of statistical techniques for modelling biodiversity using heterogeneous and biased data. In particular, Bayesian Occupancy-Detection models have been proven to be robust to many biases associated with citizen science data. I will present examples of how these methods can be used to test current ideas about biodiversity change and the drivers thereof. The hierarchical nature of these models forces us to think about the data generation process, the assumptions of the model and whether the data are fit for purpose. The suitability of any given dataset reflects not just the sampling biases, but also the 'information content', i.e. the degree to which new data contribute to reducing uncertainty in the parameter of interest. These issues highlight the need for better capture and storage of meta-data about the sampling protocol, especially in data repositories (e.g. Dryad, GBIF).

POPULATION ESTIMATION AND GENETIC INFERENCES OF MARKHOR (CAPRA FALCONERI) IN CHITRAL, PAKISTAN USING NON-INVASIVE SAMPLING

Saher Islam

Institute of Biochemistry & Biotechnology, University of Veterinary & Animal Sciences, Lahore, Pakistan
Amna Arshad BAJWA, Institute of Biochemistry & Biotechnology, University of Veterinary & Animal Sciences,

Lahore, Pakistan ; Wasim SHEHZAD, Institute of Biochemistry & Biotechnology, University of Veterinary & Animal Sciences, Lahore, Pakistan ; Kanwal ZAHRA, Institute of Biochemistry & Biotechnology, University of Veterinary & Animal Sciences, Lahore, Pakistan

The wild goat markhor (*Capra falconeri*) is national animal of Pakistan, distributed in the mountainous regions. The IUCN Caprinae Specialist Group considers markhor as endangered. Management of markhor will be necessary for several reasons. Its population is facing threats to extinction due to genetic isolation, low reproductive rates and various anthropogenic causes, including trophies hunting, meat and the indigenous medicines. So far, the population estimates of this wild goat are based mostly on observational studies lacking the scientific validation. So, this study will address major threats to markhor population using non-invasive genetic sampling techniques. Furthermore, it will demonstrate that non-invasive fecal DNA sampling is feasible for wild goat population genetic structure analysis. Host species will be confirmed by designing species specific primers. The goal of such an experimental validation is to distinguish markhor species feces from those of others, potentially occurring in the study area. Extracted DNA will further be amplified using microsatellite markers to genetically count their individuals. By obtaining the genetic variability data from this research we will be able to determine if any of the markhor has been subject to hybridization. Survival of most endangered wild goats may depend on breeding programs where sex identification plays an important role. Sex-linked DNA markers can also provide significant insights into demographic history and phylogenetic relationships among populations. Screened markhor DNA samples will be used for animal sexing, exploiting sex linked molecular markers. In particular, polymorphic Y chromosome markers are useful in tracing paternal lineages in wild populations. This study will help to evaluate existing population of markhor is breeding properly or it's facing certain ecological pressures. So it's critically important to design the active conservation strategies for an endangered markhor population.

CHANGES IN SPECIES COMMUNITIES OF DIVING BEETLES (COLEOPTERA: DYTISCIDAE) WITHIN OMBOTROPHIC PEATLAND PONDS ALONG A HUMAN IMPACT GRADIENT.

Lars Lønsmann Iversen

University of Copenhagen

Kaj SAND-JENSEN, University of Copenhagen

The ombotrophic peatlands of central and northern Europe act as vital habitats for aquatic species living open Sphagnum communities. Thus, regional and national conservation status of whole species communities is often dependent on the persistence of these peatland habitats. During the last

century, the hydrological cycle of European peatlands has been extensively modified by human activities and climate change. In many ombrotrophic peatlands this has caused a persistent lowering of the water table increasing tree growth and a succession towards forest-type ecosystems. Even though these processes are well studied little is known about changes in aquatic species communities following habitat degradation of peatland ponds. In this study we explore the changes in community patterns of diving beetles in 50 ponds along a continuous degradation gradient within an ombrotrophic peatland in western Lithuania. We document that species richness and the abundance of the entire beetle communities decreased with an increase in tree coverage. However, community diversity (measured as Fisher's alpha) remained constant across the gradient. These changes were caused by a shift from communities in the central and pristine ponds dominated by Northern range species towards communities dominated by generalist and ubiquitous species along the borders of the study area. In contrast, Southern range species were uniformly distributed across the gradient. Our work, though focused on a single assemblage, indicates that human alterations of ombrotrophic peatlands change diving beetle communities by replacing specialist species of Sphagnum habitats with generalist species. Furthermore our results suggest that the presence of species expanding their Northern range border is neither restricted nor promoted by human activities within our study area.

MODELING AND STAKEHOLDER ASSESSMENT OF UPLAND WOODLAND CREATION IN CUMBRIA, UNITED KINGDOM

Sara V. Iversen

University of Cumbria

Naomi VAN DER VELDEN, University of Cumbria ; Ian CONVERY, University of Cumbria ; Lois MANSFIELD, University of Cumbria ; Claire HOLT, University of Cumbria

Woodland cover in the UK has declined from once being the prevailing land cover to current levels of 12%. International agro-environment policies are proposing a significant increase in woodland creation and expansion to the benefits of society and biodiversity. Cumbria, in the North-west of the United Kingdom, is an upland landscape heavily influenced by agricultural and stakeholder land-use interests. The area comprises a National Park, Areas of Outstanding National Beauty, large water reservoirs, a forestry sector, a popular tourist industry, mining operations and an upland farming industry. The region's current land management is currently being debated due to an increasing emphasis on agro-environment schemes and subsidies in national and international policy. As a result, stakeholder interests and the farming industry, culture and sense of place of a unique upland region in the North-west of England are challenged. It is

suggested that there is a need for a review into stakeholder and land owner perspectives on potential land use diversification. The aim of this research is to assess stakeholder and landowner perspectives and approaches to woodland creation in the upland regions of Cumbria. Furthermore, A GIS model is applied to combine biological and social data in a spatial setting to assess woodland creation in Cumbria. Preliminary results of GIS modelling of indication differences in stakeholder perspectives and approaches to woodland creation. These results are provided and discussed in the framework of international agro-environment policy and subsidy provision within the UK and internationally.

MANAGING COFFEE AGROFORESTS FOR ECOSYSTEM MULTIFUNCTIONALITY: ROLE OF FARM MANAGEMENT AND LANDSCAPE CONTEXT

Aaron Iverson

University of Michigan

David GONTHIER, University of California-Berkeley ; Katherine ENNIS, University of California-Santa Cruz ; Damie PAK, University of Michigan ; Robyn BURNHAM, University of Michigan ; John VANDERMEER, University of Michigan

Agriculture comprises the largest land use globally; it is therefore critical to incorporate these areas into our conservation planning. Doing so requires working with farmers and determining management strategies that provide both livable incomes and that are compatible with biodiversity conservation. We addressed this challenge through an assessment of ecosystem multifunctionality and biodiversity on Puerto Rican and Mexican coffee farms. We measured how several ecosystem services and organisms were influenced by local-level (farm management-related) and landscape-level environmental variables. We assessed various taxa, including plants, insect natural enemies, lizards, and birds, as well as the ecosystem services of biocontrol of the primary coffee pests, disease regulation, carbon storage, and farm yield and profit. Central to this research is whether plant diversity or simply vegetation structure has a stronger influence on service provision and biodiversity conservation, and whether or not these depend on the landscape context. We found that the various services and taxa responded differentially to local and landscape heterogeneity. However, when considering these coffee farms for ecosystem multifunctionality, farms that had intermediate levels of shade tree biomass provided high yields of coffee with lower input costs and lower toxicity (e.g. herbicides, pesticides), while providing high levels of other ecosystem services. Furthermore, these farms harbored relatively high levels of biodiversity. In general, vegetation structure played a larger role than plant diversity and landscape elements were less important than local management. These results likely reflect the diverse and highly complex (forested) landscape backdrop in which these farms

were embedded. Our results also confirm the importance of considering multiple taxa and services when developing conservation strategies.

USING SOCIAL VALUES FOR GREEN OPEN SPACE TO ENHANCE URBAN CONSERVATION OUTCOMES

Chris Ives

RMIT University

Cathy OKE, RMIT University ; Ascelin GORDON, RMIT University ; Sarah BEKESSY, RMIT University

Urban biodiversity outcomes are largely dependent on the distribution, design and management of green space networks. While standards and metrics exist for green open space planning, there is little research on the drivers of values people have for these areas. This is a significant gap since urban conservation outcomes will depend greatly on the social acceptability of conservation actions. In this study, we spatially quantified residents' values for green space in four suburbs from the Lower Hunter Valley of New South Wales, Australia by enabling participants to mark their values for specific open spaces on interactive paper maps. The survey was designed to evaluate the effect of spatial scale by providing maps of residents' local areas at suburb and municipality scales. Modelling of data from 418 survey respondents revealed that mapped values were a function of (i) park environmental characteristics, (ii) socio-demographics, and (iii) general values for open space. Spatial scale also had a significant effect; all value types recorded a greater abundance of marker dots at the finer (suburb) scale compared to the coarser (municipality) scale. However, this pattern was more pronounced for some values than others (e.g. physical exercise value). Finally, analysis of the co-occurrence of value marker dots within individual parks revealed different levels of compatibility between conservation values and more traditional green space values (e.g. active recreation), depending on the characteristics of the space. These results indicate that the social acceptability of conservation actions in urban landscapes will depend on the individual, but it can be enhanced through careful planning and management. Further, biodiversity conservation values are not restricted to parks zoned as 'natural' areas, suggesting that many conservation opportunities may exist that are not being fully exploited.

NEW APPROACHES OF CONSERVATION PLANNING FOR MIGRANTS

Takuya Iwamura

Tel Aviv University

8,000 of animal species are migratory. Migratory species provide unique ecological functions through their seasonal journey by connecting far places otherwise not related. The

protection of these migrants is thus highly important and affect diverse habitats extending globally. Their unique behavior requires special attention for their management in the sense where migratory network must be protected carefully considering their behavioral traits. Understanding their migratory patterns and applying such knowledge is highly important not only for conservation but also for wide range of questions. For example, migratory birds are responsible bird influenza (H5N1) which affects both Asia and European health care system and agricultural production. However, so far conservation efforts are limited to either breeding or "wintering (more precisely, non-breeding)" habitats where migrants are most often observed. Recent developments in analyzing migratory flyways indicate both the shortcomings of such traditional breeding habitat management for migrants and also propose novel methods to solve management problems for conservation of migratory species. While these new approaches are useful, it is not necessarily straight-forward when and how to apply them for real-world conservation planning. Here, I present our approach to the migratory bird conservation using a maximum flow algorithm to incorporate the impacts of habitat loss on flyway populations of migratory shorebirds in the pacific coastal areas (Iwamura et al., 2013 and 2014). I will also summarize pros and cons for other emerging approaches for conservation planning of migratory species, and propose a synthesizing framework for effective managements of migratory species.

SOCIAL-ECOLOGICAL MODELING FOR ENVIRONMENTAL SUSTAINABILITY AND CONSERVATION PLANNING

Takuya Iwamura

Tel Aviv University

Human influences shape ecological and geophysical processes – thus we live in "Anthropocene". Conservation biology traditionally deals human influences as ewthreats and considers its impacts on ecosystems and biodiversity. However, it is thus necessary to establish framework to fully incorporate interactions between human and ecological systems. Recently, Coupled Human-Nature Systems (CHANS) and Social-Ecological Systems (SEs) attract lots of attention to integrate human-social dynamisms with ecological system. These approaches, originally derived from geography and economics, often simplifies ecological functions. Here I present the research results based on our social-ecological model for indigenous lands in Amazon basin (Iwamura et al. 2014). This model take advantage of vast field dataset on animal observations, land cover changes, hunting data and social parameters. We applied this model to analyze the impacts of various policies on human population, animal population and diversity, and primary forest cover in the study area. I then generalize learning from

this modelling exercise and comparative policy analyses for broader perspective and propose other applications where feedbacks between human systems and ecological systems are critical, such as Mediterranean ecosystem.

124 FILLING THE GAP IN MITIGATION POLICY IMPLEMENTATION FOR COASTAL AND MARINE DEVELOPMENT PROJECTS

Celine Jacob

CREOCEAN - Center for Functional and Evolutionary Ecology
Adeline BAS, EDF-EN, UMR AMURE ; Anne-Charlotte VAISSIERE, Ifremer, Biotope, UMR LAMETA

Although coastal and marine ecosystems are among the most productive ecosystems on Earth and are highly vulnerable to human-induced impacts, there are few data on the influence of mitigation policy implementation on slowing or stopping marine and coastal biodiversity loss. Our reviews of marine and coastal Environmental Impact Assessments (EIAs) consistently show that assessments of impacts are particularly intricate. In most cases, the analyses lead to a finding of no significant residual impacts and do not propose offsetting measures. In a review of offshore windfarm EIAs of seven European countries, we found a lack of offsetting measures and questioned the very few measures proposed to offset residual impacts in terms of equivalency and appropriateness. Further, a similar study conducted on EIAs related to different types of marine works including dredging, port extension, oil drilling, wastewater discharge, and offshore windfarms, in France, led to the same conclusions. Thus, we consider that one of the main pitfalls of the mitigation implementation for coastal and marine projects appears to be the unsuitability of the methodologies used to assess ecological losses resulting from a development project and ecological gains generated by a compensatory measure. Here we present a qualitative multi-criteria method based on indicators resulting from different European environmental policies contexts and from Rapid Assessment Methods used in wetland mitigation banking in the United States. We assess ecological losses and gains in terms of biophysical indicators linked to biodiversity structures and ecosystems functions. In doing so, our aim is to prioritize compensatory measures while placing emphasis on impacted biodiversity components and scaling the compensation when ecological engineering is available. These considerations will help feed a broader discussion on the applicability of the mitigation hierarchy to marine and coastal development projects.

PEOPLE OR THE PLOW? UNDERSTANDING RANGE COLLAPSE IN LARGE AFRICAN CARNIVORES

Andrew Jacobson

Zoological Society of London

Sarah DURANT, Zoological Society of London

East Africa holds globally important, yet declining, populations of lions *Panthera leo*, cheetahs *Acinonyx jubatus* and African wild dogs *Lycaon pictus*. However, East Africa's human population is expected to balloon, with most country populations expected to double or triple by 2050. These species contribute to multi-billion dollar tourism operations, and as apex predators help regulate ecosystems, yet are responsible for significant human and livestock deaths. Despite their status as large carnivores, these species vary in their susceptibility and reaction to threats. Illegal killing and habitat loss via land conversion are two primary threats to these large carnivores. Using recently released human population estimates and newly created maps of anthropogenic land conversion, I investigate these carnivores' susceptibility to their primary threats. With nearly 100,000 presence points, I employ a variety of distribution modeling approaches to investigate the importance of environmental layers to explain current distribution. I use three spatial scales and advanced spatial filtering to improve model results. Additionally, I summarize differences between expert-derived resident and extirpated range. Preliminary findings suggest that lions are the most susceptible to human populations possibly due to their greater reliance on large prey and role in human-wildlife conflict. Research findings will aid in determining appropriate management and conservation strategies. Additionally, identifying how species respond to land conversion and human population increases will enable better zonation to designate area where large carnivores can thrive despite burgeoning human populations.

HOW CAN WE RESTORE POLLINATION WEBS IN WETLANDS ?

Anne-Laure Jacquemart

Université catholique de Louvain

Denis MICHEZ, Université de Mons ; Laura MOQUET, Université catholique de Louvain

Habitat fragmentation has severe effects on plant pollinator interactions by modifying the abundance, diversity and foraging behavior of insect visitors. Over several years, we monitored the pollination webs in wet heathlands and wetlands in Belgium. From the plant side, we investigated pollinator generalist (*Calluna vulgaris*) and specialist species (*Erica tetralix*, *Vaccinium myrtillus*, *V. uliginosum*). We focused the study of the pollinators on bumblebees. These social insects depend on both the quality and the quantity of pollen and nectar for colony development and population survival. Nectar represents the main source for sugars while pollen is mainly collected to provide amino acids, polypeptides and sterols. We quantified the quality of both pollen and nectar of the main floral resources visited by the observed pollinators.

Diversity and abundance of pollinators differed according to plant population size and landscape. Bumblebees visiting specialist ericaceous species switched their foraging behavior according to plant population size: while they collected both pollen and nectar in large populations, they largely neglected pollen collection in small remnant populations. Reproductive success of plant (i.e. seed set) was not affected by population size. Plant species greatly differed in their resource qualities, even within the Ericaceae species. Diversity of co-flowering plant species at both local and landscape levels seems of crucial importance for pollinator survival. Overall, pollinator communities seemed much more sensible than plant communities to fragmentation. Habitat fragmentation might not immediately threaten the reproductive success of the main plant species but has rapid negative effects on their pollinators. Future management plans for wetland restoration need to consider the maintenance of floral diversity but also a landscape mosaic offering resources of different quality.

GOVERNING NATURE BY NUMBERS - EU SUBSIDY REGULATIONS DO NOT CAPTURE THE UNIQUE VALUES OF WOODY PASTURES

Simon Jakobsson

Stockholm University

Regina LINDBORG, Stockholm University

A vast majority of European farmers are dependent on EU subsidies, which make subsidy regulations through the Common Agricultural Policy (CAP) powerful tools in shaping agricultural landscapes. Unfortunately, recommendations that steer these regulations are sometimes arbitrary, like in the case of pasture management, where 50 trees per hectare constitute an upper limit to qualify for subsidies targeted to benefit biodiversity. Although pasture biodiversity is well studied and the core of many conservation programmes within CAP, it is seldom studied as direct effects of subsidy systems. In this paper, we examine how plant diversity is affected by the CAP tree density limit regulation in Swedish woody pastures along a gradient from 3 to 214 trees per hectare. We selected 64 sites where we recorded plant species richness and composition, soil properties and canopy cover. We found a general increase in total species richness (γ -diversity) and species spatial turnover (β -diversity) along the gradient, whereas plot scale richness (α -diversity) tended to drop at 100 trees/ha. The number of typical grassland species remained indifferent along the gradient. Additionally, tree density, together with organic content and C:N-ratio, were the strongest predictors of plant species composition. Hence, when CAP regulations encourage tree cutting for pastures to qualify for subsidies there is a risk of homogenisation of all EU grasslands, leading to decreased γ - and β -diversity. If a general target for the subsidies is to increase biodiversity of plants, there is a need to scrutinise these regulation details to preserve the high biodiversity values

of woody pastures. We argue that habitat variation, species diversity and low intensity management, rather than using a specific number of trees, should be the main incentives for financial support to preserve biodiversity.

TOWARDS MORE EFFECTIVE GOVERNANCE OF COMMUNITY-BASED WILDLIFE MANAGEMENT

Oria Jamar De Bolsée

Colorado State University

Damon YEH, Colorado State University

Community-based natural resource management (CBNRM) has been suggested as a means to accomplish both ecological and social objectives. However, effective governance of communal wildlife resources is critical for successful management. We present the first study to employ Elinor Ostrom's eight principles of commons governance to examine community-based wildlife management programs in Mexico. Wildlife Management Units (UMA) have become a widespread tool for managing wildlife and supporting local livelihoods throughout Mexico. The success of these programs has been mixed, but the impact of governance mechanisms remains unstudied. We examined the governance context of an UMA within an ejido in Campeche, Mexico. This UMA was created in 2011 as a means for diversifying income generation through sustainable extractive and non-extractive wildlife use. The focal point of our work consisted of using current literature on common-pool resource governance to assess the governance structure of the ejidatarios then, through a participatory process, devise practices to strengthen the governance and management of the UMA. Our participatory action research was carried out through a series of meetings and semi-structured interviews with diverse stakeholders linked to the UMA. We determined that the ejidatarios lacked clearly defined rules on how to improve the functioning of the UMA, distinct roles for each member and sufficient participation by all members, and linkages to internal and external entities that can provide assistance and resources. We then used participatory methods to jointly develop capacity-building workshops in order to address some of these shortcomings. Our research demonstrates the importance of governance for determining outcomes of community-based wildlife management, and emphasizes the power of participatory research methods to contribute to conservation.

INVESTIGATING A DINOSAUR: CONSERVATION GENETICS AND DEMOGRAPHIC ANALYSIS OF THE ENDANGERED CYCAD SPECIES CYCAS MEGACARPA AND IMPLICATIONS FOR A PROPOSED TRANSLOCATION.

Heather James

University of the Sunshine Coast

Robert LAMONT, *University of the Sunshine Coast*; Paul FORSTER, *Queensland Herbarium*; Alison SHAPCOTT, *University of the Sunshine Coast*

Cycads are iconic plant species that existed over 200 million years ago before dinosaurs roamed the earth. *Cycas megacarpa* is one of around 300 cycad species spread across the tropics and subtropics including in Australia. *Cycas megacarpa* is listed as endangered currently under threat from urban, rural and commercial infrastructure development. Cycad populations are often disjunct and scattered throughout the landscape and it has been thought that gene flow between populations is minimal or non-existent. This study investigates the effect habitat fragmentation has had on the genetic structure of *C. megacarpa* populations across its entire range as well as the implications of translocating large numbers of cycads from several populations to a single site due to the construction of a gas transmission pipeline. This study focused on three analysis levels; a landscape scale involving the whole species, a regional scale involving multiple populations in the same geographic region, and a within population scale focusing on four individual populations. 34 populations were sampled across the species' known range, 18 of these were in the translocation region; using 24 microsatellite loci developed using next generation sequencing. Habitat loss and fragmentation has had a significant impact on the amount of suitable habitat remaining. Examination of the translocation region revealed less genetic differentiation than was expected between two affected mountain ranges. Minimum pollen dispersal distance was found to average at 30m with a maximum distance of 339m. Effective population size (as a proportion of adult population) was found to be similar between demographic and genetic measures in focus four populations averaging at 0.75 and 0.79 respectively. Across the species' range genetic clustering occurs within 36km indicating regional historic gene flow in contrast to expectations highlighting the importance of maintaining population clusters for its conservation.

INVESTIGATING THE USE OF CONSPECIFIC-ATTRACTION IN THE CONSERVATION OF AN ENDANGERED AMPHIBIAN - MANIPULATING CHORUS AGGREGATION AND LANDSCAPE DISTRIBUTION

Melanie Sandra James

University of Newcastle

Michelle Pirrie STOCKWELL, University of Newcastle; Pizzatto LIGIA, University of Newcastle; Simon CLULOW, University of Newcastle; John CLULOW, University of Newcastle; Michael Joseph MAHONY, University of Newcastle

Conspecific attraction can prevent occupancy of restored or created habitats by limiting dispersal to unoccupied areas. This may cause problems for threatened taxa where habitat

restoration and creation programs are implemented as part of recovery plans. Studies on birds have found that introduction of artificial calling from speakers can increase occupancy of restored habitat. The endangered green and golden bell frog (*Litoria aurea*) has a loud conspicuous call and large chorusing aggregations. To date, attempts to repopulate restored and created habitat through natural immigration and active translocation has had limited success. We used *L. aurea* as a model species to determine if distribution could be manipulated via artificial communication cues to increase success of the recovery program in N.S.W., Australia. We undertook two studies 1. We placed speaker systems in uninhabited areas of five habited ponds across two locations and broadcast calls of *L. aurea* to see if we could manipulate distribution into previously unoccupied areas and 2. We placed speakers in five unoccupied ponds to see if we could increase occupancy. Surveys undertaken before and after speaker placement indicate for study 1 we successfully manipulated adult *L. aurea* distribution within ponds increasing occupancy and calling around speakers. For study 2 attempted manipulation to unoccupied ponds was successful in two ponds, one of which experienced a large chorus and at least one breeding event. We suggest that conspecific attraction is causing aggregatory behaviour in ponds and that manipulation of landscape distribution via conspecific attraction for conservation programs may be possible.

GEOGRAPHICAL ONTOGENETIC AND SEX BASED SEPARATION OF THE ENDANGERED GREEN AND GOLDEN BELL FROG (LITORIA AUREA)

Melanie Sandra James

University of Newcastle

Michelle Pirrie STOCKWELL, University of Newcastle; Carla Jean POLLARD, University of Newcastle; Evan John PICKETT, University of Newcastle; James Ian GARNHAM, University of Newcastle; Deborah Sheena BOWER, University of Newcastle; Ligia PIZZATTO, University of Newcastle; Simon CLULOW, University of Newcastle; John CLULOW, University of Newcastle; Michael Joseph MAHONY, University of Newcastle

Describing species distribution and habitat use can improve conservation programs by providing useful information to habitat rehabilitation and creation programs. For some taxa, the spatial distribution of juveniles, males and females can be segregated, resulting in patchy distributions within a landscape. This ontogenetic and sex based habitat disassociation may be due to intraspecific competition, cannibalism, differential predation, age or sex specific habitat requirements, sexual harassment or explosive dispersal and breeding. The endangered green and golden bell frog (*Litoria aurea*) is a focus of many conservation efforts in NSW Australia, however, a detailed analysis of age and sex based distribution

patterns has not been undertaken. In the current study, we undertook visual encounter surveys within ponds and in terrestrial areas in Sydney Olympic Park the breeding season (September - March) from 2008 to 2013. The distribution of males, females and juveniles were mapped using a Global Positioning System device. Spatial mapping indicates that distribution is primarily within ponds and within patches of emergent vegetation. Aggregations within vegetation patches were isolated using hierarchical clustering in JMP and a contingency analysis of males, females and juveniles was undertaken for all clusters. The contingency analysis indicated there is very little distributional overlap between males, females and juveniles. For species experiencing this behaviour, it is recommended that habitat rehabilitation and creation programs ensure a landscape contains multiple ponds and vegetation patches to facilitate ontogenetic and sex based segregation.

LANDSCAPE EFFECT ON THE DEMOGRAPHY OF THE LESSER HORSESHOE BAT (*RHINOLOPHUS HIPPOSIDEROS*) DETERMINED FROM A FIFTEEN YEARS MONITORING PROGRAM

Pierre-Loup Jan
INRA

Damien FOURCY, INRA ; Alice BAUDOUIN, CNRS ; Olivier FARCY, Bretagne Vivante ; Josselin BOIREAU, Groupe Mammologique Breton ; Eric PETIT, INRA

The lesser horseshoe bat (*Rhinolophus hipposideros*) has undergone a dramatic decline over the past decades, especially in northern and central Europe. In order to better understand which features impact the demography of this bat, we analyzed the outcome of a standardized demographic monitoring program of nursery roosts of the lesser horseshoe bat. This program was ongoing during the last fifteen years in Brittany, where numerous nursery roosts of this species can still be found. Bats were counted in about 90 nursery roosts twice a year, before and after birth, in order to estimate population size as well as fecundity. We found that population sizes of the lesser horseshoe bat globally increased during the program, but this evolution was extremely variable depending on roost. We tried to explain roost size and fecundity variability with roost and landscape characteristics, by means of GLMM and information criteria. Two main features influenced the lesser horseshoe bat demography, namely broadleaved woodland surface in close proximity of the roost and roost type. Unlike other European bat species, this demographic study did not find any appeal from water surfaces and coniferous woodland. However, our results were totally consistent with previous work on the lesser horseshoe bat made at the individual scale (radio-tracking), revealing the consequences of individual behaviors on population dynamics.

IS CLIMATE-SMART CONSERVATION PLANNING FEASIBLE IN EUROPE? SPATIAL RELATIONS OF NATURA 2000 SITES, SOIL CARBON, AND LAND VALUES

Kerstin Jantke

Universität Hamburg

Natalie TRAPP, Universität Hamburg ; Jana MÜLLER, Universität Hamburg

The expectations on protected areas to deliver not only biodiversity conservation but also to provide an array of different ecosystem services rise. Climate regulation and more specifically the sequestration and storage of carbon are especially seen as promising services protected areas may provide. To estimate the potential for climate-smart conservation planning in Europe, we integrate spatially explicit data on terrestrial Natura 2000 sites, soil organic carbon, and agricultural land values for the European Union. The specific objectives of this study are to analyse spatial relations between soil carbon content, land value and protected areas on European Union's land area and to locate and quantify the proportion of land with high carbon and low economic value within and outside protected areas. We apply a unique interdisciplinary framework with methods ranging from analyses with geographical information systems, agricultural economics to statistics. Findings indicate that there is a significant overlap between Natura 2000 sites and regions with a high carbon content across Europe. Economic analyses shows that carbon-rich regions have significantly lower land values than other areas. Our results suggest that biodiversity protection and mitigation of climate change through conservation of soil carbon could be simultaneously achieved in Europe's protected areas and beyond. We conclude that there is a notable potential for climate-smart conservation in Europe that needs to be further explored.

SYMPOSIUM ID 134 - THE USE OF MARXAN TO ADDRESS INVASIVE SPECIES IN CONSERVATION MANAGEMENT

Stephanie Januchowski-Hartley

Texas A & M Corpus Christi

Vanessa ADAMS, University of Queensland ; Virgilio HERMOSO, Centre Tecnologic Forestal de Catalunya ; Piero VISCONTI, Microsoft Research

Management of invasive species is a global conservation priority given their prominent impact on ecological and socio-economic values across all realms. Because costs of mitigating impact or restoring systems from invasive species can be unaffordable there is a need for methods that can allocate limited resources efficiently to control or eradicate invasive species. Systematic conservation approaches, which include

the use of spatial prioritization tools such as Marxan, can offer cost-effective and efficient solutions to guide the allocation of resources for invasive species management. However, despite these methods being widely used in protected area planning, the application of such approaches to the invasive species management problem has been extremely limited. With this in mind, we review how invasive species management has been planned for to date across ecological realms, and identify the pros and cons of different approaches. We focus on two case studies, the only studies to our knowledge, to demonstrate how Marxan can be used as a conservation planning tool to guide the control of invasive species and discuss the benefits of using systematic approaches over other non-systematic approaches. Finally, we highlight current best practice and identify opportunities for expanding the use of Marxan and systematic approaches more broadly to improve invasive species management strategies.

A STANDING OVATION FOR CONSERVATION

Rebecca Jarvis

Institute for Applied Ecology New Zealand, AUT University
Barbara BOLLARD BREEN, Institute for Applied Ecology New Zealand, AUT University

Collective action is any action taken by a group of people to achieve a common goal. In conservation, it is important to understand how groups voluntarily organise to protect biodiversity and natural resources. There is often an underlying assumption that better information will change individual motives and lead to collective results. However, different groups with similar levels of support for an action can lead to very different outcomes for conservation. Micro-motives do not equal macro-behaviour and the emergent properties of the group can be very different when individual preferences interact and aggregate. In a standing ovation, each individual decides to stand or not depending on the quality of the information they receive and the actions of others around them. A simple model will be used to demonstrate how learning, diversity, networks and uncertainty affect the likelihood of a standing ovation. This talk will explore what a standing ovation has in common with successful conservation, and how collective action depends on more than communicating information to the public. Understanding collective action as greater than a sum of its parts provides important insights relevant to capacity development, governance, policy, and social and environmental change.

THE STRUCTURE OF AN ELECTRONIC DATABASE ON CARMINE SCALE INSECTS OF EASTERN KAZAKHSTAN AND WESTERN CHINA

Roman Jashenko

Almaty Management University

Sergey KOLOV, Institute of Zoology

In the course of studies to assess the natural resources of carmine scale insects of eastern Kazakhstan and western China has developed a specialized database structure. The structure of an electronic database consists of three main elements: I. Data entry system comprising a user-friendly interface. It includes: insect taxa; host plants; localization on forage plants; geographical coordinates by GPS or GLONAS; biocenosis in the hierarchical arrangement (forest, forest-steppe, steppe, semi-desert, desert, mountain vertical zoning, intrazonal); date of collection or observation; the development stage of the insect (egg, larva of a certain age, adults); gender of collected insect; number of collection according the field notebook; the number of manufacturing permanent microscopic preparations; biological features (observation in text format); ecological features (observation in text format); the number/density of population; photos; video files; name of collector/observer; published articles; links to online resources. II. The data processing system, integrated with GIS. A data processing system is carried out using the specialized software (ArcGIS, MapInfo). III. The output system of processed data is performed in different ways: on the screen, to the printer, saved in a file (or image data), or sent to a network resource. As a result, all known up to date findings of carmine scale insects were introduced into a spreadsheet (MS Excel) and integrated into a common database with geo-referenced. On the basis of this created a series of maps of populations localization of carmine scale insects. In the future, based on the developed electronic database will be created predictive model of the spatial distribution of populations of scale insects, which takes into account the vegetation, soil cover, terrain, water, etc., as well as the model of their biological resources.

COMMUNICATION STRATEGIES FOR WILDLIFE CONSERVATION

Asher Jay

National Geographic Emerging Explorer

The consumer demand for wildlife products, exotic meats and pets to produce snake oil cures for human ailments and assert status, and individuality for the elite have created profit markets that bank on extinctions in the Anthropocene. This has resulted in a global market place that illegally capitalizes on the exploitation of our planet's finite natural resources to cater the myopic vested interests of a few at the cost of many. More recently, this demand has trebled with a rise in the purchasing power of a burgeoning middle class, which has implied the inevitable demise of various species, unless public education seeds shifts in cultural consciousness. In the digital age, where public engagement in global concerns that affect collective welfare is incited by pithy sound-bites that are 140 characters or less, it is vital not only to condense and collate

data sets but translate them into a vernacular that is familiar to the masses. Unless academic research is made accessible to the layperson in simple, mainstream vocabulary, the long-term conservation of wildlife and wilderness areas will remain a marginalized interest of an exclusive community. The work I produce bridges the hiatus between science and storytelling, it utilizes advertising and marketing tactics to galvanize community involvement. Impact is then calibrated through backend data analytics like any other marketing effort run by the corporate world. "And as far-fetched as it may sound, scientists, professors, and leading wildlife groups are flocking to the 30-year-old artist because, after their fieldwork, research, and strategizing are done, Jay can do something they can't: translate the work into images that make people take notice." – National Geographic

FINE-SCALE URBANIZATION AFFECTS ODONATA SPECIES DIVERSITY IN PONDS OF A MEGACITY (PARIS, FRANCE)

Martin Jeanmougin

Muséum National d'Histoire Naturelle[INSTITUTE]Natureparif
Fabien LEPRIEUR, Université Montpellier 2 ; Grégoire LOÏS, Muséum National d'Histoire Naturelle[INSTITUTE]Natureparif ; Philippe CLERGEAU, Muséum National d'Histoire Naturelle

Although ponds are recognized as biodiversity hotspots, very few studies focus on pond ecosystems in urban ecology and urban developments. Using Odonata as an indicator group, we explored changes in species composition in ponds localized along an urban gradient of a megacity (Paris, France). We assessed the relative importance of local- and landscape-scale variables in shaping Odonata α -diversity patterns using a model-averaging approach. Analyses were performed for adult (A) and adult plus exuviae (AE) census data. At 26 ponds, we recorded 657 adults and 815 exuviae belonging to 17 Odonata species. The results concerning both A and AE showed that the species assemblage composition was not determined by pond localization along the urban gradient. Similarly, pond characteristics were found to be similar among urban, suburban and periurban ponds. The analyses of AE census data revealed that fine-scale urbanization (i.e. increased density of buildings surrounding ponds) negatively affects Odonata α -diversity. In contrast, pond localization along the urban gradient weakly explained the α -diversity patterns. Several local-scale variables, such as the coverage of submerged macrophytes, were found to be significant drivers of Odonata α -diversity. Together, these results show that the degree of urbanization around ponds must be considered instead of the localization of a pond along the urban gradient when assessing the potential impacts of urbanization on Odonata species diversity. This work also indicates the importance of exuviae sampling in understanding the response of Odonata to urbanization.

142 FROM BIODIVERSITY CONSERVATION IN AGRICULTURAL LANDSCAPES TO THE PROMOTION OF FUNCTIONAL BIODIVERSITY: SHIFTING A PARADIGM?

Philippe Jeanneret

Agroscope - INH

Thomas WALTER, Agroscope - INH ; Felix HERZOG, Agroscope - INH

In European agricultural landscapes, the last 20 years of research and implementation of measures targeting biodiversity have been essentially focused on species and habitat conservation and promotion. Agri-environment schemes have been partly successful in achieving these goals. At the same time, agriculture has used various means to ensure and increase production, mostly by intensifying management and continuously high pesticide and fertilizer inputs. However, systemic approaches have also been implemented such as integrated pest management (IPM) which aims at preserving and promoting natural control of pests by natural enemies, and limiting and synchronizing pesticide applications. Recently, "functional biodiversity" has been introduced as a concept which highlights the role of biodiversity in the regulation of ecosystem functioning including agro-ecosystems. Moreover, functional biodiversity can provide benefits to human society known as ecosystem services which encompass pest control and pollination. In Switzerland, the agri-environment scheme has stabilized measures for biodiversity conservation and is currently developing new measures to promote functions, such as the introduction of habitats targeting population increase of common pollinators. Such measures go in the right direction but should not replace specific measures for rare species conservation. As exemplified by the Swiss case and ongoing research projects, we discuss the possible conflict or complementarity between measures focusing on biodiversity in general and service-based specific measures in the context of land sharing and land sparing. We highlight important issues for future research and implementation of agri-environment schemes in the context of the Common Agricultural Policy. We propose measures to increase the functional benefit of green infrastructure. And we discuss possible synergies and conflicts between the policy goals of promoting functional biodiversity vs species conservation.

ENGAGING PUBLIC AUDIENCES ON NATURE RESERVES: WHAT MAKES A GOOD NATURE EXPERIENCE?

Rebecca Jefferson

RSPB Centre for Conservation Science

Richard BRADBURY, RSPB Centre for Conservation Science

Nature reserves are predominantly designated and managed for conservation priorities such as habitat creation for rare or vulnerable species. Their role in providing spaces for people to be close to nature is being increasingly valued, particularly as disconnection from nature impacts on support for conservation action. This research project investigates how well these two priorities align: is a nature experience with a species of high conservation concern more powerful to nature reserve visitors than an experience with a species of lower conservation concern? To what extent do factors such as proximity to a species influence the experience? These sorts of questions have been investigated through face to face interviews with nature reserve visitors ($n = 204$) and members of the Royal Society for the Protection of Birds ($n = 1000$). Results show the relative importance of conservation based variables (e.g. rarity, endemism) against 'selfish' variables (e.g. novelty, proximity to species) in nature experiences, and assess the influence of logistics (e.g. signage, information). The findings of this study inform practice on nature reserves for providing powerful ways to engage public audiences with nature conservation, whilst supporting the conservation priorities of the site.

SYMPOSIUM 191: AUDIENCE-LED ENGAGEMENT: HOW UNDERSTANDING PUBLIC PERCEPTIONS OF NATURE CAN DELIVER MORE EFFECTIVE CONSERVATION MARKETING

Rebecca Jefferson

RSPB Centre for Conservation Science

Richard BRADBURY, RSPB Centre for Conservation Science

To address the conservation challenges currently faced, society must be engaged to change their behaviour and reduce negative impacts on natural environments. However, 'society' is not a single audience. Perceptions of nature are heterogeneous within our society, and this means that different approaches are required to engage with different audiences. This presentation will review some of the variables which lead to this heterogeneity, including gender, social values and the role of conservation importance. By understanding the lenses through which an audience views the environment or conservation issue in question, it is possible to develop engagement mechanisms which resonate with the target audience. This is illustrated with examples from the practice of the Royal Society for the Protection of Birds to connect with its audiences, which has been informed by research into audience perceptions. The new pathway for conservation is the integration of conservation biology approaches e.g. identification of ecological priorities for ecosystem health, alongside public perceptions analysis to develop engagement

mechanisms which resonate most effectively with the target audience.

ANATOMY OF A FAILED CARIBOU (RANGIFER TARANDUS CARIBOU) TRANSLOCATION

Dennis Jelinski

University of Victoria

Heather LEECH, University of Victoria

Mountain caribou, an endangered deep-snow ecotype of woodland caribou (*Rangifer tarandus caribou*) have been declining in British Columbia (BC), Canada over the last number of decades. A particularly imperilled population was experimentally augmented with 19 northern caribou, a geographically distinct shallow-snow ecotype, from northern BC. To assess ecologically meaningful seasonal variation in risk of predation by cougars we used a recently-developed clustering framework based on homogeneous space-use patterns of GPS-collared animals. We identified five resident caribou seasons, two donor caribou seasons, and two cougar seasons. Resident caribou remained at high elevations year-round and primarily selected habitats not used by cougars. In contrast translocated caribou tended to occupy habitats extensively used by cougars, resulting in predation of at least six, and possibly eight, of 19 caribou over 30 months. Additionally, translocated caribou had a significantly higher daily travel rate than resident thus rendering them to increased risk as a function of probability of encounter. We conclude that the translocated caribou ecotype either failed to have adequate innate behavioural plasticity or sufficient time to adapt to a novel landscape and a novel predator.

PROTECTED AREA ASSET MANAGEMENT

Paul Jepson

University of Oxford

Ben CALDECOTT, Smith School of Enterprise and the Environment

Competing claims for land resources are undermining PAs as a policy and cultural ideal. The 'go/no-go' question in the extractive sector and the rise of PADD (downgrading, downsizing, & degazettement) suggests that protected areas may be at increasing risk from development interests. Our new protected area asset framework (Caldecott & Jepson 2014) responds to the need to i) demonstrate the forms of value generated by PAs in ways meaningful for citizens, politicians, and markets, ii) enhance risk management science and practice and iii) attract new investment into PAs from old and new funding sources. Framing protected areas as spatial assets that are invested in to generate long term value speaks to the language of economics and investment. Whilst many type of value cannot be monetised directly they generate forms of risk that are material in investment decisions. Our asset

framework is intended to inspire work on the development of a new generation of PA metrics afforded by 'big data' and new computational techniques. These metrics are intended to support improved decision making - protected area asset management - that effectively values, maintains, operates, and defends PA assets; attracts and properly deploys the right mix of private, public, and philanthropic capital into PA assets; and also identifies assets that are under-performing or poorly utilised.

TEMPORAL FEATURES OF TUNDRA ECOSYSTEMS INFLUENCING THE DENSITY OF BARREN-GROUND GRIZZLY BEARS IN THE CANADIAN SOUTHERN ARCTIC

Tyler Jessen

University of Calgary

Marco MUSIANI, University of Calgary ; Rianne DIEPSTRATEN, University of Calgary ; Greg MCDERMID, University of Calgary ; Paul GALPERN, University of Calgary ; Alessandro MASSOLO, University of Calgary ; Alistair BATH, Memorial University ; David PAETKAU, Wildlife Genetics International

Grizzly bears inhabiting the barren-grounds of the Canadian Southern Arctic are listed as a species of 'Special Concern' by the Committee on the Status of Endangered Wildlife in Canada because of their vulnerability to population declines and human disturbance. We report initial findings of a multi-year, DNA based hair snare program and phenology study in a 30,000km² study area encompassing all 4 recently constructed diamond mines in the Northwest Territories, Canada. We also include Traditional Ecological Knowledge from the Lutsel K'e Dené First Nation. Microsatellite analysis of 2,174 hair samples collected from 2012 to 2013 identified 127 individual bears (89 female, 48 male). Motion cameras (n = 20) and time lapse vegetation cameras (n = 59) collected 10,948 and 16,783 images respectively to assess the temporal availability of bear food sources throughout the active season for bears (June – September). Our results indicate that static landscape features are having little effect on grizzly bear distributions despite occasional human-bear interactions. However, the temporal variation of food resources, including plants and barren-ground caribou, may be a better indicator of bear density in the tundra since landscapes exhibit low spatial heterogeneity and pronounced seasonality. As northern ecosystems continue to undergo rapid changes in climate and human activity, understanding the relationship between the availability of food sources and the density of species of concern such as the grizzly bear will help form the basis on which sound management decisions are made.

ARE ECOSYSTEM SERVICES THE SOLUTION TO THE DWINDLING HABITAT FOR WETLAND BIRDS?

Allwin Jesudasan

Ashoka Trust for Research in Ecology and the Environment (ATREE)

Giridhar MALLA, Ashoka Trust for Research in Ecology and the Environment (ATREE) ; T GANESH, Ashoka Trust for Research in Ecology and the Environment (ATREE)

Despite the growing anthropogenic pressures on habitat for wetland birds, there are many examples from India where local villagers go out of their way to protect such habitation. Yet, there are also recent examples of local communities' indifference towards such habitat. Very little is known about why some communities actively conserve while still others are indifferent. The objective of our study is to understand the role of ecosystem services in motivating people to conserve. Surveys were carried to elicit peoples Willingness To Pay (WTP) in eight villages in Southern India. The villages were selected in groups of two such that the two villages were similar in all characteristics except that one had a tradition of protecting bird habitat while the other did not. A total 404 respondents were interviewed. Double bound dichotomous model was used to estimate the mean WTP in each village. The mean WTP in the villages protecting the bird habitat was significantly higher than the other group. Additionally, there was no impact of personal cost on WTP. Surprisingly, households which received payment from the forest department for conserving trees had a negative and significant impact on WTP. It appears that intangible ecosystem services played a crucial role in peoples motivation to conserve. However, the role of tangible ecosystem service such as payments made by a government agency is not positive. Because WTP is a reflection of peoples' ownership towards a good, it appears that people who received payments do not have the ownership over the 'good'. Our study assumes significance because Payment for Ecosystem Services has been projected as a conservation solution in such landscapes where poverty is seen as a hurdle for conservation. However, by paying people for things that they were already doing can take away their 'ownership' and perhaps also their motivation to conserve.

EVIDENCE FOR HETEROGENEOUS EFFECTIVE POPULATION SIZE AND ITS CONSEQUENCES IN CONSERVATION

Belén Jiménez-Mena

Bioinformatics Research Centre, Aarhus University, C.F. Møllers Allé 8, DK-8000[INSTITUTE]AgroParisTech, UMR1313 Génétique animale et biologie intégrative, 16 rue Claude Bernard, 75231[INSTITUTE]INRA, UMR1313 Génétique animale et biologie intégrative, 78350

Bernt GULDBRANDTSEN, *Center for Quantitative Genetics and Genomics, Department of Molecular Biology and Genetics, Aarhus University; Thomas BATAILLON, Bioinformatics Research Centre, Aarhus University, C.F. Møllers Allé 8, DK-8000*

The drift-effective population size (N_e) is a central concept in conservation genetics. It is the size of an ideal population undergoing the same rate of genetic drift as the population under study. An accurate estimation of N_e is essential for conservation as N_e is used as a diagnosis tool for the conservation status of endangered species/breeds and the performance of the breeding programs. It is generally assumed that a single N_e can account for drift across the whole genome. However, recent studies in *Drosophila* spp. and other species suggest that different segments of the genome might undergo different rates of genetic drift, challenging this assumption. We currently lack any clear idea of how much heterogeneity in N_e is found across species, and what underlies/is causing such heterogeneity. Making use of the large genomic datasets available from cattle, we tested the hypothesis of heterogeneity of N_e using 50k SNP chip data from the Danish Holstein population. Using temporal samples, we estimated the standardized variance in allele frequency changes in different windows comprising 100 SNPs along the genome and estimated a realized N_e within each bin. We observed significant variation in N_e along the different chromosomal regions with ca. 500 chromosomal segments spanning 100 SNPs (corresponding to 4-7 Mb) exhibiting a realized N_e varying about 6-fold (N_e : 40-250). We also found significant variation in N_e between chromosomes. This variation is genuine and exceeds the mere sampling variance around our N_e estimates. We investigate whether differences in recombination rate and gene content – variables mediating effects of hitchhiking and background selection – co-vary with N_e across the genome. The implications of such N_e heterogeneity for conservation practices are substantial, as endangered populations can locally be accumulating homozygosity at a rate much faster than expected given an average N_e .

TESTING THE EFFICIENCY OF UNEVEN-AGED FORESTRY AS A CONSERVATION TOOL TO PROMOTE BIODIVERSITY AND ECOLOGICAL LEGACIES.

Klara Joelsson

Swedish University of Agricultural Sciences

Joakim HJÄLTÉN, *Swedish University of Agricultural Sciences*

Forestry in Sweden is dominated by even-aged management, e.g. clear-felling. Even-aged forestry simplifies forest structure, breaks forest continuity and negatively affects biodiversity. This has led to renewed interest in uneven-aged forestry, which maintains a layered forest structure, preserve forest continuity and have less impact on micro-climate than clear-

felling. Current knowledge indicates that uneven-aged forestry potentially preserve biodiversity better than even-aged forestry. However, we still need to quantify the differences and identify proximate reasons for this. By experimentally compare uneven-aged to even-aged forestry we will test the following hypotheses: 1) Uneven-aged forestry will retain pertinent ecological structures necessary to maintain abundance, species richness and composition of beetles at a) higher levels than observed in stands with even-aged structure and b) similar to levels in reference stands. 2) Uneven-aged forestry will favor species associated with old growth forest characteristics but disfavor species associated with early successional forests. We analysed the abundance, diversity and species composition of beetles in five different stand types; representing uneven aged forestry (selective felling), two phases in even aged forestry (clear-felling and thinning) and unmanaged forest (control stand and woodland key habitat) to evaluate the efficiency of uneven-aged forestry as a tool to promote biodiversity.

INTEGRATIVE TAXONOMY AND CONSERVATION OF THE FLY ORCHID GROUP

Nina Joffard

Centre d'Ecologie Fonctionnelle et Evolutive

Laurent DORMONT, *Centre d'Ecologie Fonctionnelle et*

Evolutive; Bruno BUATOIS, Centre d'Ecologie Fonctionnelle et

Evolutive; Bertrand SCHATZ, Centre d'Ecologie Fonctionnelle et

Evolutive

The Orchidaceae family is famous for its great taxonomic and floral diversity and has attracted the attention of the scientific community since Darwin. This is particularly true for the *Ophrys* genus, which is known for its unusual pollination strategy called sexual deception and its insect-mimicking flowers. However, the *Ophrys* genus is currently subject to "taxonomic inflation" and its taxonomy is highly debated between orchidologists. This has negative consequences for its conservation not only because it makes species identification in the field difficult, but also because it is hard to conserve taxa whose taxonomic ranks are unstable. Thus, taxonomic studies are of primary importance for the conservation of the charismatic yet endangered *Ophrys* genus, endemic from the Mediterranean region. Integrative taxonomy, by taking into account several unrelated characters, seems to be a promising approach to delimit closely related orchid species. We investigated here the fly orchid group which comprises three taxa, *Ophrys insectifera* being widely distributed across Europe while *O. subinsectifera* and *O. aymoninii* are rare endemics. Recently, Triponez et al. (2013) have shown that they were genetically very close, but morphologically and ecologically differentiated. Our objective was to complete this work by analysing floral odour, which mimics sexual pheromones of female insects and is thus of primary importance in pollinators attraction and reproductive isolation. Using solid-phase-micro

extraction (SPME) and gas chromatography-mass spectrometry (GC-MS), we showed that floral odours of these three taxa are very different. We explain the incongruence between genetic, morphological, ecological and chemical characters in the light of the evolution of the fly orchid group and conclude that *O. insectifera*, *O. subinsectifera* and *O. aymoninii* are three different species and must be considered as such in conservation politics.

EXPERIENCES OF STAKEHOLDER ENGAGEMENT IN POLICY-DRIVEN RESEARCH: A SYSTEMATIC REVIEW PERSPECTIVE

Sif Johansson

MISTRA EviEM

Neal Haddaway, MISTRA EviEM; Claes BERNES, MISTRA EviEM; Magnus LAND, MISTRA EviEM; Oona LÖNNSTEDT, MISTRA EviEM; Matilda MILJAND, MISTRA EviEM; Mats SVENSSON, Swedish Agency for Marine and Water Management; Hanna ZETTERBERG, MISTRA EviEM

Conservation practitioners and policy-makers (decision-makers) increasingly turn to evidence reviews to aid decision making: more frequently systematic reviews (SRs). The reason is the rigorous, transparent, objective and repeatable way of reviewing academic and grey literature that aims to answer specific questions or assess the state of knowledge for particular subject. SRs are undertaken according to strict guidelines to ensure that they are as rigorous as possible when searching for, screening and critically appraising the studies, and synthesising the evidence. This is done by teams of expert reviewers to ensure high quality. This high level of rigour also appeals greatly to decision-makers needing to show that their choices are based on the best available evidence. Acceptance of SRs by stakeholders is vital, particularly where there is controversy. SRs must therefore involve stakeholders to ensure that the questions of highest priority are being asked in an appropriate way using the best available information and are presented in a usable and digestible format. SR stakeholders are diverse and different groups should be involved depending on the issue being reviewed. Key stakeholders are those needing the information as a basis for decisions; from government agencies to practitioners. Stakeholders also play a vital role in directing reviewers towards evidence, particularly grey literature. As end-users of the review findings, stakeholders can also help tailor research outputs to optimise impact. EviEM is a fixed-term project aiming to summarise existing evidence relating to human interactions with the environment using SRs. By undertaking several SRs on a variety of questions we have allocated considerable resources to developing a framework for stakeholder engagement (SE) in SRs. Here we discuss our experiences in SE and introduce a framework for participatory secondary research that aims to

provide decision-makers with widely accepted best available evidence.

HARVEST OF LOGGING RESIDUES FOR BIOENERGY - IMPLICATIONS FOR SAPROXYLIC INSECT DIVERSITY

Victor Johansson

Swedish University of Agricultural Sciences

With increasing demand for non-fossil energy sources, harvest of logging residues as a source of bioenergy is increasing. Twigs and tops as well as stumps are presently used. However, with this harvest, the amount of habitat for saproxylic species will decrease correspondingly. As many saproxylic species already are considered to be under threat due to present forest management, a further harvest of wood from the managed forests may increase the problems of maintaining biodiversity. To investigate if this is true and find ways to mitigate the problems I made several surveys of the species assemblage in bioenergy wood. There are big differences between different qualities of bioenergy wood, Spruce wood have less species, especially in logging residues. Spruce has moreover increased its distribution during the last decade. Spruce could therefore be harvested more intensively than deciduous tree species. In general, however, bioenergy wood was species rich, including also red-listed species. Another study made in a managed 25000 ha boreal forest landscape, showed that several species have the main part of the population in clear felling stumps: eight out of 39 beetle species had more than 50 % in clear felling stumps. In yet another study we found that beetle diversity per stump decrease in stumps on clear cuts where 25 % of the stumps were retained compared to a non-harvested clear cut. This suggest that even with the high retention levels presently recommended, species will be lost if most clear cuts in a region are stump harvested. But it is possible to select among qualities of bioenergy wood and harvest the types with lower value for biodiversity.

ENHANCING MOBILIZATION FOR CONSERVATION GOALS VIA COMPELLING STORIES AND MYTH

David Johns

Portland State University

Most conservationists know that the most effective vehicle for communicating conservation goals and their importance to audiences whose support is needed for success is story. But they do not always consider the essential elements what makes stories persuasive and compelling—what makes stories lead to action in support of conservation goals. Stories must appeal to an audiences needs, emotions and myths (what is sacred and just); they must be familiar; audiences must be able to find themselves in the story's characters; they must be memorable

and vivid; they must answer questions existing stories fail to answer; stories must be conveyed with evocative symbols and tellable in a variety of media and time frames from soundbites, songs and short films to full-length narrative films and books; and the messenger and channels must be right. There is no substitute for charismatic storytellers, but the elements of story can be mastered by others. Compelling stories must become a bigger part of conservation work if needed support is to be mobilized on behalf of the Earth's degraded landscapes imperiled species. This paper will explain these elements of story, why each is important, and how conservationists can improve their storytelling ability. The relation of story to other elements of mobilization will be briefly noted.

LESSONS FROM ORGANIZING LARGE LANDSCAPE CONSERVATION AND THE ROLE OF NETWORKS

David Johns

Portland State University

Charlie CHESTER, Brandeis University

As early as the 1930s, the Ecological Society of America called for protecting large areas representing each ecosystem type. By the early 1990s it was apparent to conservation activists and scientists that existing protected areas were losing species and function because they were often too small, in the wrong places and were becoming islands. The Mesoamerican Paseo Pantera (Path of the Panther) was a pioneering effort to link large habitat blocks. In 1991 the Wildlands Project (now Wildlands Network) launched an effort to create a North American-scale system of large connected protected areas focused on top carnivores, wide-ranging species and ecosystem function. In 1993 the Yellowstone to Yukon Conservation Initiative was founded to ensure connectivity and enhance protection in that part of the Rocky Mountains and adjacent areas. Similar large-scale conservation efforts emerged in the late 90s around the globe, including Australia, Russia, and southern Africa. These large-scale conservation initiatives have generated similar lessons, the most important being the need to add value to existing conservation work. They must bring a bold vision & inspiration, new funding, science to bear on goals, a geographically broad structure for advocacy, institution & community building, and information sharing. There are other lessons as well—the importance of good leaders, the right core of founders, the use of iconic species and places to gain support for the less dramatic, the ability to recognize the strengths and weakness of NGO networks across large geographies, and honesty in addressing conflicts of interest among participant NGOs.

AUGMENTING SURVEY DATA WITH COMMUNITY KNOWLEDGE TO INFORM A RECOVERY STRATEGY FOR AN ENDANGERED SPECIES IN CANADA: IDENTIFYING IMPORTANT AREAS OF HABITAT FOR PEARY CARIBOU ACROSS THE CANADIAN ARCTIC ARCHIPELAGO

Cheryl Johnson

Environment Canada

Sarah BANKS, Environment Canada

Peary caribou (*Rangifer tarandus pearyi*) is listed as an endangered species under the Canadian Species at Risk Act (SARA). The Minister of the Environment is legally required to prepare a Recovery Strategy for this species under SARA that includes an identification of its critical habitat where possible. Critical habitat is protected under Canadian federal law once it is identified in a species' recovery strategy. We describe how available survey and field data on Peary caribou were used in combination with community knowledge on the species' space use patterns to model patterns of habitat use for Peary caribou across the Canadian Arctic Archipelago. We used hierarchical approach to develop a series of models that examined the relative importance of climate, vegetation and other habitat attributes, as well as human development, in describing and predicting patterns of habitat use for Peary. We describe how the spatial predictions from the habitat models were used to help inform the identification of critical habitat in the federal recovery strategy for Peary caribou. Our methods highlight the usefulness of incorporating community knowledge to help fill information gaps on species habitat use. Our results indicate that climate is a major factor influencing Peary habitat use at broad scales. We assess the models ability to predict patterns of Peary habitat use to past climate conditions and use the results to inform model performance at forecasting future patterns of habitat use to changing climate conditions. The implications of potential future changes to the species' patterns of occupancy and habitat use to the species' recovery are discussed.

NEW THREAT FROM AN OLD ENEMY: THE ROLE OF THE FERAL CAT IN THE CURRENT DECLINE OF MAMMALS ACROSS NORTHERN AUSTRALIA

Chris Johnson

University of Tasmania

Many species of small marsupials and rodents are currently declining across vast areas of the tropical savannas of northern Australia. As a result, several are threatened with extinction. The traits of declining species point to predation as the cause, and circumstantial evidence implicates the feral cat. This is surprising, because cats have been in northern Australia for more than 100 years – why might they have emerged as a

threat only recently? We identify several factors that explain this. First, we show that cats prefer to hunt in areas recently burnt by hot fires, where their hunting success is optimised and, consequently, mortality rates of small mammals are extreme. Evidently, changes in fire regimes have amplified the predation pressure on small-mammal populations. Second, dingoes suppress the activity of cats, and force changes in their behaviour that could reduce hunting success. Recent declines of dingoes could therefore have released cat populations. Third, cats are highly adept at locating sparse populations of small mammals and concentrating their hunting on them, so that the pressure on small mammals is sustained even after they have been made rare. Our studies illustrate how changes in ecological conditions can cause increased impact of long-established invasive predators. They also show how ecological factors can be managed to reduce the impact of cats in the future.

SYMPOSIUM ID 65: CONSERVATION MANAGEMENT PRIORITIZATION WITH CITIZEN SCIENCE DATA AND SPECIES ABUNDANCE MODELS

Alison Johnston
Cornell University

Efficient use of conservation resources requires prioritization of the locations in which the largest number of target species will benefit from the management. Many migratory species also use landscapes dynamically and conservation action could also be targeted to the seasons that would benefit the greatest number of individuals or species. Dynamic conservation has the potential to be a very efficient tool, particularly for migratory species, but it requires detailed knowledge of the spatial and temporal distribution of species. Additionally, these management actions will often have the greatest impacts when targeted where populations are most abundant, rather than just species presence. We demonstrate how relative abundance can be modeled with eBird, a large citizen-science dataset. These estimates of abundance can be used to more accurately prioritize times and locations for implementing conservation measures and we describe the application of these models in current conservation programs of dynamic conservation. We compare fine-scale weekly estimates of relative abundance and occurrence for migratory waterbird species in California, U.S.A. We find estimates of abundance are not linearly related to occurrence and these patterns vary by species. Occurrence and abundance exhibit markedly different seasonal trends and locations prioritized for conservation by occurrence models have only 10-58% overlap with locations prioritized by abundance models. These results highlight the ability of citizen-science data to produce models of species abundance at a fine spatial and temporal resolution throughout an entire annual cycle. The results

also demonstrate that occurrence models will not typically identify the locations of highest abundance that are vital for conservation of populations.

CONSERVATION OF CRITICAL HABITATS FOR MONTANE BIRDS THROUGH COMMUNITY PARTICIPATION IN WESTERN HIMALAYAS

Virat Jolli
Biodiversity and Environmental Sustainability
Matthew J. GRAINGER, Newcastle University

The construction of hydro-electric projects in Sainj Valley has negatively affected critical habitat for montane bird communities. These habitats can be restored but only if local communities are willing to participate. However, there is lack of knowledge among local people regarding the rich biodiversity of this region, especially avian-fauna. Therefore to inform local people of the importance of biodiversity in this region we initiated a citizen science program to target local school children and educate them regarding the importance of conservation of avian habitats. Environmental awareness lectures were delivered in four different schools of Sainj Valley. From each school a group of five students were selected and given training in bird identification, and counting. With the help of these students a community-based bird survey was carried out in the Valley. They learned to identify and count the birds of Sainj Valley. It was the first time that local people from the valley participated in bird survey. The boys and girls students have shown good efficiency and during the project, girls were found to be good bird surveyors and we would like to employ them in future surveys, this could lead to social change in Sainj Valley. The study showed promising future for citizen science projects in Western Himalayas. However local people will only participate if they can see some economic benefit from conservation. Therefore for effective conservation planning we need to launch biological conservation projects with collaboration of local people. It will ensure long term benefits for the region.

A CENTURY-OLD GRASSLAND LEGACY ON PLANTS AND BUTTERFLIES IN SWEDISH PRODUCTION FORESTRY CLEAR-CUTS

Dennis Jonason
Linköping University
Torbjörn BLIXT, Linköping University; Mathias IBBE, Linköping University; Per MILBERG, Linköping University; Albert TUNÉR, Linköping University; Lars WESTERBERG, Linköping University; Karl-Olof BERGMAN, Linköping University

Traditionally managed semi-natural grasslands (i.e., unfertilised pastures and meadows) have due to massive land-use changes lost more than 90% of the area existing a century ago. However, effects of previous habitat size and configuration

on biodiversity may linger for long times. In this project, we investigated whether signs of historical grassland management can be found in clear-cuts after at least 80 years as coniferous production forest by comparing butterflies and plants between clear-cuts with a history as meadow and as forest in the 1870s in Sweden. Study sites were selected using old land-use maps and data on present-day clear-cuts. Clear-cuts with a history as meadow had on average 34% and 19% higher butterfly species richness and abundance, respectively, and 64% and 110% higher total plant species richness and of grassland indicator species, respectively, than did clear-cuts with a history as forest. Plants are known to respond more slowly to environmental changes compared to butterflies and being dependent on host plants and nectar sources, butterfly diversity may correlate with the land-use legacy of the local plant community. The study illustrates the importance of considering land-use legacies for understanding the distribution of species in fragmented landscapes, as well as in ecological research, conservation and management.

76- WHAT DOES IT TAKE TO SAVE SPECIES: A CASE STUDY FROM MAURITIUS

Carl Jones

Durrell Wildlife Conservation Trust

Several species of critically endangered Mauritian birds have been restored from small populations. Three of these: the Mauritius Kestrel *Falco punctatus*, Pink Pigeon *Nesoenas mayeri* and Echo Parakeet *Psittacula eques* have recovered from known populations of 12 or less, to several hundred. This has been achieved by improving survival and/or breeding success through addressing proximate limiting factors. Hence nest shortages are corrected by enhancing nesting-sites and the provision of artificial nest-boxes; high rates of predation corrected by predator control, and the other limiting factors corrected respectively by competitor control, disease control and supplemental feeding. The approach starts with addressing several possible causes of the species' rarity and then reducing management until only the main ones are being corrected. The populations have all responded quickly to this management and it needs to be maintained while the ultimate causes of rarity, such as habitat modification or exotic predators, are corrected.

HOW HAVE INVASIVE MAMMAL ERADICATION PROJECTS BENEFITTED NATIVE ISLAND FAUNA? A SYSTEMATIC REVIEW

Holly Jones

Northern Illinois University

Nick HOLMES, Island Conservation ; Peter KAPPES, Oregon State University ; Ilse CORKERY, University College Cork ;

Brad KEITT, Island Conservation ; Karl CAMPBELL, Island Conservation ; Bernie TERSHY, UC Santa Cruz ; Don CROLL, UC Santa Cruz ; Dena SPATZ, UC Santa Cruz ; Stuart BUTCHART, BirdLife International ; Doug ARMSTRONG, Massey University ; Phil SEDDON, University of Otago ; Stephen KRESS, Cornell University ; Colin MISKELLY, Te Papa Tongarewa ; Andrew BURBIDGE, Retired ; David TOWNS, Auckland University of Technology ; Alfonso AGUIRRE, Conservacion de Islas ; Araceli SAMANIEGO-HERRERA, University of Auckland ; Steve EBBERT, US Fish and Wildlife Service ; Mark RAUZON, Laney College ; Franck COURCHAMP, Laboratory of Ecology Systematics & Evolution of the University Paris-Sud ; Elsa BONNAUD, Laboratory of Ecology Systematics & Evolution of the University Paris-Sud ; Gerard ROCOMURA, Island Conservation Society ; Sally PONCET, FIQQ IZZ Stanley, South Georgia Surveys ; Steffen OPPEL, Royal Society for the Protection of Birds ; Richard CUTHBERT, Royal Society for the Protection of Birds

The number of invasive alien mammal eradications has grown substantially over the last few decades, with the primary goal of biodiversity protection including protecting threatened native species. The benefits of eradication to native island species have not yet been systematically collated at the global scale. We first aimed to collate data on potential beneficiaries of invasive mammal eradication globally by quantifying highly threatened mammals, birds, reptiles, and amphibians breeding on invasive mammal-eradicated islands in the past 10 years from an existing database. We found 270 populations of 117 globally threatened species potentially benefitted from invasive mammal eradication on 159 islands across the globe. This represents 17% of globally threatened island-breeding species, leaving conservation opportunities for more threatened species benefits with further invasive mammal eradication efforts. Next we did an in-depth systematic review of realized beneficiaries, in which we identified species that 1) increased in population size or reproductive success, 2) naturally recolonized an island after being extirpated, or colonized an island for the first time (unassisted colonization or recolonization) and/or 3) had a population translocated (conservation introduction or reintroduction) following invasive mammal eradication. We assessed realized species benefits for Australia, Ecuador, France, Mexico, New Zealand, the Seychelles, the United Kingdom, and United States of America, where >80% of eradications have taken place globally. We used established databases, a literature review, and expert interviews to procure the relevant information to compile this list. At least 448 populations of 199 species benefitted, including 60 populations of 26 globally threatened species, from 250 invasive species eradications across 133 islands. We find significant potential to focus on post-eradication reintroduction of seabirds.

DO REDD+ SOCIAL SAFEGUARDS REACH THE 'RIGHT' PEOPLE?

Julia Jones

Bangor University

Mahesh POUDYAL, Bangor University ; Bruno RAMAMONJISOA, University of Antananarivo ; Rina MANDIMBINAINA, University of Antananarivo ; Alex RASOAMANANA, University of Antananarivo ; Neal HOCKLEY, Bangor University ; James GIBBONS, Bangor University ; Sarobidy RAKOTONARIVO, Bangor University

There is extensive debate about the potential impact of the climate mechanism REDD+ on the livelihoods and welfare of forest-dwelling people. To provide carbon credits, a forest carbon scheme must slow the rate of emissions. If this is achieved by slowing the expansion of agricultural land there is clearly a local cost. Madagascar has attracted significant investment in REDD+ and has a number of pilot projects with World Bank support. We focus on one such REDD+ pilot - the Ankeniheny Zahamena Corridor (CAZ). Some 2500 households around the corridor have been identified under World Bank safeguards as containing 'project affected people (PAPs)' and are receiving individual income generation projects as compensation. There has been controversy as to how such people are identified. We carried out intensive field work in one administrative unit, mapping the location of each household and selected a random sample stratified by location for detailed household interviews about livelihoods, food security, and assets. We compared the characteristics of households identified as eligible for compensation with those not identified as eligible. We found that people living closest to the forest, with livelihoods most dependent on the forest were less likely to be identified as PAPs while those living closest to the village centre and with powerful social positions were more likely (evidence perhaps of elite capture of the benefits being distributed). Given the extremely poor information available on local populations (even the location of quite significant villages is not available from maps), and the unwillingness of people's whose livelihood depends on illegal agricultural expansion to self-identify, it is unsurprising that the official process faced challenges. We question whether the approach of identifying and compensating particular households is practical in such settings and discuss alternatives.

CONTINENTAL-SCALE REWILDING OF AN INVADED ECOSYSTEM: AUSTRALIA

Menna Jones

University of Tasmania

Chris JOHNSON, University of Tasmania ; Mike LETNIC, University of New South Wales

Restoring ecosystem function by reintroducing highly interactive species, termed rewilding, is of high interest worldwide. Australia has the highest loss of mammal fauna in the world and is the largest island or continent on which there has been a general shift to an alternative stable state dominated by invasive species. Australia is an old and mostly arid continent with low ecosystem productivity, in which the relatively small human populations have had major impacts. There are plenty of rewildable landscapes, which are not intensively used for competing purposes but with lost or degraded ecological function. We will explore what has been lost through time in Australia's vertebrate fauna, from pre-aboriginal to aboriginal and recent European influences, and the extent to which it is possible to restore ecological function. Australia has some unique features that distinguish rewilding programs from those in Europe and North America. The Australian biota evolved in a higher degree of isolation for a longer period of evolutionary time than faunas on other continents, with the consequence that extinctions have resulted in the loss of entire taxons, such as diprotodons, genyornis and thylacoleonids. In contrast to northern continents, there are no close ecological analogues for some of the species and functional groups that have gone extinct in Australia. Another challenge is that population declines of once-abundant species have often preceded understanding of their ecological role in ecosystems. Consequently, important drivers of environmental change remain undiagnosed because we simply don't know how species which are now rare or extinct shaped ecosystems in the past. Invasive species dominate ecological communities across much of Australia. Reintroducing strongly interactive species may help to curb the interactions of these species. Some invasive species may, or may not, serve as functional analogues for extinct species.

SYMPOSIUM 175. STAKEHOLDERS PLAY A VITAL ROLE IN THE INTERGOVERNMENTAL PLATFORM ON BIODIVERSITY AND ECOSYSTEM SERVICES (IPBES)

Bengt Gunnar Jonsson

Mid Sweden University

In January this year the third plenary meeting of IPBES was held in Bonn Germany. In addition to outlining a set of assessments (thematic and regional), the member governments also adopted a strategy for engaging stakeholders in IPBES. In this respect stakeholders has a wide definition and includes, knowledge holders, rights holders and well as end-users of the IPBES products. The strategy establishes the possibility to create an open-ended network of organizations representing all these aspects and hence an exciting opportunity to link a

broad range of stakeholders with interests in biodiversity and ecosystem services. Stakeholders are considered essential for the four functions of IPBES (assessment, knowledge generation, policy support and capacity-building). The engagement strategy includes mobilizing stakeholders as contributors to the four functions, promote the use of the Platform's products, and to facilitate the participation of observers during IPBES Plenary sessions including reviewing documents that will be submitted to Plenary meetings. This highlights the role of scientific organizations, such as SCB, to be active in supporting the scientific quality of the work of the platform.

WILL FOREST CONSERVATION AREAS SAFEGUARD IMPORTANT FUNCTIONAL DIVERSITY OVER TIME?

Mari Jönsson

Swedish University of Agricultural Sciences
*Alejandro RUETE, Swedish University of Agricultural Sciences ;
Tord SNÄLL, Swedish University of Agricultural Sciences*

Biodiversity in conservation areas has rarely been linked to the range of functions the organisms perform in communities and ecosystems; i.e., their functional values. Incorporating functional values in biodiversity monitoring systems could add novel perspectives of the status of biodiversity in conservation areas over time. Based on regional monitoring data from 36 boreal forest old-growth conservation areas, we analyzed changes of several biodiversity components with multiple forest functional values over time. We detected significant reductions in the abundance of photoautotrophic indicator cyanolichens occurring on deciduous trees already after ten years, despite non-significant changes in their host substrates. Abundances of indicator pendulous lichens *Alectoria sarmentosa* and *Bryoria nadvornikiana* had also decreased, despite overall significant increases in the volume of large conifer host trees. In contrast to these lichens, the average abundances of saprotrophic fungi decaying coniferous deadwood and common parasitic fungi on deciduous trees (*Fomes fomentarius*) and coniferous trees (*Fomitopsis pinicola*) remained unchanged. The studied cyanolichens and fungi generally had similar area-based extinction rates over ten years, whilst only cyanolichens had substantially lower colonization rates. Reduced abundances of large foliose nitrogen-fixing cyanolichens may have negative effects on the nitrogen budget of the studied forests and represent a reduction in resources (e.g., food, material and shelter) for invertebrates, gastropods and birds. Reduced abundances of pendulous lichens represent a reduction in winter forage for reindeer and caribou. Unchanged abundances of deadwood and associated fungi represent an important supporting function for ecosystem services such as nutrient cycling, carbon storage and soil formation. Amid a severely fragmented landscape, conservation areas seem to struggle in preserving some of the basic old-growth forest functional values.

ACTIVELY LEARNING ABOUT CONSERVATION PRIORITIES

Lucas Joppa

Microsoft Research
Piero VISCONTI, Microsoft Research

Understanding where species occur (and why) is one of ecology's oldest questions - and of critical importance for biodiversity conservation. This is particularly true for invasive and endangered species, for which the distribution is often changing rapidly and is relatively unknown, and the collection of samples requires extensive resources. Active machine learning makes use of statistical models to estimate the expected information content of potential additional records, and identify the data points which would improve the accuracy of the models the most. This technique has been used for training image recognition models, web-content classifiers, among other uses, but has not yet been applied to ecological modelling. We test the applicability of active learning methods in generating the most accurate species distribution model with the fewest number of records. We use synthetic datasets of virtual species with known environmental responses and distribution, as well as real datasets of invasive plant species, and compare the performance of active and passive learning, stratified sampling and other methods commonly used to design field surveys. Performance is measured as the rate at which the model accuracy increases with number of data points collected and used for training species distribution models. We show that active learning methods are superior to all other sampling methods tested and provide recommendations on which active learning method to use depending on the distribution model structure and complexity.

97-TAKE BACK THE BLOCK: AN URBAN CITIZEN SCIENCE PROGRAM

Rebecca Jordan

Rutgers University
Amanda SORENSEN, Rutgers University

It is clear that citizen science programs result in a vast array of ecological and social outcomes. Positive outcomes recently reported in the literature include advancing conservation goals and increasing socio-ecological stewardship. Using data from the Mosquito Stoppers citizen science program, we will show that citizen science has the potential to increase socio-ecological resilience. This is supported by evidence that the act of participation in data gathering in socio-ecologically framed citizen science projects can: (1) Increase individual efficacy to drive community outcomes and that this increase in perceived efficacy need not be paired with actual efficacy; and (2) Help to build trust among members of similar or different communities that share goals. Mosquito Stoppers is the result of a collaboration between the University of Maryland Baltimore

County, The Cary Institute of Ecosystem Studies, and Rutgers University. This project is aimed at engaging local individuals of West Baltimore, MD, USA in mosquito control. This talk will first discuss how issue framing may affect the citizen scientists' perception of individual contributions and motivation for participation. Next we will discuss data about individuals' belief in personal efficacy in mosquito control, perception of mosquito effects on individuals' lives, and perception of municipal efficacy in meeting public needs. We found that individuals were less likely to report that mosquitoes kept them from enjoying the outdoors post Mosquito Stoppers participation. Additionally, individuals who reported being satisfied with their municipalities' handling of mosquitoes and pests dropped by half after participation. Finally, belief in personal efficacy in the process of mosquito remediation increased post participation. We will conclude that our findings demonstrate how appropriate coordination and framing can contribute to not only to local land stewardship but also the overall system resilience.

TWENTY TWO YEARS OF MONITORING HAWKSBILL TURTLE (*ERETMOCHELYS IMBRICATA*) NESTING AT REDANG ISLAND, TERENGGANU, MALAYSIA

Juanita Joseph

Universiti Malaysia Terengganu

Abdul Shukor YUSOFF, Universiti Malaysia Terengganu ; Siti Norazliyana ALI, Universiti Malaysia Terengganu

A tagging and nesting study was conducted from 1993 to 2014 on the hawksbill turtles nesting at Redang Island, Terengganu, Malaysia. A total of 37 individuals were tagged over the 22-year period, and deposited a total of 206 egg clutches. During the early years (1993 – 2004), all nests for in-situ incubation had to be purchased from licensed egg collectors. Only 89% of nests were incubated during that period, while the remaining nests were sold by the licensed egg collectors at the market. Finally in 2005, the beach was gazetted as a turtle sanctuary and had stopped the collection of eggs. From 1993 to 2014, a total of 196 nests were protected and from these about 12,857 healthy hatchlings were released back to the sea. The nesting females tagged ranging from 0 to 6 individuals per year, with average curved carapace length and width of 82.85 ± 6.32 cm and 72.24 ± 2.71 cm, respectively. Females nest every 2 years on average, although remigration intervals of individual females do vary (range: 1 to 5 years). The average clutch frequency was 6 nests per female with average clutch size of 123 eggs, and average nesting interval of 15 days. The average incubation period was 58 days with an average hatching success of 62.18 %. Egg losses were attributed to red ants *Darylus* sp.(12.2%), crabs *Ocypodes* sp.(10.3%), maggots from *Megasaleria scalaris* larvae (14.6%), fungus *Fusarium* sp. and *Aspergillus* sp.(22.4%), plant roots (1.2%) and other unknown causes (39.3%). Apart from that, monitor lizards (15.5%), and nesting mothers (4.9%) also

destroyed some of the nests. Hawksbill turtle nesting density is very low in Redang Island, however it is hope that long-term protection of hawksbill turtles and their eggs will one day help increase the population at this area.

INDIGENOUS METHODS, KNOWLEDGE AND VOICE: A MI'KMAW FIRST NATION APPROACH TO LEARNING ABOUT FIRE'S RELATIONSHIPS TO THE LAND

Shalan Joudry

Dalhousie University

Karen BEAZLEY, Dalhousie University ; Annamarie HATCHER, Cape Breton University

This study addresses the need for both Mi'kmaq teachings about land fire history and ecology in Nova Scotia, Canada, and Mi'kmaq-appropriate research design and implementation. Fire is one of the four sacred elements for the Mi'kmaq and it represents a powerful force in nature to change and create habitat. Through history humans have been an ecological factor in reacting to, relating to, and learning from fires, however, very little is documented about the relationship between fire and the Mi'kmaq. There has been an accelerated bloom of academic investigations on Indigenous peoples and land fire relationship histories in North America. Many academic studies on North American Indigenous peoples-fire history use mainstream scientific methods such as paleoecology and European-based historical accounts but often lack First Nations community participatory approaches. As more biological research invites Indigenous knowledge, we also have yet to see purely Indigenous voices welcomed within mainstream ecological topics that are allowed to stand alone without the framework of mainstream science methodologies. Our research design follows principles of Indigenous methodologies with a blend of qualitative approaches, including Elder Advisory check-points, reflexive journaling, incorporation of Mi'kmaq language, and ceremony. With the engagement of Mi'kmaq researchers, the project went through various stages of visioning and redirecting to allow for a different worldview than mainstream science formats. The land fire topic was stretched out and reshaped into a way of looking at the land, and questioning the land and our people in a more culturally-appropriate and meaningful way, which often included methods coming from a purely Mi'kmaq culture, language and rigor. Both the methodology and stories about fire provide valuable lessons for future biological conservation work when incorporating Indigenous or Traditional Ecological Knowledge into the research design.

SYMPOSIUM ID 20 HOW TO MAKE THE MOST OF IT - NATIONWIDE CONSERVATION TRIAGE ACROSS A WEST AFRICAN BIODIVERSITY HOTSPOT

Jessica Junker

Max-Planck Institute for Evolutionary Anthropology
Christophe BOESCH, Max-Planck Institute for Evolutionary Anthropology; *Theo FREEMAN, Forestry Development Authority*; *Roger MUNDY, Forestry Development Authority*; *Colleen STEPHENS, Max-Planck Institute for Evolutionary Anthropology*; *Hjalmar KÜHL, German Centre for Integrative Biodiversity Research*

Liberia includes almost half of the remaining Upper Guinean forests - a biodiversity hotspot and one of the most critically fragmented regions on the planet. Despite government plans to establish a network of conservation areas to cover at least 30% of Liberia's forests, only 2% of the country's land area is currently protected. We therefore systematically collected nationwide data on chimpanzee abundance, large mammal and tree diversity and human threats and related these to environmental and human impact variables. We developed spatial prediction models that served as base-layers for prioritization in MARXAN. We then identified and evaluated large mammal and biodiversity priority areas under different conservation scenarios. We improved upon standard software output to evaluate spatial properties of selected sites, determine site-specific target contributions, and estimate potential wildlife and biodiversity loss within logging and mining concessions. Last, we also assessed whether existing proposed protected areas (PPAs) achieved pre-determined conservation targets. The optimal conservation area network contained a candidate list of 92 areas that maximized biodiversity and chimpanzee abundance, minimized threats, and accomplished the preservation of 30% of Liberia's forests. It included more than half of West Africa's second largest chimpanzee population, which spatially coincided with that of some of the most species-diverse large mammal and tree communities. Logging and mining concessions largely overlapped with existing PPAs and conservation priority areas established in this study, and considerably increased their fragmentation. Existing PPAs, however, only partially covered our areas of prioritization and proved insufficient in meeting conservation targets. Our results demonstrate that in order to achieve a compromise between effective biodiversity protection and development in tropical Africa, evidence-based conservation planning is key.

SUCCESSION OF WOOD-DECAYING FUNGI IN EARLY-SERIAL FORESTS AFTER NATURAL DISTURBANCES

Kaisa Junninen
Metsähallitus

Fires and windstorms are among the most important natural disturbances in boreal forests, and the early-seral forests developing after these disturbances have been found to host diverse and distinct species assemblages. As dead wood

is abundant after stand-replacing disturbances, organisms dependent on dead wood, such as polypore fungi, are thriving during the early phases of forest succession. Results from two studies from eastern Finland are presented, one monitoring polypores in windblown areas and another one from burned areas. A 10-year monitoring of fallen trees and polypores in two windblown areas show that fallen pines can survive lying even for ten years, unlike fallen spruce trees. The number of species within the polypore community increases with time along with the change in the species composition, and ten years after disturbance some species of conservation concern, such as *Hapalopilus aurantiacus*, already inhabit fallen trunks. The polypore succession after fire has been monitored for 22 years in two forest stands that were burned for restoration purposes. On the study sites, burning has proved to be effective in facilitating the establishment of red-listed species. The post-fire succession of polypores on deciduous trees has almost come to its end within 22 years, whereas the number of species on conifers is still very high, including several species of conservation concern. The results highlight the importance of early-seral forests as habitat for organisms dependent on dead wood.

CAN YOU HAVE YOUR FISH AND EAT THEM TOO? EFFECTIVENESS OF PERIODICALLY HARVESTED CLOSURES FOR ACHIEVING MULTIPLE OBJECTIVES

Stacy Jupiter

Wildlife Conservation Society

Jordan GOETZE, The UWA Oceans Institute, The University of Western Australia; *Paul CARVALHO, Center for Coastal Marine Sciences, California Polytechnic State University San Luis Obispo*; *Joachim CLAUDET, National Center for Scientific Research (CNRS), CRIOBE*; *Richard HAMILTON, The Nature Conservancy*; *Fraser JANUCHOWSKI-HARTLEY, Geography, College of Life and Environmental Sciences, University of Exeter*; *Timothy LANGLOIS, The UWA Oceans Institute, The University of Western Australia*; *Rebecca WEEKS, ARC Centre of Excellence for Coral Reef Studies, James Cook University*; *Crow WHITE, Biological Sciences Department, California Polytechnic State University San Luis Obispo*; *Shaun WILSON, Marine Science Program, Department of Parks and Wildlife*

Historically, Pacific Island communities managed marine and coastal resources to achieve social, cultural and ecological objectives, which include: enhancing long-term fisheries sustainability; increasing short-term harvest efficiency; sustaining biodiversity and ecosystem functions; supporting local economy and livelihoods; and maintaining customs. Periodically harvested closures (PHCs) are commonly employed by Pacific communities to reach these objectives, in particular increase catch efficiency. However, increases in yields in PHCs, due to improved access to markets and technology, may be

compromising harvest efficiency and other objectives. We evaluate PHCs and address this potential problem through theoretical modelling, meta-analysis of empirical case studies and a literature review. Our theoretical model suggests that when fish behaviour is considered, PHCs can be a more efficient strategy for maximizing fish biomass and yield than permanent no-take areas or non-spatial management. Our meta-analysis indicates that PHCs can be effective at carrying more targeted fish biomass and abundance prior to a harvest than fished areas, and that they can be used as a fish reservoir for local communities during harvest events. The effectiveness of PHCs for providing a fisheries benefit to communities is greatest for large, old closures, where fishing pressure outside the PHC and harvest intensity inside is high. The literature review revealed that no data are yet available to evaluate more complex questions of recovery potential and whether PHCs can maintain absolute yields. Such questions are therefore being addressed using simulated fisheries models calibrated with empirical data from multiple PHC harvest events in Fiji. These models will provide guidance for local communities, describing sustainable PHC harvesting regimes and appropriate size of PHCs relative to the fishing grounds for best achieving socioeconomic and ecological objectives of this management system.

THE EFFECT OF FOREST MANAGEMENT, GRAZING AND AFFORESTATION ON WOOD-INHABITING FUNGI OCCUPYING DEAD WOOD OF DIFFERENT DIAMETER FRACTIONS

Katja Juutilainen

University of Jyväskylä

Panu HALME, University of Jyväskylä ; Heikki KOTIRANTA, Finnish Environment Institute, Biodiversity Unit ; Mikko MÖNKKÖNEN, University of Jyväskylä

Forest management has caused severe ecological degradation throughout the globe. One of its most prominent consequences is the drastic change in dead wood profile and, consequently, in the dead wood dependent biota. Wood-inhabiting fungi are, considering ecosystem functions, the most important species group utilizing dead wood, because they are responsible for majority of the decaying process. The earlier research focusing on the effects of forest management on wood-inhabiting fungi has strongly focused on large dead wood pieces (i.e. coarse woody debris, CWD), even though it has been shown that a major part of fungal diversity utilizes (also) small dead wood pieces (i.e. [very] fine woody debris, [V]FWD). We studied the effects of 1) earlier forest management, 2) grazing history and afforestation on the wood-inhabiting fungi occupying all dead wood diameter fractions including the smallest pieces. The study was conducted in boreal forests in Central Finland. We first surveyed corticioid and polyporoid fungi from 113 269 dead

wood pieces in 8 previously managed and 8 natural coniferous forests. In addition, we surveyed 66 929 dead wood pieces in 4 natural broadleaved herb rich forests, 4 afforested birch dominated fields and 4 birch dominated wood pastures. In both studies, we found differences among fungal communities occupying FWD in different forest types. Moreover, many rare species were detected only in one or two forest types. Spruce dominated natural forests and, surprisingly, afforested fields were especially rich in rare species. The main focus in forest conservation and restoration efforts may still be targeted on increasing CWD volume in managed landscapes, but simultaneously reasonable volume of FWD must be retained to ensure that specialist species utilizing it will not be driven to local extinctions. Combining this recommendation with increasing pressure for energy wood harvesting will remain as a challenge.

HUMAN LEOPARD CONFLICT - AN ALARMING INTIMIDATION FOR ITS CONSERVATION IN A HIMALAYAN ECOSYSTEM, PAKISTAN

Muhammad Kabir

Quaid-i-Azam University Islamabad

Angie APPEL, www.leopards.wild-cat.org ; Muhammad Ali NAWAZ, Quaid-i-Azam University Islamabad

Livestock depredation by Leopards (*Panthera pardus*) is one of the global key conservation issues in landscapes with limited wild prey resources. Any attempts to mitigate Human Leopard conflict and conserve the species involved in conflict should be based on an unequivocal understanding of the conflict patterns. A household survey was conducted to quantify livestock losses resulting from depredation by Leopards in Machiara National Park, Pakistan. A total of 301 livestock were killed between June 2007 and August 2008. The extent of loss varied in different months, small-bodied livestock such as goat and sheep were more vulnerable. Domestic animals were killed more frequently after dark than during daylight hours. About 139 Leopards have been killed between 2000 and 2013, mostly in response to livestock depredation. Accurate information about the diet of Leopards is needed to properly design conservation strategies. The study examined Leopard diet composition by analyzing 141 scat samples collected in 2010. Leopards consumed 23 different prey species comprising 7 large mammals, 11 medium-sized and five small mammals. Livestock constituted a substantial part of Leopard diet (40.43%) followed by wild meso mammals (29.75%) and small mammals (18.97%). Consumption of livestock and wild prey species did not significantly differ in winter and summer diet composition. Results confirmed the claims of local people that Leopards kill livestock, and also documented the proportion of wild prey and domestic livestock, thus providing a scientific base to take effective conservation measures. Factors most closely associated with livestock depredation included decline

of natural prey, lacking herding and guarding practices. Local people repeatedly use pastures where Leopards are known to hunt. We suggest widespread local community education, proactive Human-Leopard conflict management, particularly through adopting carnivore-friendly livestock protection measures.

IMPACTS OF INSTITUTIONAL CHANGE ON RESOURCE SUSTAINABILITY: EDIBLE CATERPILLARS AND MIOMBO WOODLAND CONSERVATION IN NORTHERN ZAMBIA

Rhoda Nthena Kachali

Zambia Wildlife Authority

James GAMBIZA, Rhodes University ; Graham WALLACE E, Frankfurt Zoological Society ; Andrea WALLACE P.C, Frankfurt Zoological Society

Availability of edible caterpillars is closely linked to healthy intact Miombo woodlands in Mpika District, northern Zambia. Without adequate trees and foliage, caterpillar populations plummet and local human communities lose a key source of protein and income. Field observations, structured interviews and focus groups were used to examine and understand institutions governing edible caterpillar use in three chiefdoms. Results showed that 82% of respondents harvested caterpillars; similarly, 77% were aware of rules and regulations for natural resource use, including traditional rules and taboos about harvesting passed down through successive generations. Of respondents aware of rules and norms, 88% had heard about them from traditional leaders. Lack of compliance with traditional governance systems was considered the driver of decline in edible caterpillar populations. However, only 19% of interview respondents reported incidents of community members being sanctioned for breaking harvesting rules, and sanctions were only mentioned twice during nine focus group discussions. Traditional leaders perceive that statutory frameworks have transferred their authority to government departments that fail to recognise traditional governance roles. While these departments are mandated to enforce statutory regulations for use of natural resources, they lack capacity due to insufficient resources. Both the traditional and government management systems have been rendered unenforceable, and thereby made caterpillar and other woodland products open-access resources. Commercialization has further eroded traditional conservation practices and incentives to overharvest are high; harvesters can earn ten times more for a five-litre bucket of caterpillars than for a similar quantity of maize, the predominant cash crop. There is an urgent need to mesh government policies with pre-existing traditional management institutions to enhance conservation and resource sustainability.

NOMADIC SPECIES AND HABITAT FRAGMENTATION - A LARGE SCALE CONSERVATION CHALLENGE FROM THE MONGOLIAN GOBI

Petra Kaczensky

University of Veterinary Medicine, Vienna

John PAYNE, Wildlife Conservation Society, Mongolia Program ; Bayarbaatar BUUVEIBAATAR, Wildlife Conservation Society, Mongolia Program ; Dennis A. HOSACK, Health, Safety, and Environment Department, Biodiversity Team, Oyu Tolgoi LLC, Mongolia ; Tsolmonjav PUREVSUREN, Health, Safety, and Environment Department, Biodiversity Team, Oyu Tolgoi LLC, Mongolia ; Saruul AMARSAIKHAN, Health, Safety, and Environment Department, Biodiversity Team, Oyu Tolgoi LLC, Mongolia ; Chris WALZER, University of Veterinary Medicine, Vienna

Asiatic wild ass (*Equus hemionus*) are among the most mobile of terrestrial mammals, ranging over thousands of square kilometers each year, a behavior that enables them to follow the unpredictable rainfall that characterizes the Gobi and to escape region-specific extreme weather events. Recent mining related infrastructure development, if not carefully managed, could fragment the range of this nomadic species in Mongolia. In summer 2013 we collared 20 Asiatic wild asses in the south-eastern Gobi. The goal of the project is to monitor space use and movement patterns, focusing on the impact of mining-related infrastructure and associated habitat fragmentation potentially caused by the Oyu Tolgoi (OT) copper and gold mine, the largest mining operations in the region. Collared wild asses are permanently "on the move" with straight line travel distances averaging 818 m/hour and 9.8 km between consecutive days. Over the 16 months monitoring period, individual wild asses have been roaming over areas of 9,942-63,641 km², covering a total area of 94,388 km². On average, 29% of wild ass locations have been in protected areas (accounting for 17% of the total range) and 22% within a 10 km restricted-entry strip along the international border with China (accounting for 6% of the total range). A dry summer followed by an unusual snowless winter in 2013/2014 highlighted the importance of specific water points. The international border fence with China is regularly approached by wild asses and walked along but never crossed. The unfenced 106 km-long OT mining road, with its currently low traffic volume of around 200 vehicles /day has been crossed a total of 100 times. Wild ass crossing times coincide with lowest traffic volumes, suggesting that if traffic volumes were to reach maximum projected traffic volumes of >1,600 vehicles/day, a significant barrier effect could be expected. We discuss the importance of our findings as a basis for achieving OT's Net Positive Impact goal.

ID38: APPLYING SITUATIONAL CRIME PREVENTION TECHNIQUES TO GLOBAL CONSERVATION CRIMES

Jessica Kahler

Michigan State University

Meredith GORE, Michigan State University

Conservation crime prevention techniques (e.g., patrolling) aiming to reduce poaching and illegal logging are in demand globally. Traditional conservation disciplines do not provide sufficient breadth or depth of training in crime prevention theories and methods. Conservation criminology is suited to provide alternative approaches and tools. One such approach is the 25 techniques of situational crime prevention (25 TSCP), which leverages 5 categories of 25 techniques to reduce crime: increase effort, increase risks, reduce rewards, reduce provocations, and remove excuses. The 25 TSCP is well known in reducing street crime: however, its suitability to conservation-based crimes is mostly unknown. The aim of this research is to adapt the 25 TSCP to conservation-based crimes. Our objectives were: apply 25 TSCP to conservation crime contexts and identify missing or unsuitable techniques within the context of conservation crime. We conducted focus groups with environmental professionals (n=80) centered on addressing illegal logging in two locations in Madagascar (Analamazaotra, Manompana) and a Delphi survey (n=20) with Global Tiger Initiative (GTI) professionals engaged in tiger (*Panthera tigris*) poaching-prevention activities. Participants identified conventional approaches (e.g., ranger patrols), discussed techniques unsuitable for species (e.g., removing targets), and added a novel category of techniques; strengthening traditional surveillance (e.g., Malagasy taboos for resource use). Results provide a foundation for developing a comprehensive TSCP tool that can be readily scaled and applied to different species and contexts (e.g., tiger poaching reduction in Sumatra, Indonesia). Interdisciplinary scholarship, such as a conservation criminology-based approach to TSCP, can provide novel tools and approaches to reduce conservation crimes.

HOW MUCH SHOULD WE COMPROMISE ON SETTING TARGETS IN CONSERVATION PRIORITIZATION PROBLEMS?

Andrea Kaim

Universität Leipzig

Systematic conservation planning is an essential part of biodiversity preservation. In the context of conservation prioritization problems, the total cost of the entire reserve system is highly dependent on how big we set targets (e.g. 10% or 30%) for conservation features (e.g. species or habitats). Thus, it is of interest for conservation planners, how targets could be adjusted in a reasonable way in order to decrease

total cost. The aim is to give a feature ranking based on their influence on the latter. Focusing on the minimum set coverage problem – an integer linear optimization problem (ILP) – we developed a method to rank features according to their influence on total cost. Since the computation time is often too high to solve the ILP, we approximated its optimal solutions by the results of a linear optimization problem (LP). For the feature ranking we used the shadow prices of the LP comparing it to rankings created by methods which used an ILP solver and the software Marxan which is based on a simulated annealing algorithm. The results showed that for the minimum set coverage problem shadow prices can be used to create an approximate feature ranking of impact on total cost – this tells us which features are having the greatest impact on the total cost. Furthermore we realized that many planning units selected for conservation by Marxan and the LP solver were the same. These results can be useful to improve Marxan. Additionally an online app has been developed which allows the user to compare the solutions of the ILP/LP solver and Marxan for some selected real-world conservation prioritization problems.

SYMPOSIUM #20- TOWARDS THE AUTOMATED DETECTION OF PRIMATES USING PASSIVE ACOUSTIC MONITORING: PROGRESS AND CHALLENGES

Ammie Kalan

Max Planck Institute for Evolutionary Anthropology
Roger MUNDREY, Max Planck Institute for Evolutionary Anthropology ; Oliver WAGNER, Max Planck Institute for Evolutionary Anthropology ; Stefanie HEINICKE, Max Planck Institute for Evolutionary Anthropology ; Christophe BOESCH, Max Planck Institute for Evolutionary Anthropology ; Hjalmar KUEHL, Max Planck Institute for Evolutionary Anthropology

Advancements in remote sensing technology have opened up the field of biomonitoring to new methods. Here, we investigated the potential for passive acoustic monitoring (PAM) of terrestrial animals using autonomous recording units (ARUs). Our study focused on primates, hitherto understudied in the field of applied bioacoustics. Firstly, we developed a customized algorithm for the automated detection of sounds produced by three sympatric primate species living in Tai National Park, Côte d'Ivoire: chimpanzee buttress drumming and the loud calls of the King colobus and Diana monkey. Secondly, we used occupancy modelling to derive occupancy probabilities for all three species from data generated by the algorithm, as well as from human collected data from point transects in the same area. Due to the probabilistic nature of automated approaches, algorithms produce false positive and false negative detections, thereby requiring some cleaning before accurate inferences can be made. Therefore, we investigated to what degree these data needed to be manually verified by a human expert to provide reliable occupancy

probability estimates. We simulated various ARU datasets for each species, with varying degrees of cleaning for false positive and false negative detections. Our results show that occupancy estimates from automatically processed ARU data were robust to the degree of cleaning effort and approximated occupancy probabilities obtained using human point transect data. Also, we found some variation in detection probability of sounds according to environmental covariates such as temperature, rainfall and time of day. We suggest that occupancy probabilities derived from PAM could be used to longitudinally monitor vocalizing terrestrial species and even act as an early-warning system for detecting population shifts or disturbances. We provide concrete recommendations on how the current method could be improved to further its application as a conservation tool in the field.

BUMBLEBEE DIVERSITY AND DENSITIES IN MODERATELY INTENSIFIED NORTHERN FARMLANDS

Eveliina Kallioniemi

Norwegian Institute for Nature Research

Jens ÅSTRÖM, Norwegian Institute for Nature Research ; Sandra ÅSTRÖM, Norwegian Institute for Nature Research ; Sondre DAHLE, Norwegian Institute for Nature Research ; Jan Ove GJERSHAUG, Norwegian Institute for Nature Research ; Heidi MYKLEBOST, Norwegian Institute for Nature Research ; Arnstein STAVERLØKK, Norwegian Institute for Nature Research ; Graciela RUSCH, Norwegian Institute for Nature Research

Recent pollinator declines have raised concerns about maintenance of biodiversity as well as stability of food production (Potts et al. 2010, Vanbergen et al. 2013). Despite bumblebees being important wild pollinators, landscape scale studies of bumblebees to date have mainly focused on highly modified landscapes (but see Diaz-Forrero 2013) while in moderately modified systems pollinators can show different responses to landscape use and features (Winfree 2013). We bridge this knowledge gap by studying factors influencing bumblebee diversity and abundance in a gradient of moderately intensified farming landscapes. We also investigate how spatial and temporal variability of food resources influence bumblebee diversity and density over the two-year study period. Using bumblebee and flower transects and ground-truthed land cover maps we calculated bumblebee diversity and density, flower resources and landscape characters for 25 Norwegian landscapes of 2km radius. We found that land-use diversity, measured as a Shannon diversity index, was positively correlated with both bumblebee diversity and density. Bumblebee diversity was also positively linked to flower diversity and abundance "flower poor" land, i.e. silage unfarmed land and grass crops. In contrast, bumble density was positively linked with forest cover, but negatively to "flower poor" land. These results suggest that while landscapes with abundant "flower poor" land-use types might not be able to sustain large

population sizes they can be important for populations of different species in providing other resources, such as variety of nesting places. This means that certain land-uses can have a trade-off between their influence on bumblebee diversities and densities. It is important for development of more pollinator friendly farming practices to understand how flower resources and land-use influence bumblebees in less intensively modified landscapes.

RESEARCH AND CONSERVATION OF LILYPAD WHITEFACE LEUCORRHINIA CAUDALIS (ODONATA: LIBELLULIDAE) IN LATVIA

Martins Kalnins

JSC "Latvian State Forests"

Lilypad Whiteface *Leucorrhinia caudalis* is one of the species of dragonflies occurring in Latvia, which is considered to be endangered and is included in the regulatory enactments of different levels of conservation of the species. The natural data management system contains only a few, including inaccurate entries on the fields of the species; therefore it is not possible to plan and carry out appropriate conservation of the fields of the species. When planning the measures of freshwater habitat management, the coastal habitat needs are not assessed in connection of the conservation of Lilypad Whiteface (and other specially protected species of dragonflies). The aim of the study was to summarize information on current research and conservation status of Lilypad Whiteface and give suggestions for conservation measures. The influencing factors of the population of Lilypad Whiteface are the following: their natural enemies and non-native species, collecting, extreme weather conditions, toxic substances in the environment and the minimum size of the population. However, all these factors hold an unknown or low to medium risk. The non-native species and the minimum size of the populations can be a high risk factor too. The loss of a habitat of the species is a medium risk factor, because it has been established only in some specific places. The fragmentation of habitats (isolation of fields), habitat management (cleaning of water bodies) and mismanagement of habitats of coastal zone (overgrowing) are assessed similarly. The protection plan of the species contains a description of the conservation measures of Lilypad Whiteface in the following areas: legislation and conservation planning, conservation of the species and habitats of it, research and monitoring, as well as information and education. A part of the described measures are attributable to the protection of invertebrates or even species and habitats as a whole.

CONSERVATION BIOLOGY OF CEPHALANTHERA CUCULLATA, A EUROPEAN PRIORITY ENDEMIC ORCHID OF CRETE (GREECE)

Apostolos Kaltsis

National & Kapodistrian University of Athens
Katerina KOUTSOVOULOU, National & Kapodistrian University of Athens ; Christini FOURNARAKI, Mediterranean Agronomic Institute of Chania ; Costas Thanos, National & Kapodistrian University of Athens

Cephalanthera cucullata is an endemic orchid of Crete, growing in forests on all four mountain massifs of the island. It is a species of European priority (Annex II, 92/43/EEC Directive) and is characterized as Endangered (EN) in the Red Data Book of Rare and Threatened Plants of Greece (2009); its total population size is estimated to less than 500 individuals. Starting in the 1980s, field observations by various researchers have indicated a decline in the overall population size, mainly due to overgrazing and habitat degradation. It was under the LIFE project CRETAPLANT (2004-2007) that the first systematic attempt of in situ conserving this plant was implemented and a Micro-Reserve (12.1 ha large) was established in Western Crete (Lefka Ori massif, 1200-1380 m asl) to safeguard the largest subpopulation of the species. Fencing of the Micro-Reserve offered protection from grazing but also made feasible the monitoring population dynamics of the species, throughout the period 2006-2015. Mapping and tagging each flowering individual (with the use of plastic labels placed on metal stakes) has revealed an interannually erratic, above-ground growth (due to vegetative dormancy) of *C. cucullata*, with a mean interval of emergence estimated at c. 2.75 yrs. A total of 235 individuals have been observed and labeled over these years, with the maximum number recorded in 2007 (146) and the minimum in 2011 (63). Meteorological data obtained from a micro-station (placed in the Micro-Reserve) are currently analyzed in an effort to correlate the microclimatic conditions to the population parameters (presence/absence, number of flowering stems etc.). In addition to long-term monitoring and in situ management of the species, an ex situ conservation initiative has been pursued. However, preliminary data on asexual, lab germination and propagation of this orchid confirm the general notion that seeds of *Cephalanthera* spp. are extremely difficult to sprout.

ECOLOGY AND CONSERVATION OF ENDANGERED DHOLES IN SOUTHEAST ASIA

Jan Kamler

University of Oxford

Dholes (*Cuon alpinus*), or Asiatic wild dogs, are the least studied and understood of the endangered large carnivores

in Asia. They have disappeared from >80% of their range during the past 50 years, and there are now < 2,500 adult dholes remaining in the wild. I reviewed the current status and distribution of dholes throughout Southeast Asia, and show that current populations are small and highly fragmented. In order to better understand their conservation needs, I carried out recent ecological research on dholes in Bhutan, Laos, and Cambodia. Results showed that in Bhutan, dholes have made a comeback in recent years, after being nearly extirpated from the country due to poisoning campaigns. However, current populations are limited by a low prey base. In Laos, dholes still occur in evergreen forests in the northern parts of the country, although packs were small and predation occurred on relatively few species, factors which likely limited their population size. My current research in the open deciduous forests of eastern Cambodia showed that predation by dholes focused almost exclusively on two common species, wild pig (*Sus scrofa*) and muntjac (*Muntiacus muntjak*). However, the population of dholes in the region is limited primarily by disease transmission from village dogs. Overall, dholes in Southeast Asia appear to be limited by different factors, including low prey base, human persecution, disease transmission from village dogs, and habitat loss. The future conservation of dholes in the region will be dependent on large protected area complexes, where high prey numbers are maintained and access by poachers and village dogs is limited.

IMPACTS OF COMMON FOREST RESOURCES MANAGEMENT IN BIODIVERSITY CONSERVATION IN THE MOUNTAINS OF NEPAL

Pratikshya Kandel

ICIMOD

Under community forestry (CF) program, the forest user groups take forest management and benefit distributions decisions. CF is envisioned as an appropriate mechanism for addressing local people's need for fodder, firewood and timber in the mountains of Nepal. By the end of the year 2014, it has been established as the largest social mobilization program involving one third of all households of Nepal. The program has been successful in restoring greenery of hills, forming local level institutions for resource management and improving the supply of forest products to farmers in the hills of Nepal. However, the biodiversity conservation outcome is less studied which is the focus of this study. The CF may have positively contributed to biodiversity conservation by restoration and rehabilitation of the landscapes. The increased incidences of human leopard conflicts causing 31 human deaths in last 4 years, may serve as a good example of the habitat restoration followed by habitat utilization by wild animals in hills of Nepal. Similarly, recent photographic evidence of trans-boarder movement of tigers and rhinos between Nepal and India through community-

restored forest landscape in western Nepal is another good example. The same landscape in addition to providing habitats for the flagship species; is conserving thousands of other less conspicuous species. It can also be urged that CF can fulfil the gaps in protected area network in mid-hills where expansion of protected area is limited. To facilitate this, it is urgently required to incline management objectives of CF towards biodiversity conservation. Biodiversity impact of CF includes prevention of local extinction of species and creation of corridors for wildlife. Biodiversity conservation needs clustering of CFs within landscape level. Modifications of management regimes is necessary to commensurate with that of biodiversity conservation.

MODELLING HUMAN PRESSURE IMPACT ON PROTECTED AREAS IN THE CZECH REPUBLIC

Helena Kaňková

Environment Center, Charles University in Prague

Protected areas should serve as the reserves of biological diversity in human dominated landscape. This poster presents spatial analysis of human pressure on ecosystems in the Czech Republic and its impact on biodiversity loss. The aim of the work was to quantify the extent of main anthropogenic pressures on ecosystems, assess their spatial patterns and compare impacts in protected areas with other landscape. One of the main tools used in the study is Mean Species Abundance indicator (MSA) developed for model GLOBIO3 assessing human-induced changes in biodiversity based on simple cause-effect relationships between environmental drivers and biodiversity impacts. Drivers considered in this study are land-cover change, land-use intensity and fragmentation as they are assumed to be the main cause for biodiversity loss. MSA values indicate relative remaining mean species abundance of original species compared to primary vegetation scaled between zero and one (1 = all original species, 0 = no original species). To calculate MSA values based on land use and land cover data, the Consolidated Layer of Ecosystems of the Czech Republic was used as the most detailed currently available dataset of ecosystem distribution on the national-wide level. Results show significant impact of long-term human influence resulting in decrease of Mean Species Abundance in the Czech Republic to 31% of original biodiversity in intact ecosystems. The biggest impact was located in intensively used agricultural areas in the lowlands. Protected areas presented by forested mountain ranges in the border areas, as well as other forested interior parts of the country, achieved significantly higher values of MSA indicating they represent relatively best preserved ecosystems in comparison with others. However, the MSA in protected areas is still decreased on average by over 50 % which documents huge human pressure on protected ecosystems and threat for preserving their original diversity.

USING UNIVERSAL HUMAN NEEDS TO UNDERSTAND THE COSTS OF LIVING WITH DAMAGE CAUSING MAMMALIAN WILDLIFE

Ruth Kansky

University of Stellenbosch

Martin KIDD, University of Stellenbosch ; Andrew KNIGHT, Imperial College London, Silwood Park Campus

Human Wildlife Conflict (HWC) is increasing globally and has been recognized as a major priority by conservation organizations as it can lead to a loss of support for conservation in general. Individuals vary in their tolerance towards living with damage causing wildlife but the drivers of tolerance are not well understood. We developed the Wildlife Tolerance Model (WTM) to predict drivers of tolerance across species and cultures and apply it in a case study of human-baboon conflict in Cape Town, South Africa. The WTM was developed from meta-analytic reviews as well as reviews of theories and concepts from a variety of disciplines. It aims to guide development of strategies and policies that can potentially be applied over landscapes. The WTM consists of two components; an outer model proposes that the net outcome of the extent to which a person is exposed to a species as well as the types of experiences (positive or negative) determine perceptions of the costs relative to benefits of living with a species. These in turn determine tolerance. A second component, the inner model, predicts eleven variables that impact on tolerance through costs and benefits. Baboons are one of the most common primate species involved in human-wildlife conflicts in Africa but few studies have examined the attitudes and tolerance of people towards them. We surveyed 403 residents living in five urban areas adjacent to the Table Mountain National Park. Using Structural Equation Modeling we tested and found support for the outer model. Overall 60% of tolerance was explained by perceptions of costs and benefits. We distinguished between tangible (monetary) and intangible (non monetary) costs and benefits and found that while intangible costs and benefits equally contributed to driving tolerance, tangible costs had no significant effect on tolerance. We use a "universal needs" approach to explain these findings.

MATRIX TYPE AND PROTECTED AREA CONSERVATION: THE ROLE OF BUFFER ZONES IN CHIMPANZEE CONSERVATION

Beth A. Kaplin

Antioch University New England

Robin MARTINO, Antioch University New England ; Phillip DUGGER, Antioch University New England ; Sylvia KAWERA,

University of Rwanda ; Jean Paul KUBWIMANA, University of Rwanda ; Methode MAJYAMBERE, University of Rwanda

Protected areas represent a cornerstone in biodiversity conservation. A key factor influencing protected area (PA) effectiveness is the surrounding matrix including land use type and intensity. Research has shown that matrix surrounding a PA mediates intensity and frequency of edge effects resulting in changes in biodiversity and ecosystem function. Buffer zones are a tool in PA management and can represent hard or soft matrix, yet few studies have evaluated efficacy in protecting biodiversity while contributing to local communities or reducing wildlife conflict. We studied the relationship between matrix type and an endangered species important for ecosystem services (seed dispersal) and tourism revenue, chimpanzees (*Pan troglodytes schweinfurthii*) in Nyungwe National Park (NNP), Rwanda. The park is partially surrounded by contrasting buffer zone types, tea (considered hard edge) and pine (considered soft edge) plantations. We compared chimpanzee and human sign along transects in forest adjacent to tea and pine and in interior forest, and in transects just outside the PA. Chimpanzees were more common in forest adjacent to pine buffer than tea (based on nest counts and sign). Human sign was more common in forest adjacent to pine and in interior forest. Transects sampled outside forest along PA edge showed more human sign in tea than pine buffer, and more chimpanzee sign outside forest adjacent to pine. These results suggest that matrix type affects quality of buffer zone benefits for the PA; hard matrix was better at reducing human disturbance within the forest, but human sign outside the forest was greater. Conversely, soft matrix effectively increased the area of the PA for chimpanzees, a key wildlife species, but also may increase probability of wildlife leaving the park. These findings highlight the importance of linkages between PAs and surrounding landscape, and the nuanced role of buffer zones in contributing to biodiversity conservation in PAs.

171 CITIZEN SCIENTISTS AS AGENTS FOR CONSERVATION

Krithi Karanth
WCS

Citizen scientists participation in conservation research – has become an important tool for monitoring and evaluating local and global conservation science and action. Citizen science projects enable large-scale data collection, increase scientific literacy, and monitor conservation management efforts. Few studies have examined the individual-level motivations and impacts of citizen science participation. I evaluate the experiences of citizen scientists volunteering with two conservation organizations based in Bangalore, India

that have engaged more than 4000 volunteers and trained them to contribute to conservation research projects over the past two decades. Citizen science can contribute to increased conservation awareness among the general public. Specifically, understanding processes whereby highly motivated individuals, seek out citizen science opportunities due to an interest in one or more environmental issues; gain expertise through citizen science participation; and diffuse acquired skills and knowledge to peers through social networks, education of other non-scientist Indian citizens, and/or changes in career or education trajectories. As a result, citizen scientists in India promote conservation principles through an active advocacy network.

195 UNDERSTANDING HUMAN-WILDLIFE INTERACTIONS IN INDIA: INSIGHTS FROM 10,000 SURVEYS

Krithi Karanth
WCS

Preventing and mitigating human–wildlife conflicts are a top conservation priority, particularly in India where wildlife and high densities of people co-occur. We surveyed more than 10,000 households in a 20,000-km² area in forest, scrub and grasslands areas in India from 2009-2014. We visited more than 3000 villages in 26 districts from Rajasthan, Madhya Pradesh, Maharashtra, Andhra Pradesh, Tamil Nadu and Karnataka, surveying households in protected and unprotected areas. Our observational study modeled self-reported crop and livestock loss, and compensation access by households. Many (>60%) households are agricultural and crop loss was higher around central and southern Indian forests compared to other ecosystems. Crop loss was associated with growing more crops and proximity to forest or grassland cover. Crop loss was attributed to 25 different species with wild pigs and elephant being most common. Overall, livestock loss was lower than crop loss across all sites, and highest in Central India. Livestock loss was associated with grazing animals inside reserves and collecting resources such as fuel wood from reserves. Livestock loss was attributed to 10 different species with leopard and tiger top ranked predators. Common mitigation measures for crop protection were night watching, fencing, guard animals and scare devices; and for livestock protection were closer watch on animals, guard animals, physical structures and fencing. Efficacy of these mitigation measures varied hugely by location, with many measures being completely ineffective. Compensation was universally low to non-existent and a serious evaluation of compensation practices in different states is needed.

MAPPING AND MODELLING LAND USE CONFLICT TO INFORM NATURAL RESOURCE PLANNING AND MANAGEMENT

Azadeh Karimi

PhD student, University of Queensland Australia, Lecturer Ferdowsi University of Mashhad, Iran.

Greg BROWN, University of Queensland ; Marc HOCKINGS, University of Queensland

Land use conflict is endemic to natural resource management given the limited availability of resources and multiple stakeholders' interests in those resources. Recent research in public participation GIS (PPGIS) has sought to identify and measure the potential for land use conflict using a two dimensional model that combines spatially-explicit place values with land use preferences (Brown and Raymond, 2014). Based on this framework, potential land use conflict is determined by differences between perceived acceptable and unacceptable land uses in the same location that is weighted by level of place importance, as measured by the intensity of mapped landscape values in the same location. However, this perceptual model of conflict does not account for landscape heterogeneity that may (or may not) inform participants' perceptions. We seek to understand whether the perceptual model of land use conflict is associated with specific types of physical landscapes and locations to enhance land use conflict mapping and identification methods. Using empirical PPGIS data collected from a regional natural resource study in the Baffle Basin region, Queensland, Australia, we evaluate an expanded model of land use conflict that includes both perceptual and landscape attributes. We discuss the implications of our findings for natural resource planning and management that seek to use collaborative or participatory mapping methods.

INTEGRATING ECOSYSTEM THRESHOLDS INTO ADAPTIVE MANAGEMENT OF MARINE RESOURCES

Kendra Karr

Environmental Defense Fund

Rod FUJITA, Environmental Defense Fund

Ecosystem-based management of coral reef fisheries aims to sustainably deliver a diverse portfolio of ecosystem services. This goal can be undermined if the ecosystem shifts into a different state, with altered ecosystem functions and benefits to people. If levels of drivers that cause transitions between states are identified, management measures could be aimed at maintaining drivers below these levels to avoid ecosystem shifts. To find management targets for coral reef fisheries that could result in good sustainable yields while at the same time maintain the production of other ecosystem services at desirable levels, we examined empirical relationships between metrics associated with coral reef ecosystem structure and

function along a gradient of total fish biomass (proxy for fishing pressure). Several metrics (e.g., macroalgal cover, change in fish assemblage) show thresholds — abrupt non-linear changes — at high fish biomass levels supporting the concept that coral-dominated states are associated with high fish biomass. Other metrics show thresholds at lower fish biomass levels, suggesting that such levels may be associated with transitional states and finally macroalgae-dominated states. If the thresholds in this study are generalizable to scales relevant to management, it may be possible to produce sustainable yield while simultaneously maintaining coral-dominated reefs by restricting fishing mortality to levels that result in biomass ratios near 0.5. Fishing down to biomass ratios near 0.3 may increase the risk of overfishing (resulting in lower long-term yields) and transition to macroalgal-dominated reefs. Thresholds offer a simple and powerful way for managers to operationalize precautionary ecosystem-based fishery management by adaptively limiting fishing pressure in order to (i) maintain desirable coral reef conditions, (ii) establish a system-specific target for generating pretty good yield and (iii) maintain sustainable multi-species fishery yields.

HUMAN OR TIGER: WHO WINS? UNDERSTANDING KEY DETERMINANTS AND HUMAN DIMENSIONS OF HUMAN TIGER CONFLICT IN WEST SUMATRA INDONESIA

Erlinda Cahya Kartika

Ministry of Forestry of Indonesia

Ignas HEITKONIG, Wageningen University

The human wildlife conflict (HWC) comprehends a large range of species, and contributes to declining wildlife populations. The impact of wild animals on humans and their activities can promote a negative attitude toward wildlife, including retaliatory killing. This is particularly the case when large carnivores like tigers are involved. Quantifying the direct impact of HWC only without taking into consideration the indirect impact of HWC may lead to a wrong conclusion about how big the impact of HWC is for entire communities. This paper is focusing on the magnitude and human dimensions of HWC. In this study, conflicts between humans and the Sumatran tiger (*Panthera tigris sumatrae*) as a model species (human tiger conflict, HTC) were analysed to understand the human dimension and factors associated with the HTC. A semi-structured interview was conducted in West Sumatra, Indonesia among 128 respondents. This study shows that calculating indirect impacts can explicitly explain the magnitude of the HTC in the community. In the case of human attacks, direct impacts seem to affect only 1.5% of the community members. Yet, by including indirect impacts too, over 98% of the community members were affected by HTC incidents. Furthermore, the analysis of the human dimension of HTC found that the emotions of people toward

tigers are inversely correlated with their conservation attitude and their level of tolerance toward tiger. Key determinants explaining human dimension factors are impact perceived as a result of HTC the intensity of environmental educations in the village, field location and ethnicity. Frequency of HTC, knowledge and gender each seem to have only a small impact on shaping human dimension factors. This study suggests that an integrated program combining environmental education, compensation for livestock and human losses, and community involvement to handle the HTC are recommended to improve local people's tolerance for tigers

ART MEETS CONSERVATION: STORYTELLING AND PARTICIPATORY VIDEO HELPS UNDERSTAND TIGER-HUMAN CONFLICTS

Erlinda Cahya Kartika

Ministry of Forestry of Indonesia

To increase people awareness toward environment is challenges. Giving oral presentation or directly speak to people about conservation can be so boring and make them did not aware with what we are trying to deliver. Using art for delivering messages can be an alternative to gain people attention. Storytelling and participatory video are part of art which can be powerful educational tools to help school children and adults in Indonesia understand tiger-human conflicts (THC). The problem of THC in West Sumatra, has emerged due to a number of factors. One of these is believed to be a lack of knowledge about tigers and their importance in the ecosystem. Our environmental education project aims to rectify this situation. Conducted from January to September 2014 with support from the Rufford Foundation, the project was divided into two segments that focused on children and adults. For children, the environmental education was delivered through storytelling. For adults, it was delivered by a participatory audio-visual campaign. In West Sumatra, children usually go to regular school in the morning and Islamic school in the afternoon to learn the Qur'an. We went to a junior high school and an Islamic school to carry out storytelling activities. We found that students were very enthusiastic to hear the story of tigers and their ecosystem. To help the students understand, we used the local language, Minang instead of Bahasa Indonesia, the national language. Participatory videos are a great way of bringing people together to explore issues, voice concerns or simply to be creative and tell stories. This process can be very empowering, enabling a group or community to take action to solve their own problems and to communicate their needs and ideas to decision-makers and other groups within the community. As such, participatory videos can be highly effective to engage and mobilise marginalized people to implement their own sustainable development activities based on local needs.

HOW RELIGION CAN INFORM FOREST MANAGEMENT FOR BIRD CONSERVATION: THE CASE OF SACRED GROVES IN GREECE

Vassiliki Kati

University of Patras

Eleftherios KAPSALIS, University of Patras ; Fotios XYSTRAKIS, University of Patras

Sacred groves are ancient natural sites, established and preserved since the 15th century through the Orthodox religion in Greece. They are small old-growth woodlands, locally managed and maintained by local communities. We selected 20 oak sacred groves in NW Greece (17 for passerines), and we employed a random selection algorithm to select an associated set of 20 (17) control oakwoods in the broader area, which are regularly managed by National Forest Service for wood harvesting. We sampled small terrestrial birds in 2012 using the point count method, and woodpeckers in 2011, using the playback method, while recording nests and tree holes from drumming (2782 trees examined). Sacred groves held a significantly more abundant forest bird community (22 species, 584 individuals) than control woods (18 species, 286 individuals) (U test: $z=8.037$, $p<0.0001$), attributed to the greater abundance of eight species associated with mature wood. Sacred groves had also greater species richness and abundance of woodpeckers (7 and 2 species, 55 and 7 individuals, respectively) (Friedman rank tests; $p<0.01$). They included significantly more trees with woodpecker nests and tree holes from drumming, whereas trees had significantly greater diameter (dbh) and height than trees in control woods. Our results provide a forest management guideline for bird conservation, towards the preservation of uncut mature forest stands in the managed oak zone, with a median tree diameter (dbh) of 45-85 cm and median tree height of 8-14 m. In conclusion, our results provide strong evidence towards the great conservation value of sacred groves for forest bird community and their value as a reference point for forest management.

197-PERSPECTIVES ON NATURA 2000: FROM DESIGN TO CONSERVATION

Vassiliki Kati

University of Patras

The European Union (EU) has succeeded in establishing Natura 2000, a transnational network of protected areas to conserve species and habitats of conservation concern. The terrestrial component covers to date 17.9% of EU land territory, while the marine component is under development. A suite of legal, policy, and financial instruments are currently provided by the EU to facilitate Natura 2000 management (estimated cost of €5.8 billion/year). The successful implementation of Natura

2000 depends on seven key drivers: network design, use of external resources, legal frame, scientific input, procedural frame, social input, and national/local policy. The design of the network in terms of area and representativeness, and the relevant legal frame as provided by the Birds and Habitats Directives, are recognized as adequate. However, the two conservation directives are currently being audited and changes may weaken their strength, much more as only 17% of habitat and species of European concern merited a favourable conservation status (based on pre-2007 assessment). EU member states should invest great effort in the social and policy fields that appear the most problematic, as negative attitudes of local communities and a lack of political will towards conservation action at local and national levels are widely recognized. European conservation scientists emphasize the need for public awareness with special focus on local communities, the employment of high-quality conservation experts in all stages of Natura 2000 implementation, the improvement of studies that assess the impact of development projects within the network, and a permanent funding flow through a specific fund, in order to substantially increase Natura 2000 effectiveness.

MONITORING SELECTIVITY PATTERNS: A TOOL TO MANAGE UNGULATE-RELATED CONSERVATION PROBLEMS

Krisztián Katona

Szent István University

Ádám FEHÉR, Szent István University; Norbert BLEIER, Szent István University; Péter HEJEL, Szent István University; László SZEMETHY, Szent István University

Ungulate populations in Europe have increased during the last decades. This is a source of different conflicts to biodiversity conservation. However, hunting pressure could not compensate for this boom and could not provide a universal solution to those ungulate-related problems. Successful conflict management would require deeper understanding of ecological complexity of ungulate-habitat relationships. In Hungary, there are also serious conflicts linked to the "intolerable" impact of "overabundant" red deer and wild boar. The unbalanced definition of the role of ungulates in the ecosystems leads to causal oversimplification focusing only on their excessive negative effects. But red deer and wild boar are native ecosystem engineers, having regulatory functions in the near-natural ecosystems. Neglecting their positive effects and low consideration of the joint impact of different factors in the related conservation issues makes the implementation of adequate conservation measures difficult. We elaborated and apply an ungulate impact monitoring system in Hungary supporting conservation and management decisions. Standard and comparable evaluations based on ecological bioindicators, provide a tool to predict the relative

overabundance of ungulate species and the overutilization of vegetation. We have already collected data about the relationships between the patterns of vegetation (availability of saplings, shoots, and trunks) and selective utilisation of those natural resources by ungulates in about 20 different forested areas of different forest types and management regimes. Our results reveal that the important ecological role of selective ungulate feeding can be obvious especially in case of close to nature forest management. In those, more diverse areas the less "prioritized" woody species are mainly selected and the total ungulate impact is also at a moderate level. Selectivity patterns, therefore, can provide a useful set of bioindicators of forest naturalness.

INDIGENOUS KNOWLEDGE IN ECOLOGICAL CONSERVATION, A CASE STUDY FROM THARU COMMUNITY OF NEPAL

Rajan Kc

SchEMS, Pokhara University

In this paper, I summarize some of the contemporary practices in quantitative anthropological research of indigenous knowledge and economic systems which finally leads to the conservation of ecology. First, I concentrate on the different research methods prevailed in ethno-ecology by providing an overview of the quantitative studies of indigenous knowledge. Anthropologists use tools and techniques such as free lists, pile sorts, semi-structured interviews with major informants and objective tests to depict the indigenous knowledge regarding the ecological conservation. Demographic model of culture are drawn from the data to indicate distribution patterns of traditional knowledge in cultural groups. Variables like gender, age, social class and mode of subsistence are included in traditional environmental knowledge's patterns of distribution. Next, I reviewed the contemporary understandings of nature and environment in the reference of economic systems of Tharu community. Participation, access and approach ways of indigenous people are relatively studied to the distribution pattern in traditional environmental knowledge. Finally I urge some possible linkages between indigenous knowledge, economic market approach and ecology conservation.

106 UNDERSTANDING LOCAL STAKEHOLDER'S PREFERENCES FOR INTERVENTION DESIGN: THE CASE OF CONSERVANCIES IN KENYA'S MAASAI MARA

Aidan Keane

University of Edinburgh

Conservation interventions often set out to improve environmental and economic conditions by influencing

local people's livelihood choices. However, conflicts can arise when certain groups of stakeholders feel disadvantaged by the changes that ensue. To achieve success, conservationists should therefore aspire to understand the preferences of their target population and how they shape their responses to change. Here, we present the results of a case study of conservancy initiatives around the Maasai Mara National Reserve in southern Kenya, where there is a long history of conflicts over conservation. Conservancies are community-based organisations whose members lease their land for conservation and eco-tourism, foregoing rights to graze livestock on it in return for regular payments. Over the last decade, they have spread rapidly throughout Kenya but their effects remain poorly understood. Using discrete choice experiments (DCEs) and structured interviews, we quantified the preferences of local pastoralists for alternative livelihood options and conservancy designs. We show that despite rapid political and economic change in the region, Maasai retain a strong preference for diversified pastoral livelihoods, favouring scenarios in which they are able to maintain livestock herds with sufficient access to grazing land. However, we also demonstrate that there exists considerable variation in preferences between individuals, with important differences between men and women. Our findings show that conservancy managers must take particular care to ensure that they produce equitable outcomes within heterogeneous local communities, and suggest that the success of conservancies will depend on finding new and creative ways of integrating pastoralism, conservation and tourism.

HEDGEROWS INCREASE NATIVE CROP POLLINATOR OCCURRENCE BUT DO NOT INCREASE FUNCTIONAL REDUNDANCY OR RESPONSE DIVERSITY OF THESE COMMUNITIES

Emily Kearney

University of California, Berkeley
Adrian LU, University of California, Berkeley; Lauren PONISIO, University of California, Berkeley; Leithen M'GONIGLE, University of California, Berkeley; Claire KREMEN, University of California, Berkeley

Currently, pollinators are integral to the production of 75% of leading global food crops but managed pollinators, such as the European honeybee, are experiencing drastic declines. This makes native, crop-pollinating bee species even more important as they provide direct pollination services and can increase the effectiveness of pollination by managed honeybees even at low abundances. However, in intensively managed agricultural landscapes where demand is highest for pollination services, abundance of native pollinators is lowest. Restoration techniques, like hedgerows, can enhance native pollinator communities but it is unclear if they adequately

support resilient communities that can survive disturbance or adapt to climate change. Functional redundancy or the number of species that have similar roles in ecosystem processes has been used as a predicative measure of community resilience. Along the same lines, response diversity or the diversity of phenotypic traits within a group of functionally redundant species can be used to assess how environmental changes might impact a community. Using a comprehensive dataset of native pollinators collected on hedgerows and unrestored weedy strips in California's Central Valley, we found that hedgerows increased the occurrence of crop-pollinating native bee species. However, hedgerows did not increase functional redundancy or response diversity of crop-pollinating native bee communities. These results suggest that hedgerows can be an important part of pollination management in highly modified agricultural areas but more action may be necessary to increase community resilience.

DO LEAST-COST MODELS PREDICT ANIMAL MOVEMENT?

Annika Keeley

Northern Arizona University
Paul BEIER, Northern Arizona University; Jeff GAGNON, Arizona Game and Fish Department

Least-cost models are commonly used in conservation planning to identify areas that should be conserved as wildlife corridors. These models rely on estimates of landscape resistance which is a measure of how much landscape variables impede an animal of a focal species moving through the landscape. If these resistance values are wrong, then land-use planners, transportation agencies, and other decision-makers may be implementing poor corridor designs. For elk (*Cervus canadensis*) and desert bighorn sheep (*Ovis canadensis nelsoni*) we used three models to estimate resistance values: expert opinion, resource selection functions, and step selection functions. We calculated the costs of actual long distance movements based on each set of resistance estimates, and compared these costs to the costs of the least cost paths and 48 rotated and shifted versions of the long distance paths. The mean cost rank of the observed paths was a measure of aptness of the models. For elk (a habitat generalist), all three models performed better than chance, but not much better, with little difference among the 3 models. For desert bighorn sheep, aptness of all three models performed much better than chance, with little difference among models. Because the expert opinion model performed as well as the data-intensive models, practitioners can rely on the expert opinion model because it is cheap and easy to produce.

#165 HOW CAN EVALUATIVE THINKING HELP CONSERVATION BIOLOGY LEARN TO BE MORE EFFECTIVE?

Matt Keene

US Environmental Protection Agency

Carly COOK, Monash University ; Kent REDFORD, Archipelago Consulting ; Andrew KNIGHT, Imperial College ; Duan BIGGS, University of Queensland ; Glenda EOYANG, Human Systems Dynamics Institute ; Cameron NORMAN, CENSE Research + Design ; Beverly PARSONS, InSites ; Martin REYNOLDS, The Open University ; Bob WILLIAMS, Williams

With the rise of evidence-based conservation, it is increasingly recognized that to improve the effectiveness of conservation outcomes we need to evaluate whether actions have been successful and use that information to learn and adapt management practices. In conservation, the approach to evaluation has generally focuses on a narrow set of quantitative methods that are focused on reducing uncertainty for simple management problems (e.g., which herbicide is most effective). However, most conservation problems are high complex, with social, political and economic aspects that are as influential as the biology. As predominantly natural scientists, conservation biologists are trained to think about the natural system, and often do not have the tools to understanding the broader socio-ecological system. However, the field of evaluation has a wide range of tool well suited to understanding these complex systems. In this presentation we will introduce the idea of evaluative thinking. Evaluative thinking has emerged from a co-learning process between systems thinkers, evaluators and conservation biologists. Based on a systems approach to evaluation, evaluative thinking is based around finding more effective conservation solutions by evaluating a conservation problem within the context of the broader system in which it functions. Evaluative thinking is underpinned by four key principles that we believe can help reframe the way we think about conservation problems: 1) Understand where a problem fits within the broader system; 2) Recognize that values are a fundamental part of making wise decisions; 3) Make learning a process of continual reflection; and 4) Accept that our understanding will always be incomplete. Building on the many things we already do well in conservation, enacting these four principles will provide a tool-kit to learn to do conservation more effectively.

PREDATION OF ATHERINA BOYERI UPON THE ENDANGERED FISH ECONOMIDICHTHYS TRICHONIS: THE ROLE OF THE PURSE SEINE FISHERY LIGHTS

George Kehayias

University of Patras

Anastasia TZAVALI, University of Patras ; Marilia GINI, University of Patras ; Ekaterini MICHOPPOULOU, University of Patras

Atherina boyeri dominates the fish community in Lake Trichonis (Greece) and it is the target species in the professional purse seine fishery, conducted mainly during the night by the use of lamp rafts. Previous studies concerning the diet of this fish in the area showed that it is strictly zooplanktivorous, preying heavily on copepods and larvae of the bivalve *Dreissena blanci*, while it showed preference in its diet acting as visual predator. However, these studies were based on gut content analysis of specimens caught during the day. Thus, there is no information on its feeding preferences close to the artificial lights of the lamp rafts. Considering this, a five months study of the feeding of *A. boyeri* around light rafts revealed interesting results. Among the most striking differences of this study to the previous ones was the presence of large numbers of larvae of the native and endangered species *Economidichthys trichonis* in the diet. This prey showed higher frequency of occurrence in the gut contents of the larger stages of *A. boyeri*, while the smaller specimens fed on copepod nauplii and larvae of *D. blanci*. Greater predation on the larvae of *E. trichonis* was found during the summer months and coincided with the seasonal maximum of its pre-recruiting larval stage in the lake. A rough estimation of the *E. trichonis* larvae preyed per night around a single lamp raft by *A. boyeri* revealed an average number of nearly 50000 specimens between June and August. Although there are no estimates on the population size of *E. trichonis*, this decimation of its larvae by another fish species due to the use of fishery lights poses a great conservation issue. Considering the absence of similar studies, the present results may be a stimulus for analogous investigations in other marine and freshwater ecosystems worldwide.

ACCOUNTING FOR LAND-USE INTENSITY AND MAMMAL TRAITS IN SPECIES-AREA RELATIONSHIPS

Laura Kehoe

HU Berlin

Tobias KUEMMERLE, HU Berlin ; Cornelius SENF, HU Berlin ; Carsten MEYER, Georg August-University of Göttingen ; Katharina GERSTNER, UFZ, Helmholtz Centre for Environmental Research ; Holger KREFT, Georg August-University of Göttingen

Land use change is a main driver of the on-going biodiversity crisis. Assessing the impact of land use on biodiversity is therefore crucial. Species-area relationships (SARs) provide an avenue to assess such impact. Classic SARs assume a hostile matrix, where no species survive in an agricultural landscape. Recent developments now classify between agricultural land (where some species can survive) and natural land, thus better representing the impact of agricultural expansion in species-area relationships. However, classifying an area as either

agricultural or natural land may also be an oversimplification considering the large variety in intensity of agricultural land-use and species mechanisms for coping with land-use change. We propose a species-area relationship that accounts for land-use intensity (LUI) by systematically testing a range of intensity indicators. We show how different species cope with varying intensities of land use by utilizing recently available mammal species traits datasets. We found that the base model was improved by the inclusion of land-use intensity metrics. Fertilizer input was the best predictor of species richness on a global scale, followed by rice harvested area. For species traits, we found that herbivores and species under 10kg exhibited the highest sensitivity to area. We found interesting interactions between species traits and LUI. For instance, omnivores exhibited highest species richness in areas of high irrigation, perhaps due to food availability in such areas, conversely, high species richness for carnivores were in areas of low irrigation. A deeper understanding of the different relationships between land-use and species richness are gained by the inclusion species traits and land-use intensity. Results allow us to better predict and understand species richness patterns on a global scale and may help in guiding conservation and management actions.

IMPACT OF INTRODUCED ANURANS ON NEWFOUNDLAND ECOSYSTEMS

Dion Kelly

Memorial University of Newfoundland

The successful establishment and dispersal of invasive anuran populations is influenced by competitive exclusion and/or niche differentiation with competing species. Invasive species often perpetuate an imbalance among native fauna and flora; effects of which are more pronounced for insular ecosystems. In Newfoundland, originally devoid of anurans, tadpoles may potentially be reshaping aquatic ecosystem structure by modifying biomass accumulation. I used a combination of anuran calling surveys and pond-edge transects to assess the relative regional distribution and ongoing dispersal for 2 of the 4 introduced anurans in western Newfoundland. The recently established Mink Frog, *Lithobates septentrionalis*, has dispersed ~50 km northeast and ~34 km southwest from the original (2001) discovery location; this population displays an unexpected spatial separation from long-established Green Frog populations, *Lithobates clamitans*, at landscape and local scales. To evaluate the effect of these introduced species on biomass accumulation in aquatic communities, I provided epilithon covered substrates for American Toad, *Anaxyrus americanus*, tadpoles taken from local sources and raised in Laboratory or Field enclosures at varying densities relative to that of local populations. Population densities significantly influenced weight rather than total length of tadpoles, while

lower population densities resulted in larger tadpoles that removed more organic material from substrates. The short term effect on organic resources appears to be influenced by the presence of anurans rather than existing population numbers. With greater dispersal of anurans in Newfoundland, greater reduction of pond epilithic layers may result in changes to ecosystem invertebrate abundance and community richness.

ISLAND BIOGEOGRAPHY OF BIRDS: TESTING CORE ASSUMPTIONS OF MACARTHUR AND WILSON 50 YEARS ON

Luke Kelly

UNIVERSITY OF MELBOURNE

*The QUANTITATIVE AND APPLIED ECOLOGY GROUP,
UNIVERSITY OF MELBOURNE*

Island Biogeography Theory (IBT: MacArthur and Wilson 1963; 1967) has been highly influential in the development of ecology over the last 50 years. In their 1963 paper, 'An Equilibrium Theory of Island Biogeography' MacArthur and Wilson presented a classic case study which showed that the number of bird species increases with island area and decreases with distance from a single source area. The recent development of approaches that link species distribution modelling with functional traits provides an excellent opportunity to revisit MacArthur and Wilson's Pacific Island data. Here, we test two assumptions that underpin IBT: 1) that distance to a single source island is the most appropriate representation of island connectivity and 2) that patterns of bird distributions on islands are not related to the functional traits of individual species. First, we examined land bird data from 261 oceanic islands in Melanesia: the Bismarck Archipelago, Solomon Islands and Vanuatu. We used generalized linear regression models to explore three predictors of bird species richness: island area, distance to a single source area and distance to all possible source areas. Second, we used hierarchical regression models to examine how bird functional traits (body size, wing-length and diet) modulate species responses to island area and connectivity. We found that a measure of connectivity that accounted for multiple sources of colonisation was a better predictor of species richness than a measure based on a single source area. However, island area was the primary driver of bird species richness and had a much greater influence on model predictive ability. We also found strong evidence for interactions between island area and bird functional traits. For example, vertivores were more likely to experience a positive effect of island area than other dietary guilds. Our work shows that advances in quantitative ecology can improve IBT.

DYNAMIC APPROACHES TO CONSERVATION: DELIVERING COST-EFFECTIVE HABITAT FOR MIGRATORY BIRDS IN AGRICULTURAL LANDSCAPES

T. Rodd Kelsey

The Nature Conservancy

Mark R. REYNOLDS, *The Nature Conservancy*; Eric HALLSTEIN, *The Nature Conservancy*; Catherine HICKEY, *Point Blue Conservation Science*; Meghan HERTEL, *Audubon California*; Sandi MATSUMOTO, *The Nature Conservancy*; Matthew E. REITER, *Point Blue Conservation Science*; Steve KELLING, *Cornell Lab of Ornithology*; Brian SULLIVAN, *Cornell Lab of Ornithology*

Conservation on private agricultural lands has many challenges. We strive to create and incentivize the most effective management practices to conserve biodiversity in ways that work for farmers and that are durable. However, this objective is challenged by poor information about effectiveness, lack of tools for deploying conservation actions efficiently, and the cost of implementation at meaningful scales. In addition, agricultural landscapes are spatially and temporally dynamic, adding to the complexity of delivering valuable habitat reliably. We have been developing and testing new approaches and tools to address these challenges, as applied to creating migratory waterbird habitat at the right times and places in intensively cultivated agricultural landscapes of California. Working with farmers, agencies, and research partners, we have developed three approaches that have broad applicability to conservation in agricultural landscapes. First, we demonstrated application of scientifically robust adaptive management to implementation of a federal incentive program that assisted farmers to create habitat. Second, we have applied big data analytics and emerging precision science tools to enable more precise delivery of habitat investments on farmlands. Third, we have developed a novel habitat procurement market in which farmers are paid to modify their practices in order to create bird habitat. These approaches to delivering temporary habitat serve to meet the needs of migratory species and the practical reality of sourcing habitat from an intensive agricultural system. Through these approaches we have also demonstrated that temporary habitat can be more cost-effective than permanent protection when this is appropriate. These approaches and tools combined have resulted in over 90,000 hectares of habitat delivered. Through agency and industry collaborations we have partnered with over 200 farmers, demonstrating the large-scale applicability of these approaches.

UNDERSTANDING THE LINKS BETWEEN CARBON STOCK AND PLANT DIVERSITY IN SACRED GROVES IN SEMI-ARID AREAS OF CAMEROON

Victor Aimé Kemeuze

University of Ngaoundere

Denis SONWA, *CIFOR*; Pierre Marie MAPONGMETSEM, *University of Ngaoundere*; Evariste FONGNZOSSIE FEUDOUNG, *Higher Teacher's Training School for Technical Education, the University of Douala.*; Evariste FONGNZOSSIE FEUDOUNG, *Higher Teacher's Training School for Technical Education, the University of Douala.*; Bernard-Aloys NKONGMENECK, *Millennium Ecologic Museum*

Sacred groves worldwide are known for their great potential in conserving not only traditional cultural heritage but also biodiversity. Adequate management of such land use systems in semi-arid areas like the Far North region of Cameroon can also contribute in combating desertification and climate change. However, these ecosystems so far have undergone limited investigation from a biodiversity and carbon storage perspective. A floristic survey was conducted in 04 main sacred groves of the Diamare plain using nested circular plots of 1257 m², 616 m² and 50 m². A total of 24 plots were established. In each plot, all plant species were identified and measured. Above-ground carbon was estimated using generic allometric equation and species-specific wood density derived from wood density databases. Different types or purposes of sacred groves were identified: chieftom cemetery, initiation and other rites, forest of gods and Residence of village Totems. The highest tree density value were obtained in initiation and others rites sacred grove (4743.0 stems/ha) and the lowest value in Chieftom cemetery sacred grove (198.2 stems/ha). Mean aboveground carbon stock of 120.4 ± 71.7 tC/ha was obtain in the study area. *Khaya senegalensis* showed the greatest carbon stock (41.0 tC/ha) followed by *Anogeissus leiocarpus* (13.8 tC/ha), *Celtis integrifolia* (9.6 tC/ha), *Azadirachta indica* (4.7 tC/ha) and *Tamarindus indica* (3.8 tC/ha). This study demonstrates the key role of native species of sacred groves of semi-arid areas of Cameroon in storing carbon and therefore the significant contribution of indigenous protected areas in biodiversity conservation and climate change mitigation.

99. COMMUNITY-BASED CONSERVATION WITH AN URBAN PUBLIC

Dave Kendal

Royal Botanic Gardens Victoria

Lily PEARCE, *Royal Botanic Gardens Victoria*; Alison FARRAR, *Royal Botanic Gardens Victoria*

Protectionist conservation excludes local people from land they have traditionally managed. In response to criticism of protectionism, conservation strategies in developing and rural areas have been adopted that include local people such as allowing economic production and maintaining traditional practices. In cities, different strategies are required to incorporate local people (the urban public). This project explored how the urban public is incorporated into

management of 79 high conservation value grasslands in the western suburbs of Melbourne, Australia. Semi-structured interviews were conducted with a representative sample of 44 grassland managers including professionals and community volunteers. Thematic analysis identified the underlying values shaping manager's attitudes. Some managers with strong intrinsic values saw the public as a threat that needed to be excluded from the reserves, while others believed that public involvement was required to ensure the ongoing future of the conservation reserves. Other managers had more human-centred values and saw the grasslands as important for improving people's wellbeing and connecting people to place. Two main conservation strategies involving the urban public were identified: 1) decentralised management involves the public in the planning and on-ground management of some reserves and 2) public use provides access for the public to the reserves for a variety of educational and recreational activities such as walking, using playground equipment and experiencing nature. Many risks were associated with these strategies, such as weed invasions, trampling or uninformed management. There was great uncertainty about the effects of public use of conservation reserves in cities, which often led to the blanket exclusion of the public by managers. A better understanding of the real impacts of different public uses is required to foster the emergence of norms and rules around the appropriate use of the reserves by the public.

DEMOGRAPHIC MONITORING TO DETECT CLIMATE CHANGE IMPACTS ON THREATENED POPULATIONS

Bruce E Kendall

University of California, Santa Barbara

Elizabeth H HIROYASU, University of California, Santa Barbara

Climate change will have negative impacts on many species of conservation concern. At the population level, this will manifest as a change in long-term abundance trends, with populations shifting from stable to declining, or declining more rapidly over time. However, given the difficulty in accurately quantifying average abundance trends against a background of inter-annual variability, detecting changes in such trends will usually be impossible on time frames relevant to conservation decision-making. The changing trend in abundance is driven by a trend in mean demographic rates, which, as a simple trend, should be easier to detect than a change in a trend. We investigated the hypothesis that monitoring demographic rates would provide a more powerful indicator of climate change impacts on population dynamics than would monitoring abundance. Using age- and size-structured matrix models of real plant and animal populations, we simulated trends in various demographic parameters against a background of natural annual variability. We found that, using ten years of simulated data, the P values for tests of no trend in regressions of demographic rates on time were consistently smaller, and

usually much smaller, than the P values for tests of a nonzero quadratic term (identifying a change in trend) in a regression of abundance on time. The difference was greatest in long-lived species and for demographic rates to which population growth is not very sensitive; but was pronounced even for short-lived species and vital rates with elasticities close to one. Our results suggest that demographic monitoring will be much more powerful than abundance monitoring for detecting climate change impacts. However, differences in costs mean that future work must develop a framework that includes sampling uncertainty and costs to identify circumstances is the most cost-effective approach.

RANGE SIZE DOESN'T MATTERS, IT'S HOW YOU USE THE HABITAT

Corinne Kendall

North Carolina Zoo

Large range sizes are correlated with higher extinction risk, but specific patterns of habitat use within the range are often not considered. African vultures can travel substantial distances thanks to the low energetic costs of soaring flight. A single Ruppell's vulture can use an area of over 250,000 km² in one year, possibly the largest range of any non-migratory terrestrial vertebrate. However, Ruppell's vultures do not appear to be declining as rapidly as African white-backed vultures which have a significantly smaller range size. Using movement data from three species of vulture in East Africa, I evaluate how the interactions between range size, habitat selection, and behavior may mediate extinction risk in wide ranging species. Using information on altitude and speed of flight as well as distance between consecutive readings, I assess how differences in behavior in areas of high human habitation versus protected areas may lead to differences in extinction risk. Given that the primary risk to vultures in this region is poisoning of carcasses, which occurs mostly on pastoral lands, it is predicted that species that spend more time feeding in unprotected areas will suffer higher rates of decline and greater extinction risk even if they have smaller range sizes than other species.

ENHANCING THE PROFILE OF THREATENED PRIMATES: IMPACT OF 'TOP-25' LISTING ON THE CHOICE OF SPECIES FOR SCIENTIFIC STUDY

Daphne Kerhoas

Bristol Zoological Society

Alberto ACERBI, University of Bristol ; Amanda WEBBER, Bristol Zoological Society ; Christoph SCHWITZER, Bristol Zoological Society

A list of the World's 25 Most Endangered Primates is decided by consensus biennially since 2000 in order to draw attention and

action towards a few species that are considered as amongst the most endangered primates worldwide. We investigated, for the first time, whether the inclusion of a species in the Top-25 list had an influence on the number of peer reviewed articles published on that species in the following years. This is of vital importance because policy-makers and funding agencies rely mostly on scientific reports. Therefore, an increase in published literature about the most endangered primate species would promote action to save them. We performed text-mining of the metadata made available by several major publishers (namely PLoS, BMC, Elsevier, Springer, Nature and HighWire/Pubmed), analysing a total of about 40 million articles. We extracted articles where the name of a species present in any of the seven Top-25 lists published since 2000 appeared at least once (N= 69 species, found in 7,469 articles), and where the name of a primate control species (never included in the Top25 list) appeared at least once (N = 85 species, found in 13,656 articles). We calculated the trend per species during the years preceding the mention and we compared it with the trend during the years following the mention, over a time lag of 2, 3 and 5 years. According to our results, 2 years is a too short period to see any effect of a mention in the Top-25 list. However, within 3 or 5 years of a species being mentioned in the Top-25 list, there is an increase in the scientific output on these species, compared with the control species never mentioned in the list. In conclusion, the inclusion of a species in the Top-25 has a positive effect on the scientific output and may promote conservation actions on these endangered species.

POTENTIAL TOXICITY OF A NONSTEROIDAL ANTI-INFLAMMATORY (NSAID) FAMILY'S SALICYLATE ON AN ALTERNATIVE BIOLOGICAL MODEL: PARAMECIUM SP

Fella Kermiche Achaichia

University Badji Mokhtar

Houria DJEBAR, University Badji Mokhtar ; Mohamed-Reda DJEBAR, University Badji Mokhtar

Water is essential to life, however, the current globalization continues to deteriorate its properties instead of preserving and protecting it. With soil, surface water is the final recipient of countless persisting pollutants in the environment; they contaminate the food chain causing damage throughout. Agricultural and industrial sectors are primarily responsible for this situation, however a third contamination way is often underestimated which is the one via drugs. Indeed, human beings constantly consume various drugs that are often released naturally in their active form. This environmental contamination, due to the persistence of these pharmaceutical residues, can cause serious ecosystem disruptions and often irreversible damage to non-targeted organisms. This is the case of anti-inflammatory drugs which are considered moderately

toxic to humans, but their effects on other living organisms are yet to be studied and assessed. In this work, we investigated the potential toxicity of a well-known Non-Steroidal Anti Inflammatory (NSAID): Acetylsalicylic acid or Aspirin on an alternative biological model known to be very sensitive to minor changes to its external environment: *Paramecium* sp. It was exposed to various concentrations of xenobiotic (1 µg/l, 10 µg/l, 100 µg/l and 1 mg/l). The cell growth kinetics were appraised and changes in the respiratory metabolism were observed. The results obtained revealed a remarkable toxicity of acetylsalicylic acid.

BEAR PREDATION SIMPLIFIED: USING JUST FREQUENT LOCATION DOWNLOADS AND SPACE-TIME STATISTICS

Joseph Kermish-Wells

University of Calgary

Gordon STENHOUSE, Foothills Research Institute Grizzly Bear Program ; Terry LARSEN, Foothills Research Institute Grizzly Bear Program ; Paul GALPERN, University of Calgary ; Alessandro MASSOLO, University of Calgary ; Marco MUSIANI, University of Calgary

Accurate detection of kill sites and events remains an important objective of predator-prey studies. However, obtaining this information is often constrained by the cost and labor of fieldwork. To resolve this issue, researchers have used telemetry and targeted visits to identify kill sites. However, locations were often investigated well after the kill event due to limited data retrieval options, thus decreasing potential for remaining kill site evidence (carcass consumption by predators and scavengers). We adapt an existing clustering method (SaTScan) to detect kill sites of grizzly bears (*Ursus arctos*; n=18) fitted with Global Positioning System (GPS) satellite collars. This approach reduces delays between predation events and site visits. We visited 464 grizzly bear locations, 187 within clusters and 277 outside of clusters. The majority of kills (23 out of 27; $\chi^2 = 22.064$, $p = 0.0000026$) were found within clusters, with a location error of 15 metres (SD 12). We used logistic regression to assess the probability of kill occurrence using only time-space information contained in the collars. The top model's predictability was tested using k-fold cross validation and assessed using Pearson's correlation ($r = 0.334$, $p = 0.003542$). We, therefore, could predict predation events by grizzly bears without need for detailed habitat information. Using GPS-satellite technology and clustering analysis diminishes the need for fieldwork and still provides precise kill locations. Although this approach was tested specifically on grizzly bears predation, it can potentially be applied more generally to any terrestrial mammal that exhibits clustering movement patterns, provided the parameters are adjusted according to the species' biology. This approach also has the opportunity to predict behaviors beyond that of predation events, such as bedding

and grazing and could provide substantial insights into behavioural ecology and the resulting management decisions of other species.

EVOLUTION AND CONSERVATION OF THE COASTAL VEGETATION IN THE REGION OF TLEMCCEN

Rachida Kerzabi

University of Tlemcen

Evolution and conservation of the coastal vegetation in the region of Tlemcen Kerzabi Rachida, Merzouk Abdessamad Cherif Ismahane, Boubleneza Ibtissem, Bekkouche Assia didou_rach@yahoo.fr Laboratory of Ecology and Natural Ecosystems Management, University Abou Bekr Belkaid – TLEMCCEN
Abstract : The natural environment is a very complex system to master, because any irrational exploitation of biological resources, water and soil leads to an imbalance of increasingly important ecological and socio-economic plans. The circum-méditerranéenne region thus appears globally as a major center of differentiation of plant species for this reason, one of the first concerns of géobotanistes is to know the floristic diversity and distribution of species and higher units of purely biogeographic perspective. Mediterranean coastal ecosystems are characterized by strong climatic and soil constraints, salinity, wind, drought and shallow soils or mobile. Among the what The Algerian coast as a whole is subject to significant human pressure, more intense than in the rest of the country. This pressure is for decades on vegetation and is ongoing. The preservation of biological diversity is a priority in Algeria with regard to the variety of existing ecosystems, their sensitivity and speed of degradation. The Mediterranean coastal sand formations are invaded every year by a crowd of more and more numerous of summer. The coastal development rework the mid destroying parts being fixings natural vegetation and enriching the sand with organic matter, it follows that the various species are very mixed. Most invasive gaining ground and the procession of plants related to the presence of man made his intrusion with the inevitable piles of garbage that bloom in unsupervised areas. Key words: Algerian coast, biodiversity, inventory psammophile, ecological factors

UTILIZING CITIZEN SCIENCE AND NEW TECHNOLOGY TO IMPROVE THE PALAU NATIONAL BIRD MONITORING PROGRAM

Heather Ketebengang

Palau Conservation Society

Islands are known to have high biological diversity and high concentrations of endemic species, but also have high rates of species decline and extinction. Managing island resources to ensure that species decline and extinction is stemmed

requires a range of capacities that most small islands do not have. This is particularly true for small Pacific Island nations such as Palau. Limited scientific and technical capacity to engage in data collection needed to manage natural resources has been identified as a barrier to effective natural resource management in Palau. Fortunately, technological advancements and the citizen science movement are measures to narrow that capacity gap. The Palau National Bird Monitoring Program launched in 2010 provides a framework for engaging amateur naturalists and avid bird watchers to document their observations in a database for use by the natural resource management community in Palau. New and innovative technology has eased the data collection and management efforts. These innovative platforms for learning allow both residents and visitors to Palau to support and improve Palau's natural resource management regimes.

123 ECOSYSTEM SERVICES PROVIDED BY DRAINED PEATLANDS

Petri Keto-Tokoi

Tampere University of Applied Sciences

Drained peatlands are novel ecosystems with distinctly different soil conditions and vegetation communities than on upland forest sites or on pristine mires. Ditching has lowered their water table thus improving tree growth and accelerating the decomposition of surface peat. In Finland 4,76 million hectares of peatlands have been drained for timber production, mostly between 1960's and 1980's. This has increased the growth of forests by 14 million m³ per year. However, the harvesting potential of drained peatlands is underutilized due to high timber procurement costs. 830 000 hectares of drained peatlands are so low-productive sites, that further investments to forestry are unprofitable. How these sites should be managed in the future is unclear and therefore an important research question. Drained peatlands produce several ecosystem services, including production of timber, berries and game, control of water quality and carbon sequestration. So far they have been managed primarily for timber production. Better understanding of the ecosystem services they produce is necessary for better informed decision making and management. Currently drained peatlands act as carbon sinks because carbon sequestration of the rapidly increasing growing stock clearly exceeds the release of carbon dioxide from the peat soil. However in the long run the continuous release of carbon dioxide from the drained peat will exceed the sink effect of the growing stock on nutrient rich sites. On nutrient poor sites it will probably be possible to carry out carbon neutral forestry also in the long term. Ditch network maintenance is a significant source of suspended solids to watercourses. Uneven-aged management can provide one way to reduce the negative impacts of peatland forestry on water

quality. An important research question is how large growing stock is needed for maintaining the water table low enough by evapotranspiration.

POPULATION VIABILITY ANALYSIS OF RHINOS RHINOCEROS UNICORNIS IN NEPAL: ASSESSING IMPACTS OF ANTIPOACHING AND TRANSLOCATION STRATEGIES

Madhav Khadka

WWF Nepal Program

Hemanta Kafley, University of Missouri / Nepal Nature Foundation ; Matthew GOMPPER, University of Missouri ; Mandira SHARMA, Lincoln University ; Rupak MAHARJAN, Department of National Parks & Wildlife Conservation, Govt. of Nepal ; Bishnu THAPALIYA, Chitwan National Park

Small populations of the large-bodied species, such as rhinoceros (*Rhinoceros unicornis*), that are restricted to a limited geographical range are always prone to extinction. Identifying factors underpinning the fate of such species is critical to addressing their ultimate persistence. We used VORTEX population viability analyses to assess the viability of rhino population in Nepal. We simulated deterministic single-population models under different scenarios to assess the impacts of poaching and the potential for rhino translocation in achieving viable rhino populations in Chitwan and Bardia National Parks in Nepal. Population and demographic data were obtained from censuses and from the published literatures. Model output predicted that the Chitwan population is stable and capable of supplying at least 10 rhinos per 3 years for translocation, provided poaching is restricted to 2 animals per 3 year intervals. However, the Bardia population is more vulnerable and unable to persist without supplementation even at the lowest rate of poaching (2 animals/yr). Supplementation of at least 10 animals added every 3 years for 30 years is crucial for establishing a viable population of rhinos in Bardia. This level of supplementation can withstand poaching of 2 animals/yr per year. Our study demonstrates that poaching is the major factor determining the fate of rhino population viability in Nepal. The supplementation of animals to Bardia from Chitwan, and increased effort in reducing poaching, will enhance the viability of rhino populations in Nepal.

AVAILABILITY OF PREY AND NATURAL HABITATS ARE RELATED WITH TEMPORAL DYNAMICS IN RANGE AND HABITAT SUITABILITY FOR ASIATIC CHEETAH IN IRAN

Leili Khalatbari

Gholam Hosein YUSEFI, CIBIO - Centro de Investigaç o em Biodiversidade e Recursos Gen ticos Universidade do

Porto[INSTITUTE]Mohitban Society ; Fernando MART NEZ-FREIR A, CIBIO - Centro de Investigaç o em Biodiversidade e Recursos Gen ticos Universidade do Porto ; Houman JOWKAR, Conservation of Asiatic Cheetah Project ; Jos  CARLOS BRITO, CIBIO - Centro de Investigaç o em Biodiversidade e Recursos Gen ticos Universidade do Porto

Understanding how species have been affected by recent human mediated landscape transformation is critical for designing effective conservation strategies. The Critically Endangered Asiatic cheetah (*Acinonyx jubatus venaticus*) has faced dramatic range decline and currently occurs in small populations restricted to the mountain deserts of Central Iran. Few data is available about these highly isolated and threatened populations. In this study, we quantified temporal changes in ecological requirements and availability of suitable areas for the Asiatic cheetah in Iran and adjacent areas. Ecological models for historical and contemporary time-periods, based on past and present species records and using a set of 11 ecogeographical variables including abiotic (climate, land cover) and biotic factors (prey availability), were built using maximum entropy modelling. Probability of cheetah presence was associated to prey availability (small distance to *Gazella bennettii*) and natural habitats (small distance to wildlands) in both time periods. There were differences in the response of cheetahs to distinct factors between time-periods that suggested shifts in the ecological preferences of the species. Availability of suitable areas was estimated to have declined by 37.1% during the last century. The apparent change in ecological requirements is probably related to the dramatic range regression experienced by cheetahs. Our results have direct implications for improving the ongoing conservation programs and management of this endangered cat in Iran, and provide as well directions for further research.

DOLPHINS AND FISHERIES: CAN THEY CO-EXIST?

Gopal Khanal

Tribhuwan University

Sandeep Kumar BEHERA, National Mission for Clean Ganga ; Keshav Dutt AWASTHI, Tribhuwan University ; Jennifer LEWIS, Tropical Dolphin Research Foundation

River dolphins are increasingly threatened by high resource extraction (e.g., overexploited fisheries) worldwide. We asked if the Ganges river dolphin, a freshwater dolphin endemic to the Indian-subcontinent can co-exist alongside with the current level of fisheries in the Ganges river system. We investigated the potential for resource competition between dolphins and fishers by assessing the extent of spatial overlap between dolphin's distribution and fishing activities. We also determined the factors that affect the distribution of river dolphins. We conducted sighting surveys using a motorized boat along a 65-km channel of the Karnali river of Nepal and

India. We recorded the presence/absence of dolphins and measured the habitat variables in each 1 km long sampling segments (n=65). Our results show that the probability of dolphin presence increases in downstream segments, which may be due to reduced stream velocity and high fish biomass in downstream segments. Downstream habitat in Karnali River offers favorable sites for ferry crossings and fishing activity. Almost two-third of the dolphin sighting locations overlapped considerably with the ferry crossings and high fishing areas, suggesting a high potential for resource competition mostly in downstream habitat. A high spatial overlap between dolphin distribution and fishing activity may indicate either resource competition or co-existence. At the current level of fishing activity, dolphins seem to co-exist with fisheries. But because fishers in this region have experienced serious decline in fish catch over years, use of more destructive fishing gear (e.g. large fishing nets) may become pervasive, which can jeopardize the fish population leading to high resource competition while also increasing the risk of dolphin entrapment in such fishing gears. Our results demonstrate the need for curbing destructive fishing practices to restore fish populations for sustainable fisheries and river dolphin conservation.

COMMUNITY BASED ASIATIC WILD DOG AND CHINESE PANGOLIN CONSERVATION IN EASTERN HIMALAYAS OF NEPAL

Ambika Prasad Khatiwada

National Trust for Nature Conservation

Carly WATERMAN, Zoology Society of London ; Kyran KUNKEL, University of Montana ; Monsoon POKHAREL KHATIWADA, Tribhuvan University

The eastern Himalayas of Nepal is a biodiversity hotspot and a crises eco-region. Agriculture is the traditional occupation and main source of livelihood of local people, including shifting cultivation, livestock husbandry for dairy and transport of goods. This paper presents case studies of community initiatives for two important species in eastern Nepal. Asiatic wild dog or dhole (*Cuon alpinus*) is the most imperiled pack hunting carnivore worldwide. Fewer than 2500 dholes remain and declining population trends continue. Human-dhole conflict is major conservation issue in Kangchenjunga Conservation Area. We initiated first ever conservation effort to save dholes in 2010 and implemented Community Managed Livestock Insurance Scheme (CMLIS) in 2013. Three self-sustaining CMLIS are established in priority areas and run by local people where 137 herders included their 801 livestock into the scheme. Herders started to get relief fund if livestock is killed by dholes. The CMLIS also supported invested in livelihoods. This approach is working toward long term conservation of a viable population of dholes and can be replicated elsewhere for large carnivore conservation. Chinese pangolin (*Manis pentadactyla*), the burrowing small

mammal-known as scaly ant eater, is a critically endangered species. More than a million pangolins were illegally traded in last ten years. We piloted a project in human dominated landscape covering 40 sq.km areas in 2012 where eighteen sub-committees and two pangolin conservation committees are established directly engaging 263 people and informed >1182 individuals for pangolin conservation. The committees started to raise awareness among villagers, stopped poaching and if any one captured pangolin, the committee members help to release back to its natural habitat. This approach supported conservation of Chinese pangolin controlling illegal trade locally. Communities now believe that Chinese pangolins are worth more alive than dead.

SPECIES RICHNESS PATTERNS IN SMALL MAMMALS ALONG AN ELEVATIONAL GRADIENT IN EASTERN HIMALAYA, INDIA

Sunita Khatiwara

National Centre for Biological Sciences

Joya THAPA, Salim Ali Centre for Ornithology and Natural History ; Ajith KUMAR, National Centre for Biological Sciences

Although only about 7,000 km² in area, because of its extreme elevation range (from 200 m to 8000 m) the Himalayan state of Sikkim in India has faunal components from three major biogeographic realms – the Indo-Malayan, Palaeartic and Ethiopian. This provides a unique situation to examine species richness patterns along an elevation gradient. In this study we examined the species richness patterns of small mammals (murid rodents, pikas, ground and tree shrews) along the elevation gradient from 230 m to 4200 m. We trapped small mammals using Sherman live traps, laid at 10 m interval along traplines in seven elevation zones, with one trapping session lasting for 5 consecutive nights. We sampled 38 trap lines in 7 elevation zones, with a total sampling effort of 9069 trap nights. We recorded 430 individuals belonging to 22 species, with 15 species of murids, 5 ground shrews, one species each of tree shrew and pika, the latter occurring only >3000 m. Species richness showed a bimodal elevation pattern with low species richness at mid elevation (1500 m) and high species richness at low and high elevations, the latter due to the presence of Palearctic species, such as *Ochotona tibetana*, *Microtus* sp., *Sorex* sp. and *Pitymus sikkimensis* which were limited >3000 m. There are also several species restricted to <1500 m, e.g. *Rattus sikkimensis*, *Mus musculus castaneus*, *Suncus murinus* and *Tupia belangeri*. In contrast, the mid elevation had relatively very few exclusive species (e.g. *Niviventer niviventer*, *Rattus rattus brunneusculus* and *Rattus rattus tistae*) and only very few species occurred in the mid elevation. Range profile shows the restriction of most of the species either in the higher or the lower elevation. The region undergoing rapid unsustainable developments, therefore we recommend immediate conservation attention.

THEY DON'T COME EASY; FEASIBILITY OF ASIATIC LION REINTRODUCTION TO IRAN

Sam Khosravifard

ITC, Faculty of Geo-Information Science and Earth Observation of the University of Twente

Aidin NIAMIR, Senckenberg Biodiversity and Climate Research Centre

Despite being extinct in Iran's wilderness, Asiatic lions (*Panthera leo ssp. persica*) are still alive in literature and fine arts. This charismatic species has been Iran's national emblem and known as a symbol of glory, grandeur and power since Mithraism era. The last report of Asiatic lion in Iran goes back to 60 years ago and therefore our understanding of the habitat characteristics is limited to historical observation records and travelogues. Asiatic lions had a wide historic distribution from Greece and Syria in the west through Azerbaijan, Iraq, Iran, Afghanistan, Pakistan, and up to India in the east, but is now restricted to a single isolated population in India's Gujarat State. In 1973, the Department of Environment of Iran conducted preliminary studies to reintroduce Asiatic lion to Iran. The reintroduction project was postponed and never executed on that time, though the tendency to put the project into effect remained with the decision makers. In this study we predicted the habitat suitability for Asiatic lion in Iran. We first trained ensemble of species distribution models using historical observations and physical variables. The outcome of the ensemble models were updated by the local expert knowledge using biological and anthropogenic variables. The final model was then used to predict the habitat suitability for Asiatic lion in all protected areas in Iran. Our study revealed that none of the protected areas at the current condition are ready to accommodate the Asiatic lion. According to the elicited knowledge, land cover, anthropogenic conflicts, and prey population are the most important factors, determining the habitat suitability for Asiatic lion. Any reintroduction plan for the Iran's national emblem requires a comprehensive carrying capacity study, intensive habitat restoration and preparation, as well as public awareness and participation.

PREDICTING THE POTENTIAL INVASIVE DISTRIBUTION OF RACCOON IN IRAN

Sam Khosravifard

ITC, Faculty of Geo-Information Science and Earth Observation of the University of Twente

Aidin NIAMIR, Senckenberg Biodiversity and Climate Research Centre

Raccoon (*Procyon lotor*) is a native species in the Western Hemisphere, ranging from central Canada to Panama. In early 1930s, it has been introduced to the Eastern Hemisphere in USSR for its fur. This introduced species has been extending its range and apparently has been changed to an invasive species

in western Asia and Northern Europe. In 1991, for the first time, raccoon was observed and reported in the Hyrcanian mixed forests ecoregion in Iran, near the border of Azerbaijan. Since then, scattered observation records of this non-native mammal implied that the distribution of raccoon not only confined to the forests and woodlands, but has been extended toward forest steppes and urban areas in the south and in the east of the ecoregion. Unfortunately, the rapid march of raccoon in Iran (~400 km in 10 years) has been ignored and its impacts on native species, and the potential invasive distribution remained poorly-studied. In this study we employed an ensemble of species distribution models to predict the potential invasive distribution of raccoon in Iran. To do so, we trained the models using species distribution data and environmental explanatory variables in north and center of America. We then extrapolated the models into space to obtain the habitat favorability map for the raccoon in Iran. Ultimately we evaluated the local favorability map using independent observation records. Our results revealed that the potential invasive distribution of raccoon in Iran is tremendous, covering more than one-fifth of the country. However long freezing period and severe drought might limit their survival. We hope that our finding rings the bell and persuade the national and international authorities for a comprehensive conservation plan. Though in the absence of a north American parasites, potential predator, and lack of local expertise that might be a challenge.

BIODIVERSITY CONSERVATION CORRIDORS CAMBODIA PROJECT

Bunnath Khun

Biodiversity Conservation Corridors Cambodia

The Project is promoting sustainable resource use, and restore and enhance these productive landscapes. It will do so through conservation and development activities. The design of the biodiversity corridors is embedded within a multipurpose, sustainable, biodiversity landscapes approach. The Project will cover 22 communes (12 in Monduliri and 10 in Koh Kong) located across 8 districts with a total population of approximately 68,048 (2008 census) in both provinces and households numbering just over 14,000. The Project in both Koh Kong and Monduliri provinces is predominantly in mountainous areas covered with protected forests, NPs, and wildlife sanctuaries. An estimated 17,500 households will benefit from the Project, of which about 25% are indigenous peoples of Monduliri largely from the Phnong group, and 50% are women. The Project is (i) providing forest tenurial security to local communities and indigenous groups for collective management of forest resources; (ii) restore habitat on degraded forest lands with tree planting of natives species and agroforestry models with improved sources of non-timber forest products; (iii) improve livelihoods and income enhancing

small scale infrastructure; and (iv) generate over 1 million cash-based labor days through project activities. Delineation and demarcation of these corridors will be in consultation with primary beneficiaries based on a participatory land use planning approach. The project is now reaching of it midterm review which is starting from year 2011 to 2018, and that is great opportunity to sharing and receiving project feedback and construction recommendations to make it more quality effectives and biodiversity sustainability as we do expected.

SYCAMORE PASTURES IN THE NORTHERN ALPS: A HOTSPOT OF BIODIVERSITY

Thomas Kiebacher

WSL

Matthias BÜRGI, WSL ; Christine KELLER, WSL ; Christoph SCHEIDEGGER, WSL ; Ariel BERGAMINI, WSL

Sycamore pastures are a traditional land management system in the montane region of the Northern Alps. Like many other old cultural landscapes they are threatened by on-going land use changes which may reduce the typical biodiversity associated with these landscapes. Old sycamore trees on these pastures are especially rich in epiphytic cryptogams with up to 100 bryophyte and lichen species co-occurring on one tree and can thus be considered as hotspots of biodiversity. Moreover they are the main habitat of the moss *Tayloria rudolphiana* (Splachnaceae), which is a priority species for nature conservation listed in the FFH - directive, and other rare and threatened species such as *Lobaria pulmonaria* and *L. amplissima*. There is thus a high responsibility for nature conservation authorities to protect this ecosystem. So far hardly anything is known about biodiversity patterns of bryophytes and lichens in this ecosystem. Here we conduct an in-depth analysis of species richness patterns of bryophytes and lichens and their dependencies on different environmental variables. Although bryophytes and lichens are similar with respect to a number of functional traits (e.g. they are poikilohydric organisms), species richness patterns of these two groups may not necessarily coincide. That means that richness hotspots or rarity hotspots between these two groups or even within the groups between different subgroups (e.g. functional or taxonomic groups like liverworts and mosses or macro- and microlichens) may show considerable variation. In the talk we will focus on patterns of species richness of bryophytes and lichens, their relation to environmental variables (e.g. tree parameters and connectivity) as well as to the occurrence of our target species *Tayloria rudolphiana*.

124-THE NEXT GENERATION OF MITIGATION: LANDSCAPE PLANNING IMPROVES OUTCOMES FOR PEOPLE AND NATURE

Joseph Kiesecker

The Nature Conservancy

Christina KENNEDY, The Nature Conservancy ; Daniela MITEVA, The Nature Conservancy ; James OAKLEAF, The Nature Conservancy ; Mike HEINER, The Nature Conservancy ; Kei SOCHI, The Nature Conservancy

Mitigation offers the opportunity to address the impacts of development through application of the mitigation hierarchy: avoid, minimize, restore, offset. But there are many problems with how mitigation is currently applied. Applying the mitigation hierarchy on a project-by-project basis, often at small spatial extents, underestimates the cumulative impacts of multiple current or future projects and undermines the hierarchy's purpose and utility. The development of mitigation policy is beginning to explore a move away from site-based, piecemeal mitigation - which often results in a patchwork of isolated and difficult-to-manage projects - to a scale that is able to account for impacts affecting an entire region. For example, new mitigation regulations in several countries now require the adoption of a landscape-scale approach to facilitate investment in key regional conservation priorities and to ensure early integration of mitigation considerations in development projects. Impact mitigation at broader scales is expected to provide more effective conservation outcomes, reduce regulatory hurdles, and potentially offer cost savings to developers. Here we will discuss a series of projects from the United States, Mongolia and Brazil that provide early support for the benefits that landscape level mitigation can deliver.

PERFORMANCE OF WILDLIFE CONSERVATION APPROACHES IN NORTHERN TANZANIA

Christian Kiffner

The School For Field Studies

In most ecosystems of sub-Saharan Africa, the extent of protected areas is not sufficient to conserve the functional connectivity that is required for large mammal conservation. Similar to other ecosystems, the Tarangire-Manyara ecosystem in Northern Tanzania contains a patchwork of conservation and land-use utilisation approaches. Unfortunately, we know little how different conservation approaches affect wildlife populations and which measurable wildlife parameters effectively mirror conservation performance. To address these questions we estimated illegal hunting pressure, and assessed behaviour, population densities and community structure of large mammals in different multiple-use areas and national parks. Evidence for anthropogenic drivers of wildlife declines (hunting and livestock) was highest in the game controlled area (CA), immediate in a pastoral area (PA) and lowest in national parks (NP). Large mammal species richness in PA and NPs were similar but the mammal community was considerably impoverished in CA. Most, but

not all large mammal species showed a gradual adjustment of responsiveness towards humans according to conservation status and were most responsive in CA and least responsive in NPs. However, behavioural budgets of common herbivores did not differ consistently between study areas. Matched comparisons of population densities revealed that CA and PA occasionally held higher species-specific densities than adjacent NPs. Most wildlife populations in the study areas have remained fairly stable in the past decade but current wildlife densities are below historic baselines. Results suggest that only species richness unambiguously reflected the level of human disturbance in a management unit. In this dynamic and fragmented ecosystem, potential early warning indicators of human exploitation were not reliable indicators of conservation performance, highlighting the need for ecosystem-wide monitoring and management of threats and wildlife populations.

DISTRIBUTION PATTERN OF WOODY ENDEMIC PLANT SPECIES IN GEORGIA (THE SOUTH CAUCASUS)

Mariam Kikvidze

Ilia State University

Marina MOSULISHVILI, Ilia State University ; Ketevan BATSATSASHVILI, Ilia State University

The book „Red List of the endemic plants of the Caucasus: Armenia, Azerbaijan, Georgia, Iran, Russia, and Turkey“ published recently by Missouri Botanical Garden Press provides a comprehensive list of more than 2,700 endemic vascular plant species of the Caucasus biodiversity hotspot, 1,300 of which occur in Georgia. 150 of these Caucasus endemics recorded in Georgia are woody plants. In the present article we analyse distribution pattern of the woody species of endemic plants along the elevational gradient in Georgia within West Caucasian or Colchic, East Caucasian and South-Caucasian (West Asian) vegetation zonation types given in the publication “Main types of vegetation zonation on the mountains of the Caucasus”, on the one hand, and the vegetation map on the Caucasus as in the „Karte der natürlichen Vegetation Europas“, on the other (the elevational patterns of woody endemic plant distribution at the family level, the elevational pattern of endemic distribution of the entire woody flora, the elevational pattern of different life forms such as trees, shrubs and semi-shrubs, the correlation of each variable with each other and the elevation as such). We also consider results of species richness and complementarity (reserve selection) analysis of rare woody endemic species distribution as well as GAP analysis to reveal the picture of their presence on protected areas and identify Important Plant Areas in order to focus on those, which are not under legal protection and thus require particular conservation attention.

IDENTIFYING AND MAPPING ECOSYSTEM SERVICES SUPPORTING TOURISM: THE ECO-PARCEL APPROACH

Halima Kilungu

Wageningen University

Rik LEEMANS, Wageningen University ; Pantaleo. Kirari. Thomas MUNISHI, Sokoine University of Agriculture ; Bas AMELUNG, Wageningen University

The wide variety of the world's ecosystem services that tourism depends on necessitates the use of specific approaches for their identification and mapping. In fact, not all ecosystems and their services serve as tourist attractions in any given landscape. Yet no approaches are available to date that cluster ecosystem services into patches or other ecological unit(s) that are meaningful to tourism stakeholders to enhance their decisions. Therefore, our study developed an approach 'Eco-parcel' that isolate and group uniquely attractive ecological units that holds more potential as tourist attractions and referred them as ecological parcels 'Eco-parcel'. The Eco-parcel approach integrates GIS techniques to identify, map, delineate and group tourist attractions according to their similarities and differences and questionnaire survey to determine which eco-parcels are more appealing. The approach shows even in small area a wide variety of eco-parcels arising from topographic gradients, watershed characteristics, and physical landscapes can be identified while Eco-parcels that contain multiple attractions tend to be more preferred. For instance, 72% tourists climb Mount. Kilimanjaro due to its height and snow atop while 98% tourists visit the Serengeti due to attractions within endless plains. This study suggests the eco-parcel as useful unit and tool for identifying tourism resources.

HUNTING FOR THE PROBLEM: INVESTIGATING BUSHMEAT USE AROUND NORTH LUANGWA NATIONAL PARK, ZAMBIA

Emily King

Imperial College London

Aidan KEANE, Edinburgh University ; Andrea WALLACE, Frankfurt Zoological Society ; Graham WALLACE, Frankfurt Zoological Society

Bushmeat is an important source of protein and income in the rural tropics. Growing human populations are making it unsustainable, threatening wildlife as well as rural livelihoods. Successful conservation projects rely on understanding the scale and drivers of bushmeat use; however, it is often illegal and a sensitive topic within rural communities, making it difficult to obtain accurate information. This research used a specialised method, the double-list Unmatched Count Technique (UCT), with a structured interview to indirectly survey households across Zambia's North Luangwa ecosystem

about the prevalence and drivers of bushmeat use, and attitudes towards it. This survey method reduces bias due to question sensitivity but to date has rarely been used in conservation research. Results were triangulated with focus group and key informant data to characterise bushmeat use in this little-studied wilderness area. Estimates of prevalence were low, with less than 1% of the population hunting or trading bushmeat and 13.5% consuming bushmeat. Primary drivers of bushmeat use were taste, low food and income security, and human-wildlife conflict. Bushmeat hunting and trading has traditionally commanded high levels of social respect within local communities; however, this is no longer the case and the shift has coincided with an increase in the perceived probability of being arrested, fined, and/or imprisoned. The research informs conservation interventions addressing the drivers of bushmeat use by providing alternative sources of food and income, such as establishing local butcheries or community banks. This may be facilitated by pooling resources and knowledge with development agencies to increase food and income security. However, hitherto unconventional approaches such as community-managed wildlife farming may be required to address bushmeat consumption driven by taste. The research also demonstrates the value of the double-list UCT when examining bushmeat issues.

CHANGING CONSERVATION POLICY AND MANAGEMENT - SOME EXPERIENCES FROM THE SWAMPS

Richard Kingsford

Centre for Ecosystem Science

As scientists, we are increasingly challenged and often frustrated by the inertia of conservation policy and management to change in response to scientific evidence. Many governments and their agencies are committed to base conservation policy and management changes on scientific evidence. But there are small and large barriers everywhere from the political to vocational. There are few professional incentives and some disincentives for scientists to change the way we do things. We are paid and rewarded for successful grants, mentoring postgraduate students and publishing in high impact journals. But are we failing to make a real impact in changing the world? The burgeoning extinction crisis continues to bear testament to our collective inability to change the business as usual model. I will present a series of case studies from wetland and river research in Australia which have improved conservation policy and management outcomes. These include the declaration of national parks, forging of conservation agreements for whole river systems, environmental flows and stopping the building of dams. There are also plenty of failures. Despite this, there are some clear lessons and generalities to be drawn. I aim to focus

on the critical aspects of engagement, trust, confrontation, communication, politics, media and advocacy, as well of course good science. As conservation biologists, we need to find effective ways of influencing conservation policy, given the ongoing extinction crisis. This means expanding our influence beyond the echo chambers of our scientific world.

24. CLOSING THE COLLABORATIVE GAP: ALIGNING SOCIAL AND ECOLOGICAL CONNECTIVITY FOR BETTER MANAGEMENT OF INTERCONNECTED WETLANDS

Stuart Kininmonth

Stockholm University

Arvid Bergsten, Stockholm University ; Örjan BODIN, Stockholm University

Understanding how governance structures align to ecological processes in a landscape is critical for effective management of ecological resources. Ecological resources are not independent from each other, instead they are interconnected, and their well-being is often critically dependent on upholding ecological connectivity, especially in times of change and disturbances. Coordination and collaboration among managing actors, each managing their own piece of the puzzle, is therefore essentially a requirement for effective management. We present a conceptual model that includes ecological resources, managing and coordinating actors, along with an explicit representation on how all these entities are connected to each other. We apply this model to 25 municipalities that manage 408 wetlands in central Sweden. The study shows a good social and ecological alignment, however with a high prevalence for coordination through third parties. We discuss this pattern emergence, its potential implications, and examine which municipalities adopt these coordinating functions.

HUMAN WILDLIFE CONFLICT IN KENYA

Jonathan Kirui

Kenya wildlife service

Human wildlife conflict in Kenya , has been on the increase in the recent past, occasioned by increase in human population and encroachment onto the wildlife dispersal areas. There are six major types of human wildlife conflict in Kenya , which are crop destruction, livestock depredation, property destruction, threat to humans security, human injury and human deaths. between 2008 and 2013' nine thousand eight hundred and ninety three cases of human threat reported in Kenya, nine hundred and four persons injured while three hundred and eighty four persons were killed by wildlife in the same period. seven thousand and ten cases of crops destruction were encountered over the same period. Mitigation measures were

carried out. This paper will endeavor to explain the challenges in mitigating this phenomenon.

ADDING UP THE EFFECTS OF CLIMATE CHANGE FOR MONTANE AMPHIBIANS: STAGE-SPECIFIC EFFECTS OF WARMING, DRYING, AND INCREASED CLIMATIC VARIABILITY

Amanda Kissel

Simon Fraser University

Wendy PALEN, Simon Fraser University ; Maureen RYAN, Simon Fraser University ; Michael ADAMS, U.S. Geological Survey

Anthropogenic climate change is expected to alter the access of wetland obligate species to crucial habitat, which may in turn disrupt important phenological processes. Specifically, changes in the timing and form of precipitation are likely to alter wetland hydroperiods such that ephemeral wetlands dry sooner, and permanent wetlands become ephemeral. This phenomenon is expected to be exacerbated at high elevations, where climatic processes such as precipitation and snowmelt influence wetland hydrology. Species that rely on consistent water sources for reproduction, such as amphibians, may experience a phenological mismatch between the periods in which offspring are dependent on water for growth and development, and the period of time in which wetlands physically hold water. Potential consequences of early drying are increased levels of embryonic or larval mortality if wetlands dry before eggs hatch or larvae metamorphose, and if mortality is high enough, could scale up to affect population stability. To address this, we collected baseline data on >60 Cascades frog (*Rana cascadae*) breeding sites within Olympic and Mt. Rainier National Parks in Washington state, USA, that span a range of hydroperiod types (short, intermediate, perennial, and permanent) and quantified the proportion of reproductive effort that was lost as a result of wetland drying. We found that mortality occurs in all wetland types (short to permanent), and can result in a loss of up to 37% of reproductive effort in a population. Combining these data with existing demographic data and site-specific predictions of future warming and drying rates allows us to explore how climate change will affect *R. cascadae* populations now and in the future. These results can then be used to inform conservation decisions, for example removing non-native, predatory fish in permanent wetlands that may act as refuges for amphibians in the future.

62. A DYNAMIC SYSTEMS APPROACH TO CULTURAL VALUES: IMPLICATIONS FOR HUMAN-ENVIRONMENT INTERFACE

Shinobu Kitayama

University of Michigan

The development of sustainable eco-cultural systems is an agenda of the utmost significance today. One central question pertains to the notion of cultural values, i.e., positively valenced goal states that are shared by a historically, regionally, and ethnically defined group of people. In the present talk, I will propose a dynamic systems view of cultural values. This view is based on three important considerations. First, cultural values are historically path-dependent. A variety of ecological, social, economic, and political factors are associated with the development of different values. For example, histories of frontier settlement foster independence and, thus, are associated with less appreciation of interdependencies between humans and the nature. Likewise, farming, particularly farming of crops like rice, tends to foster values of interdependence. Second, our approach is informed by recent work highlighting the power of cultural values in fostering neurobiological changes. Evidence is growing that culture's beliefs and practices can plastically change processing pathways of the brain. For example, interdependence requires close attunement to goals and interests of close others because these others are psychologically incorporated into the self. Those who value interdependence tend to have brain pathways set up such that they respond at least as strongly when others' goals are at stake as when their own goals are at stake. The third pillar of our approach, gene x culture interactions, is suggested by an observation that not everyone in a cultural group acquires norms of their culture. One hypothesis that is being currently investigated is that some people are genetically more sensitive to social and cultural norms than others. Overall, the current view, emphasizing dynamic systemic interdependencies among culture, brain, and the mind, offers some implications for human-environment interface.

15. BIODIVERSITY CONSERVATION FOR ECOSYSTEM SERVICE DELIVERY OR ECOSYSTEM SERVICES FOR BIODIVERSITY CONSERVATION

David Kleijn

Alterra

Biodiversity conservation is increasingly being justified because of the ecosystem services it delivers. The basic evidence for more diverse ecosystems delivering more benefits comes from experimental studies. Such studies do not consider the costs of maintaining or promoting biodiversity. When costs are taken into account, justifications based solely on ecosystem service delivery could result in optimization rather than maximization of biodiversity conservation. Using wild bee species as a concrete example of an important service providing group, we examine in real world landscapes what the economic

contribution of wild pollinators is to crop production, what proportion of the total species pool is making significant contributions to crop pollination, how this varies in space and time, how common these species are in the wider countryside and how easily they can be enhanced. We examined these issues using existing datasets of bee pollinators from five continents. Wild bee communities contribute on average over \$3000 per ha to the production of insect-pollinated crops. However, a limited subset of all known bee species provides the majority of pollination services because, across crops, years and biogeographical regions, crop-visiting bee communities are dominated by a small number of common species and rarely contain regionally threatened species. These species are dominant crop pollinators because they are able to exist in agricultural landscapes and many are enhanced relatively easily by simple conservation measures. Focusing conservation on the services delivered by pollinators may therefore lead to management strategies that predominantly benefit the limited set of species currently providing the majority of crop pollination. Consequently, conservation of the biological diversity of bees should be motivated not only by immediate benefits from ecosystem services, but by the full richness of arguments for conservation.

A NEW TOOL TO CALCULATE ROADLESS SPACE IN FOREST LANDSCAPES, APPLIED IN THE CONGO BASIN

Fritz Kleinschroth

CIRAD

Sylvie GOURLET-FLEURY, CIRAD ; Frédéric MORTIER, CIRAD ; John R. HEALEY, Bangor University ; Radu STOICA, Université Lille 1

New global strategies for road building require innovative tools to analyze linear patterns and their spatial distribution and to evaluate their environmental impacts. Roads not only present physical barriers to wildlife but also provide access for human and biological invasions. In tropical regions especially, forest degradation has been associated with roads built for selective logging into formerly intact forest landscapes. To quantify to what extent ecosystems are influenced by roads, it is important not only to know road length density but also their location in a landscape unit. The concept of roadless space is based on distance to the nearest road from any point. We present the computation of this distribution using the Empty-Space-Function, a general statistical mathematical tool based on stochastic geometry and random sets theory. We demonstrate the applicability of this well-defined probability function to calculate roadless space based on vector road data. In a Congo Basin case study we compared the temporal development of road networks inside different logging concessions over time. We hypothesized that roadless space decreases, even when the rate of wood volume harvest remains constant.

Based on LANDSAT time series covering the last 29 years, we assessed accessible roads in relation with the river network and calculated the roadless space at different points in time. As expected, roadless space decreased continuously throughout most concessions, despite a drop in total annual harvest volume after 2008 and independent of forest certification schemes. We recommend that measures to reduce impacts of selective logging should not only be based on the extraction of timber, but should also include the total area impacted by roads. The Empty-Space-Function provides a rigorous mathematical description and a straightforward way to assess intact forest landscapes and is therefore highly applicable to road impact evaluation in conservation science.

218 NATURA 2000 IN GERMANY

Frank Klingenstein

German Federal Ministry for the Environment

The EU habitats and birds directives are the basis for protecting biodiversity in the European Union by mainly three instruments: Establishing protected areas (= the Natura 2000 network) with obligations to protect and actively manage these sites perform impact assessments and compensate possible negative influence of plans and projects on these sites protect species in and outside these areas. For the selection and designation of the Natura 2000 sites only scientific criteria should have been used. Economic or social interest e.g. of land users should be integrated when the conservation measures are defined (e.g. management plans). In Germany, there are at about 5.300 Natura 2000 sites covering 15.4 % of the terrestrial surface and at about 45% of the sea. The designation of these sites in Germany has been a long and difficult process leading to the conviction of Germany by the European Court of Justice. In this process, scientific data gathered mainly by the civil society had a significant impact: The so called Important Bird Areas became a strong argument for site designation and lead to legal uncertainties and a lack of planning reliability endangering economic activities. After the establishment of the German Natura 2000 network the rules and procedures of the EU habitats and birds directives become more and more part of the everyday business of administrations and companies. The contribution will focus on the role of scientific data in the German Natura 2000 process and will try to explain why any changes in the directives may have serious impacts on the legal certainty and the achievements of the directives that have already been reached.

THE USE OF MICROSATELLITE, MAJOR HISTOCOMPATIBILITY COMPLEX, AND TOLL-LIKE RECEPTOR MARKERS TO EXAMINE BOTTLENECK EFFECTS IN THREE DIVERSE NEW ZEALAND SPECIES

Gabrielle Knafler

University of Otago

Catherine GRUEBER, University of Sydney, NSW ; Bruce ROBERTSON, University of Otago ; Ian JAMIESON, University of Otago

Studies exploring the genetic consequences of population bottlenecks are increasingly examining the loss of diversity at functional loci such as those associated with adaptive (major histocompatibility complex, MHC) and innate (toll-like receptors, TLRs) immunity while using neutral microsatellite markers as a control. Aspects that require further research include whether remnant genetically depauperate mainland and insular-originating source populations differ in immune-gene diversity, whether contemporary bottleneck circumstance (i.e. human-induced via translocation vs. natural via pathogen outbreak) differentially affects the genetic diversity of various molecular markers, and whether signals of selective responses to disease can be detected in threatened populations. I will discuss the findings of my PhD research, addressing these questions in three of New Zealand's endangered bird species. In kakapo (*Strigops habroptilus*), results reveal that MHC but not TLR markers generally support findings based on neutral markers; that mainland-originating kakapo contain unique alleles not found in insular-originating kakapo and indicate that the MHC is an important tool to rank individuals for breeding opportunity/artificial insemination procedures. Anthropogenic and natural contemporary population bottlenecks differentially affected patterns of diversity loss at microsatellite, MHC, and TLR loci in South Island saddlebacks (*Philesturnus carunculatus*). Finally, preliminary results indicate that a selective response to a viral outbreak may be responsible for TLR1LA genetic diversity loss in a population of red-crowned parakeet (*Cyanoramphus novaezelandiae*). Taken together, these studies show that genetic diversity patterns across loci reflect the species-specific narratives of population decline.

URBANIZATION CAUSES RELATIVELY HIGH LOCAL BIODIVERSITY BUT LARGE SCALE BIOTIC HOMOGENIZATION

Eva Knop

University of Bern

Tabea TURRINI, University of Bern

Cities are growing rapidly worldwide, yet the impact of urbanization on arthropod diversity remains ambiguous. Also, urbanization is regarded as one of the major causes for global

biotic homogenization. Evidence for the homogenization hypothesis is mostly derived from plants and birds, whereas arthropods have so far mostly been neglected. We thus asked whether a) species diversity and abundance of arboreal arthropods is higher in intensively managed farmland areas as compared to cities, and b) species communities between cities are more similar than between rural sites. We further were interested whether the presence of non-native species explains the pattern observed. To do so we used species community data of three indicator groups, namely true bugs, leafhoppers, beetles. The specimens were sampled on a total of 36 standardized birch trees in a total of 6 cities and 6 rural areas nearby. Species richness of bugs was significantly higher in cities than in rural sites, and for the other two indicator groups it did not differ between the two ecosystems. Species abundance of all indicator groups was significantly higher in cities than in rural sites. In contrast, species turnover of two indicator groups (bugs and leafhoppers) was significantly higher between rural sites than between urban sites, and did not differ for beetles between the two ecosystems. The exclusion of non-native species did not change the pattern found. Our study shows that cities might harbour similar or even higher species diversity than intensively managed rural sites nearby. However, on a very large scale, urbanization seems to homogenize species communities. Specific measures in cities targeted at species typical for the biogeographic region might help to counteract the on-going biotic homogenization due to urbanization.

15 QUANTIFYING THE SOCIO-ECONOMIC IMPLICATIONS OF MOBILIZING ECOSYSTEM SERVICES IN AGRICULTURE

Thomas Koellner

University of Bayreuth

Patrick POPPENBORG, University of Bayreuth ; Alison BAILEY, University of Reading ; Mark BRADY, Swedish University of Agricultural Sciences

Meeting growing demand for food and bio-fuels from agricultural landscapes is a challenge that is exacerbated by needing to account for biodiversity and associated provisioning of ecosystem services. Successful implementation of such a multi-criteria objective not only requires appropriate agricultural management systems, but crucially depends on farmers' willingness to implement them as well. One part of the Liberation FP7 project thus deals with the socio-economic implications of eco-functional intensification. We therefore integrated spatial production functions with economic optimization models to evaluate the impact of landscape structure on supporting ecosystem services, crop yields and farmers' incomes for a cross-section of European landscapes. Special focus was put on agricultural production risk, as higher biodiversity levels might reduce the relative variability

of yields and reliance on external inputs. Furthermore, we conducted interviews to identify farmers' acceptance of different landscape management options. We hope to make general conclusions about the potential benefits of cooperative solutions and what landscape characteristics are important for combining biodiversity conservation with agricultural production.

ID 68 / SUPPORTING BIODIVERSITY IN LANDSCAPES OF MANAGED FORESTS: INVERTEBRATES AS RESEARCH AND APPLICATION CHALLENGES

Matti Koivula

University of Eastern Finland

In Northern Europe, modernized forest legislation, certification systems and guidelines encourage forest owners to apply continuous-cover retention forestry, and the public acceptance of this regime increases with wider acknowledgement of forest values other than economics. This can be seen as a welcome trend for diversity, but in reality the paradigm shift is slow. The tardiness is due to several obstacles, such as financial losses and slow regeneration, but also because the biological outcome of a considerably more widespread application of retention and rehabilitation applications is uncertain. This shortcoming is pronounced concerning invertebrates, even though some field explorations suggest forestry-initiated changes in the geographic distribution of forest specialists. Invertebrates are often considered irrelevant for the landscape scale because of their small home ranges, or because representative sampling is thought to be too labor intensive and expensive. Moreover, continuous-cover forestry is still seldom applied by forest owners. Accordingly, a 2014 review showed that only two out of 45 North American and Fennoscandian continuous-cover experiments had an intended goal of comparing landscapes with different harvesting regimes. An understanding of landscape-level phenomena is, however, crucial for justifying continuous-cover forestry: does its large-scale application support recoveries of specialized forest species? I will demonstrate human impacts on invertebrates using two real-life landscape approaches. Lesson learned is that landscape is a relevant, achievable scale to study invertebrates. The biggest challenge in landscape experiments is to motivate forest owners to apply continuous-cover forestry, but it also requires careful a priori consideration of research questions and sample representativeness.

123 AFFORESTED FIELDS AS NOVEL ECOSYSTEMS: BIODIVERSITY AT DIFFERENT TROPHIC LEVELS

Atte Komonen

University of Jyväskylä

The agricultural legacy in afforested fields is manifested in the physical, chemical and biological features of the soil. Afforested fields can thereby harbor novel species assemblages and interactions. Based on an extensive field experiment, I present results on biodiversity patterns at afforested fields 25 years after afforestation. Many rare, calciphilous and herb-rich forest specialist fungi (Basidiomycete: agarics and boletales) were recorded. The carabid beetle (Coleoptera: Carabidae) and ant (Hymenoptera: Formicidae) assemblages were dominated by generalists. Different trophic levels responded differently to tree species identity. Fungal diversity was highest in spruce and pine plots, whereas both the carabid and ant assemblages were more diverse in birch plots. Similarities in species composition varied depending on the trophic level. Fungal community was the most dissimilar among birch plots, whereas carabid and ant communities were the most dissimilar among birch plots and among spruce plots. Overall, there was great variation in community composition among geographical locations. The results show that early successional afforested fields can be valuable compensatory habitats for calciphilous and herb-rich forest fungal species, and can also harbor species rich arthropod assemblages. Field afforestation is therefore a potential conservation tool that could be used to complement rare habitat types in the highly fragmented protected area networks. The diversity and species composition of fungal and arthropod assemblages are influenced by tree species identity. This is evident already at early successional stages and is likely to become more prominent as succession proceeds. Thus, the identity of the tree species used in afforestation is one important factor, if field afforestation has biodiversity objectives.

126 BIODIVERSITY CONSERVATION AS FACILITATOR OF DEVELOPMENT: THE CÔTE D'IVOIRE EXAMPLE

Souleymane Konaté

University of Nangui Abrogoua

Côte d'Ivoire is a West African country that is characterized by an outstandingly high biodiversity, which is heavily threatened due to its socio-economic development since independence. The importance of this biodiversity is indicated, on one hand, by the fact that most of the protected areas of the country belong to the global priority zone for the conservation of biodiversity in West Africa (the Upper Guinea biodiversity hot spot); and on the other hand, by the presence two important UNESCO Biosphere reserves and World Heritage Sites in the country (Taï NP with the last continuous primary moist rain forest in West Africa, and Comoé-NP as largest savannah NP in the region). However, from 1958 to the present, the country lost nearly 90% of its original forest cover (at a rate of 7.6% per year), as well as many species due to exploitative

land use practices and conversion of large proportions of natural habitats into cropland triggered by its unprecedented economic growth. Aware of the environmental and long-term socio-economic consequences of such a development, the country has recently committed itself to a sustainable development policy for an emerging economy by 2020. It involves all business actors including those of economy, environment, higher education and scientific research. To achieve these objectives, the country has launched a five years National Development Plan (NDP). What are the foundations of this new development policy? How can the particular biodiversity of the Côte d'Ivoire contribute to achieve this goal? What is the contribution of scientific research on biodiversity and climate change in order to enhance sustainable development and a green economy by 2020? These are the questions addressed in this presentation, which represents the vision of the Research Unit on Ecology and Biodiversity of the Research Pole in Environment and Sustainable Development of the University Nangui Abrogoua in Côte d'Ivoire.

URBAN CULTURAL LANDSCAPES AS MODELS OF URBAN BIODIVERSITY MANAGEMENT

Teodora Koos-Morar

Institute of Innovation for Transition to Sustainability - INTRAS

Kalliopi NTANOU, Institute of Innovation for Transition to Sustainability - INTRAS ; Ioan Manuel Ciumasu, Institute of Innovation for Transition to Sustainability - INTRAS

Cities cannot be sustainable without their hinterlands, but they are key to sustainability because the global network of cities appropriates most of the Earth's ecosystem services. Cities epitomize the conflicting priorities between development and sustainability. When cities face fundamental issues like resource scarcity, strong population growth and accelerated expansion of built areas, the existing green spaces are threatened because they are regarded as barriers against progress. The most visible losses are terms of physical disappearance of green areas, along with all its immediate benefits. But even more important is the loss of the daily interaction between humans and nature, which logically results in continuing and reinforcing the recent divergence between prosperity and nature inside (and beyond) the city itself. Solving this problem in cities - i.e. at human community levels - is fundamental to global nature conservation and sustainable development. In this paper, we review the issue of urban policy contradiction between development and sustainability, and we propose to address it by an integrative urban sustainability model which allows a holistic and coherent view upon urban green spaces. We apply the concept of Urban Sustainability Nexus (USN), a recently developed model, in which a landscape model is understood as a sub-model of a holistic eco-city model that comprises at its core the interdependencies between energy, water,

landscape and transport. In the model, we frame urban green areas as urban cultural landscapes, as applied to case studies in Versailles and Paris. We discuss the limits to ecosystem planning and the emergence of a city's genius loci from the interaction between nature and culture. Further, we use the model to generate a set of urban development and biodiversity conservation scenarios. Finally, we discuss the relevance of this approach for biodiversity conservation in different biogeographical and cultural areas of the world.

EFFECTS OF OIL AND GAS INFRASTRUCTURE AND OPERATING NOISE ON GRASSLAND SONGBIRDS IN ALBERTA, CANADA

Nicola Koper

University of Manitoba

Jacy BERNATH-PLAISTED, University of Manitoba ; Heather NENNINGER, University of Manitoba ; Bridget ANTZE, University of Manitoba

New oil wells are continually being drilled across the Great Plains, but we have little understanding of their impacts on grassland songbirds. We evaluated effects of oil well pumpjacks and screwjacks on abundance, nesting success and behaviour of grassland songbirds in 47, 65-ha mixed-grass prairie sites in southern Alberta, Canada, from 2012-2014. We compared the impacts of two types of wells, powered by two different power sources, and compared impacts of active and inactive (silent) infrastructure, with control sites with no infrastructure. Most species responded positively or neutrally to infrastructure. Baird's sparrows and Sprague's pipits, both species showing significant population declines, had lower abundances in sites with oil infrastructure. This effect was greater in sites with noisy infrastructure for Baird's sparrows, whereas effects of noisy and silent infrastructure influenced Sprague's pipit abundances equally. Although vesper sparrows and Savannah sparrows had equal or higher abundances in sites with infrastructure, their nesting success was lower in these sites, suggesting that sites with infrastructure might be ecological traps. Clutch sizes were higher far from roads for several species. Behavioural experiments demonstrated that some observed effects may be caused by a breakdown in communication, as Savannah sparrows could not detect alarm calls in the noisiest sites. While most ecological effects were driven by the presence of infrastructure, not noise, Baird's sparrows might benefit from noise mitigation measures. The presence of anthropogenic infrastructure significantly influences the distribution and productivity of several species of grassland songbirds across the prairie landscape; efforts to minimize noise from infrastructure might mitigate some but not all negative effects.

EFFECT OF PEAT CHARACTERISTICS ON P, N, AND DOC MOBILIZATION FROM RE-WETTED PEAT SOILS - A LABORATORY COLUMN STUDY FOR THE IMPACTS OF RESTORATION ON FORESTRY-DRAINED PEATLANDS

Markku Koskinen

University of Helsinki

Annu KAILA, Natural Resources Institute Finland ; Zaki ASAM, Trinity College ; Risto UUSITALO, Natural Resources Institute Finland ; Aino SMOLANDER, Natural Resources Institute Finland ; Oili KIIKKILÄ, Natural Resources Institute Finland ; Sakari SARKKOLA, Natural Resources Institute Finland ; Veikko KITUNEN, Natural Resources Institute Finland ; Hannu FRITZE, Natural Resources Institute Finland ; Hannu NOUSIAINEN, Natural Resources Institute Finland ; Arja TERVAHAUTA, Natural Resources Institute Finland ; Li XIAO, Trinity College ; Mika NIEMINEN, Natural Resources Institute Finland

Peatlands are an integral part of the hydrological cycle in the boreal and temperate zones, providing ecosystem services such as water filtering. From the mid to late 1900's, over 15 ha of peatlands and wetlands were drained for forestry in the temperate and boreal zones, causing deterioration of biodiversity and loss of ecosystem services. They are now being restored in order to reverse this development. Restoration of peatlands has been found to cause leaching of DOC and nutrients after water level rise and expansion of reducing conditions in the peat. A molar ratio between redox-sensitive Fe and P in the peat of < 10 has been previously suggested as a limit value indicating risk of high P export. The ratio, however, does not predict the level of P release well when the value is < 10 . It has also been suggested that redox-sensitive Fe is involved in the export of DOC via consumption of protons during reduction reactions of Fe, which reduces the soil positive charge and makes the DOC molecules more electronegative, which makes them repel each other. An incubation experiment was conducted to study factors affecting P, N and DOC release from inundated peat from forestry-drained peatlands of several fertility classes. It was discovered that in addition to Fe, a high ratio of Al to P in the peat reduces P export under reducing conditions. High peat Fe content was also found to predict high DOC export, suggesting that minerotrophic sites are susceptible to post-restoration DOC leaching due to the Fe in their peat. Microbial biomass and mineralization potential of the peat were not found to be important for the export of DOC or P. High NO_3 content in the peat predicted high export of NH_4 under reducing conditions.

THE NATIVE TREE FLORA OF GREECE: AN OVERALL ASSESSMENT OF REPRODUCTIVE TRAITS, SEED GERMINATION AND EX SITU CONSERVATION

Katerina Koutsovoulou

Hellenic Agricultural Organisation 'DEMETER' - Institute of Mediterranean Forest Ecosystems & Forest Products Technology [INSTITUTE] National and Kapodistrian University of Athens

Evangelia N. DASKALAKOU, Hellenic Agricultural Organisation 'DEMETER' - Institute of Mediterranean Forest Ecosystems & Forest Products Technology ; Costas A. THANOS, National and Kapodistrian University of Athens

The native tree flora of Greece comprises c. 2% of the general Greek flora. Data concerning flowering and fruiting season, masting, dispersal type, seed mass, seed germination, dormancy class, field seedling emergence and seed storage behaviour have been gathered for more than 100 taxa and are currently being analyzed. For the majority of the taxa, there exist either no scientific information on seed germination and seed storage behaviour for plant material collected in Greece or only a few, largely incomplete studies, which make ex situ conservation extremely difficult. In order to effectively protect and conserve the native tree taxa and their forest ecosystems, it is essential to investigate their reproductive biology. In the framework of a post-doc research, seed collections of 13 Greek tree taxa (including endemic and rare ones) have been carried out and experiments of seed germination and storage behaviour are currently being realized. Germination cases of the studied taxa will be presented (e.g. *Abies cephalonica*, *Alnus incana*, *A. glutinosa*, *Liquidambar orientalis*, *Platanus orientalis*). Part of this research is funded under the Project 'Research & Technology Development Innovation Projects'-AgroETAK, MIS 453350, in the framework of the Operational Program 'Human Resources Development'. It is co-funded by the European Social Fund through the National Strategic Reference Framework (Research Funding Program 2007-2013) coordinated by the Hellenic Agricultural Organization - DEMETER.

175-PARTICIPATION IN IPBES THROUGH UN REGIONS: OPPORTUNITIES AND BARRIERS FOR MEPS

Eszter Kovacs

The University of Cambridge

In this presentation, I will outline the expectations and experiences of Multidisciplinary Expert Panel (MEP) members from the first two years of the operationalisation of the Intergovernmental Panel for Biodiversity and Ecosystem Services (IPBES). MEPS are responsible for spearheading and directing work programme packages, fast track assessments,

the selection of experts in relevant areas, and the collation and writing up of scientific reports and assessments that will form the core of IPBES' outputs. However, the ability of MEPs to participate in the processes are uneven, constrained or enabled by their Regional networks, backgrounds, institutional affiliation and levels of financial support. These variations are also reflected in the geographical realisation of IPBES' work programme, and speak to a need to understand and to take into account the often politically inflected processes of "doing" science.

EVALUATION OF PARTICIPATORY MANAGEMENT PLANNING PROCESSES FOR NATURA 2000 SITES IN HUNGARY

Eszter Kovács

Institute of Nature Conservation and Landscape Management, Szent István University[INSTITUTE] Environmental Social Science Research Group (ESSRG) *Gabriella KISS, Budapest Business School, College of Finance and Accountancy; Veronika FABÓK, Institute of Nature Conservation and Landscape Management, Szent István University[INSTITUTE] Environmental Social Science Research Group (ESSRG); Ágnes KALÓCZKAI, Institute of Nature Conservation and Landscape Management, Szent István University[INSTITUTE] Environmental Social Science Research Group (ESSRG); Barbara MIHÓK, MTA ÖK Lendület Ecosystem Services Research Group, Centre for Ecological Research, Hungarian Academy of Sciences; György PATAKI, Department of Environmental Economics and Technology, Corvinus University of Budapest[INSTITUTE] Environmental Social Science Research Group (ESSRG); Bálint BALÁZS, Institute of Nature Conservation and Landscape Management, Szent István University[INSTITUTE] Environmental Social Science Research Group (ESSRG); Györgyi BELA, Institute of Nature Conservation and Landscape Management, Szent István University[INSTITUTE] Environmental Social Science Research Group (ESSRG); Boldizsár MEGYESI, Institute for Sociology, Centre for Social Sciences, Hungarian Academy of Sciences; Katalin MARGÓCZI, Department of Ecology, University of Szeged; Ágnes ROBOZ, Department of Environmental Economics and Technology, Corvinus University of Budapest*

The Natura 2000 network of the European Union consisting sites of community importance is considered as one of the largest networks of protected areas in the world. Preparation of management plans is recommended by one of the guiding directives, the Habitats Directive, as a means to maintain or restore the favourable conservation status of related habitats and species. Guidelines also emphasise the importance of stakeholder participation in the planning process in order to secure the support and involvement of locals in the management of designated areas. The present

research evaluates participatory processes of developing management plans for Natura 2000 sites in Hungary between 2007 and 2014. This evaluation aims to identify the main factors determining the quality of the participatory planning processes and their outcomes. Transcriptions and notes of semi-structured interviews and consultation forums, other documents and reports of the planning processes were analysed applying a qualitative content analysis method. A priori theoretically based codes were used to evaluate the process and the outcome along a set of criteria derived from the scientific literature on participation tailored to conservation related management planning. Our results demonstrate that regulation on management planning, early involvement of stakeholders, engagement of state officials with decision-making power, time and resources allocated to the process, available incentives for land users to comply with the measures are all important factors to make the planning process successful. Professional facilitation and involvement of social scientists are also crucial to ensure the quality of the process and assist in the resolution of conflicts that may arise.

SYMPOSIUM ID 175 - IPBES - THEMATIC ASSESSMENT OF POLLINATORS, POLLINATION AND FOOD PRODUCTION

Anikó Kovács-Hostyánszki

MTA Centre for Ecological Research
Simon G. POTTS, School of Agriculture, Policy and Development, Reading University; Vera Lucia IMPERATRIZ FONSECA, Instituto de Biociências, Universidade de S. Paulo; Anne LARIGAUDERIE, IPBES Secretariat

The thematic assessment of pollinators, pollination and food production is the first in a series of biodiversity assessments by the Intergovernmental Platform on Biodiversity and Ecosystem Services (IPBES). More than 60 experts from around the world are working on the six chapters of assessment and will deliver the final report in early 2016. The assessment will review the diversity, status and trends of pollinators and pollination systems and their role in supporting food production, in human well-being and biodiversity maintenance. Direct and indirect drivers of change of pollination systems will be detailed, such as land-use, agricultural management, pesticide use, pests or changing climatic conditions. It will assess economic methodologies for determining the value of pollination for food production and the economic impacts of declines in pollinator populations. In addition, the assessment will include indigenous and local knowledge perspectives on pollinators and pollination systems and their benefits to those knowledge holders. Responses to risks associated with the degradation of pollination services and opportunities to restore and strengthen those services will be addressed. The assessment aims to understand the reasons of pollination declines and deficits and how this knowledge can help to

advance practices and policies, particularly for land-use management, horticulture and agriculture, including through innovative approaches such as ecologically intensified agriculture as well as those used by indigenous and local communities, to mitigate the further loss. The assessment represents an early deliverable IPBES that will identify policy-relevant findings for decision-making in government, the private sector and civil society. It will also help demonstrate how an essential ecosystem service contributes to the post-2015 development agenda and contribute to Aichi Biodiversity Target 14 on safeguarding and restoring ecosystems that provide essential services.

IDENTIFYING AFRICAN PROTECTED AREAS AT RISK FROM THE ILLEGAL WILDLIFE TRADE

Olena Kovalenko

University of Helsinki

Atte MOILANEN, University of Helsinki ; Enrico DI MININ, University of Helsinki

The illegal trade in biodiversity, which is estimated to be the world's second largest illegal market after narcotics, is undermining conservation efforts in many parts of the world. Africa hosts some of the most iconic species, which are in high demand in the illegal wildlife market. In this study, we identified the protected areas that will increasingly be targeted by criminals for the illegal harvesting of iconic African species listed under the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) and the IUCN Red List. We did so by identifying the priority areas where these species are most abundant and, at the same time, more accessible to poachers according to continental and international illegal wildlife trade routes. We then identified which protected areas are most at risk by overlaying the priority areas for poachers with a layer including all African protected areas. Our results highlight where resources should be allocated immediately for improved protection of these species and have policy implications reaching beyond the conservation of iconic species.

SINANODONTA WOODIANA AS A GOOD SURROGATE SPECIES IN ENVIRONMENTAL ASSESSMENT

Nora Kováts

University of Pannonia

Eszter HORVÁTH, University of Pannonia ; Bettina ECK-VARANKA, University of Pannonia ; Gábor PAULOVITS, Balaton Limnological Institute, Centre for Ecological Research

Bivalves are sentinel and filter-feeding organisms, which make them ideal for toxicity testing as they are able to accumulate and bioconcentrate most pollutants. Due to their sensitivity, however, native Unionid populations have shown a serious

decline. As such, while native Unionid species are holding a specific nature conservation status, the alien and invasive Chinese pond mussel (*Sinanodonta woodiana* LEA) raises no ethical constraint to collect or to sacrifice. In order to use it as a good surrogate species, however, it should show comparable sensitivity with native Unionids. In our study, sensitivity of *Sinanodonta woodiana* was compared to that of *Unio pictorum* to evaluate the genotoxic potential of two well known pollutants with high relevance in fresh water pollution: CuSO₄ and benzo(a)pyrene (B[a]P). For genotoxicity assessment, the micronucleus (MN) test was applied where MN formation indicates mitotic chromosome breakage or chromosome mis-segregation. Results show that under laboratory conditions *S. woodiana* shows good sensitivity and therefore can replace native species. On the contrary, there is a serious constraint: being an alien species, it cannot be used in situ when transplanted mussels are required.

210 AN OUTLINE OF A POLICY FOR ROADLESS AREAS CONSERVATION ACROSS SCALES

Stefan Kreft

Centre for Economics and Ecosystem Management, Eberswalde University for Sustainable Development

Nuria SELVA, Institute of Nature Conservation, Polish Academy of Sciences ; Dominick DELLASALA, Geos Institute ; Simone R. FREITAS, Centro de Ciências Naturais e Humanas, Universidade Federal do ABC ; Vassiliki KATI, Department of Environmental & Natural Resources Management, University of Patras ; Mariana M. VALE, Departamento de Ecologia, IB, Universidade Federal do Rio de Janeiro ; Pierre L. IBISCH, Centre for Economics and Ecosystem Management, Eberswalde University for Sustainable Development

In the past few years, roadless areas have received increasing attention as effective conservation targets of great potential. This leaves the global society, particularly conservation biologists, advocates and policy-makers, with the task to explore an almost entirely new field of policy (laws, strategies, funding). Transparent definitions are needed to operationalise general strategic goals of roadless areas conservation. Existing concepts comprise assumptions regarding minimum size or maximum tolerable impact that varies with their regions of origin, but such basic conceptual work is still lacking for most regions. A policy analysis shows roadless areas so far are hardly taken into account in any relevant policy field, such as conservation, development cooperation, or traffic infrastructure planning. Few exceptions exist, of which roadless areas and wilderness legislation in the U.S. stands out. The current primary goals of most other policy fields are driven by interests in (economic) development and are thus at odds with roadless areas conservation. However, many other environmental policies promise to be synergistic. Examples

on the continental scale is the EU No Net Loss initiative, and, on national level, the German Federal Defragmentation Programme. Protected areas have proven to vary in their effectiveness as a barrier to road building. Similarly, a stakeholder analysis highlights wide gaps in all stakeholder groups needed for effective conservation of roadless areas. Among others, advocacy by NGOs as an interface between science and policy will be of key importance. A global roadless ecology framework is currently being developed. It lays the foundation for a global policy of roadless areas conservation that should be established in relevant sectors (e.g. CBD, World Bank programmes etc.). Clearly, an equivalent challenge is regionalisation of both basic scientific knowledge and policy implications, such as traffic infrastructure planning.

NATURA 2000 - SOLUTION FOR EASTERN EUROPE OR JUST A GOOD START? THE ŠUMAVA NATIONAL PARK AS A TEST CASE.

Zdenka Křenová

Global Change Research Centre, AS CR

Pavel KINDLMANN, Global Change Research Centre, AS CR

Natura 2000 is a unique EU-wide network of protected areas, which aims to maintain European biodiversity or at least prevent its worsening based on two Directives: Bird Directive 79/409/EEC and Habitats Directive 92/43/EEC. It is assumed that this will assure the long-term survival of Europe's most valuable and threatened species and habitats. The new member states implemented the Natura 2000 Directives in their own legislation as a part of the EU-integration process. Here we present the practical difficulties of implementing these directives in the Czech Republic as a warning of the problems likely to be encountered in post-communist countries. Our results are mainly based on a case study of the Šumava National Park. We analyze, why Natura 2000 may not work here and look for possible solutions, which would require changes in Natura 2000 policies and their implementation in national policies. We conclude that the problems encountered in implementing these directives in the Czech Republic are likely to affect their successful implementation in most other post-communist countries.

INFLUENCE OF EXURBAN RESIDENTS' ENVIRONMENTAL VALUES, MANAGEMENT OBJECTIVES AND REGIONAL LAND-USE CONTEXT ON PRIVATE LAND ACTIVITIES AND BEHAVIORS

Heidi Kretser

Wildlife Conservation Society

John VOGEL, Cornell Univeristy ; T. Bruce LAUBER, Cornell Univeristy ; Shorna BROUSSARD, Cornell Univeristy

Exurban or low-density residential development is an increasingly common form of sprawl that impacts rural areas of North America, with particularly deleterious impacts on native wildlife. We examined how environmental values and management objectives within the regional land-use context influence the type of activities exurban landowners engage in around their homes at two study sites: the Adirondack region of northern New York and the Greater Yellowstone Ecosystem in Montana. We administered a mail survey to over 200 exurban landowners and conducted in-depth interviews with landowners and decision-makers that govern land use, such as town and county planning departments and homeowner associations. This mixed methods research design builds on social-psychological frameworks to develop an understanding of hierarchical elements that impact how landowners manage their land. We found that exurban landowners' environmental values may be characterized into one of four types previously identified in the literature: mastery over nature, stewardship of nature, partnership with nature and participation in nature. Exurban residents identified with stewardship of and participation in nature most strongly. We investigated how these values relate to how landowners' management desires and the heterogeneity of activities found on private lands. Values tended not to be strongly associated with levels of activity and property management behaviors, however norms from family and neighbors were influential. An explicit understanding of how exurban landowners navigate external constraints and internal values indicates that management opportunities for engaging homeowner associations and individual or neighborhood incentives could potentially lead to improved habitat for wildlife in private lands of exurban landscapes. Incorporation of data from two distinct study areas allows for wider applicability of the findings to other regions experiencing exurban development.

IMPORTANCE OF BEAR MANAGEMENT FOR CONSERVATION OF EURASIAN LYNX

Miha Krofel

University of Ljubljana, Biotechnical Faculty

Klemen JERINA, University of Ljubljana, Biotechnical Faculty

Interspecific interactions are one of the key factors in the evolution and ecology of animal communities. However, managers, conservationists and decision-makers rarely consider potential side-effects of management of one species for the conservation of other species. For example, kleptoparasitism can have a wide range of consequences for numerous host species, but it is poorly understood how management of dominant scavengers affect their interactions with predators and other scavengers. As the largest terrestrial

scavengers with superb olfactory abilities, bears are one of the most important dominant scavengers and kleptoparasites in the Holarctic region. At the same time, bears are usually actively managed, e.g. through culling, supplemental feeding, and translocations. Here, we studied how management of the brown bear (*Ursus arctos*) affected its interactions with an apex predator, the Eurasian lynx (*Lynx lynx*), in Dinaric Mountains of Slovenia. Brown bears in this area are intensively managed through zone-specific hunting and supplemental feeding, which considerably alter bear distribution and local densities. We showed how bear management indirectly affected endangered Dinaric lynx population by altering interaction intensity. Locally, lynx were observed to be under strong pressure of kleptoparasitism by brown bears, resulting in substantial energetic loss for lynx and potentially affecting lynx reproductive success. Ability of lynx to compensate the losses by increasing their hunting frequency was limited after certain level of kleptoparasitism intensity. Based on our results, we call attention to the importance of considering interspecific interactions in wildlife management. In the concrete case, we suggest that existing bear-feeding regimes should be reconsidered, in order to reduce side-effects of this controversial management measure that can lead to locally high concentrations of bears.

THE WASHINGTON-BRITISH COLUMBIA TRANSBOUNDARY CLIMATE-CONNECTIVITY ASSESSMENT: ENGAGING SCIENCE-MANAGEMENT PARTNERSHIPS TO ADDRESS CLIMATE IMPACTS ON WILDLIFE CONNECTIVITY

Meade Krosby

University of Washington

Maintaining and restoring ecological connectivity is a primary conservation need and the most frequently recommended climate adaptation strategy for biodiversity conservation. And yet, little guidance exists regarding where and how to connect fragmented habitats to facilitate climate-driven shifts in species ranges, or how to anticipate and address climate impacts to existing habitat corridors. We will describe an effort to address these needs in the transboundary region of Washington State, USA, and British Columbia, Canada, where we have engaged international science-management partnerships to inform the decision-making of land and wildlife managers tasked with maintaining connected, resilient ecosystems in the face of climate change. We will describe the history of the project, which was conceived as a direct response to feedback from regional managers; highlight the diverse management scales, objectives, and activities of participant agencies, tribes, First Nations, and NGOs; describe our project approach and results, which illustrate a range of possible solutions to the

technical and conceptual challenges associated with adapting connectivity conservation to climate change; and share insights gained from our efforts to bridge the significant technical, institutional, and political barriers that international borders pose to climate adaptation and landscape conservation.

LINKS BETWEEN ON FARM HABITAT, BIRD DIVERSITY, PEST CONTROL AND CROP DAMAGE IN CALIFORNIA'S CENTRAL VALLEY

Sara Kross

University of California, Davis

Rodd KELSEY, The Nature Conservancy ; Candan SOYKAN, National Audubon Society ; Sacha HEATH, University of California, Davis ; Karen VELAS, Audubon California

In many of the world's agricultural regions, farmland is virtually the only habitat available for wildlife. Agricultural lands are therefore a critical, but often overlooked, opportunity for conservation efforts. Conversely, intensification of agricultural practices has been identified as a major threat to many of the species that rely on farmland, and conservationists advocate wildlife-friendly farming practices, including preserving habitat remnants and establishing linear features such as hedgerows, to offset the negative impact of farming on biodiversity. However, farmers often view this as a tradeoff between conservation and their economic bottom lines. Birds, as one of the most well-studied and ubiquitous taxa persisting in farmland, offer a unique opportunity for measuring the benefits of wildlife-friendly farming practices for biodiversity, while simultaneously measuring the beneficial and detrimental impacts that these practices can have on farmers. The few studies that have examined pest control services by birds have shown that some species can be beneficial to agriculture, yet birds are often maligned by farmers and their efforts to drive birds from fields can compound the detrimental impact of agricultural intensification on wildlife. We will present a synthesis of multiple studies in California's Central Valley, one of the world's most productive agricultural landscapes, which have sought to understand these relationships. Our results show a positive relationship between avian diversity and both field- and landscape- level habitat features. We will also show that birds provide insect pest control for multiple crops including alfalfa, walnuts, sunflowers and tomatoes, and that the benefits of avian foraging on insect pests outweigh the damage that birds cause to economically-valuable sunflower seed crops.

A CONTINENTAL APPROACH TO ORCHID CONSERVATION AND RESTORATION

Gary Krupnick

Smithsonian Institution

Dennis WHIGHAM, Smithsonian Institution

Many species are at risk globally, and species in the Orchidaceae, one of the most species rich families of flowering plants on earth, are no exception. More than half of native orchid species in North America have been listed as threatened or endangered at local, state, regional, or national levels. To respond to the ever increasing threats to native orchids (e.g., habitat alteration, climate change, invasive species, illegal harvesting), organizations need to aggressively pursue approaches that reduce the risks to orchids while providing a mechanism for restoration and conservation. The North American Orchid Conservation Center (NAOCC) has a goal of conserving the genetic diversity of all native orchid species in the U.S. and Canada. NAOCC is developing a network of botanical gardens, researchers, and public and private organizations to focus on efforts to conserve orchid genetic diversity. This will be done through the implementation of seed and mycorrhizal fungal banks and the development of botanical garden protocols for the establishment of sustainable populations of all orchid species. NAOCC is also developing educational tools including an interactive online website (GoOrchids) that can be used to identify any native orchid species in the U.S. and Canada. This presentation will share the experiences during Phase 1 of NAOCC development.

PROMOTION OF BIODIVERSITY IN AGRICULTURAL LANDSCAPE VIA UMBRELLA BIRD SPECIES, AGRICULTURAL ENVIRONMENTAL SCHEME AND CITIZEN SCIENCE PROJECT: LESSONS FROM CENTRAL EUROPEAN COUNTRY

Vojtech Kubelka

Department of Ecology, Faculty of Science, Charles University

Vaclav ZAMECNIK, Czech Society for Ornithology; Miroslav SALEK, Department of Ecology, Faculty of Environmental Sciences, Czech University of Life Sciences

Biodiversity and ecosystem functioning are highly deteriorated in current agricultural landscape in many countries across the world. A huge conservation effort has been devoted to improve this issue, however so far with only limited evidence of success and ambiguous results. Agri-environmental schemes (AES) represent a promising tool how to encourage biodiversity of agricultural landscape on larger scale. However, the best localities for AES implementation on national level have to be chosen in advance and the efficacy of the prescription has to be monitored, i.e. two very time and money demanding operations are necessary parts of the AES. Here we report about our hopeful approach using suitable umbrella species, public volunteers and user-friendly on-line database. The Northern Lapwing (*Vanellus vanellus*) is a suitable species as it is well known and unmistakable shorebird for public, representing endangered wetland species inhabiting
